FOREWORD TO SOMMERFELD'S COURSE

P. P. EWALD

POLYTECHNIC INSTITUTE OF BROOKLYN, NEW YORK

The author of this Course on Theoretical Physics, Arnold Sommerfeld, was one of the central figures in achieving the transformation through which physics passed in the two decades from 1910 to 1930. Without his inspired and untiring efforts both the tumultuous advance and the wide-spread dissemination of the quantum theory of the atom would not have been what they were. Sommerfeld's Institute for Theoretical Physics in Munich became a school from which issued a steady stream of research papers by German and foreign, young and mature students of atomic theory. His famous book "*Atombau und Spektrallinien*," followed later by the companion volume "*Wellenmechanik*," was for a long time the only full and authoritative account of this fundamental subject; its successive editions unroll an impressive survey of the rapid development of atomic theory following Niels Bohr's first papers.

Both by his training and previous research Sommerfeld was firmly rooted in the mathematical methods of classical physics, and to this fact he owes much of his mastery of the newly created methods of quantum physics, especially after the advent of Schrödinger's wave mechanics in 1926. It was therefore natural for Sommerfeld to give his students a thorough training in classical methods, all the more so since he himself took great delight in the aesthetic beauty of classical theory. The harmony between mathematical formalism, its physical interpretation, and experimental materialization was cast in relief in Sommerfeld's lectures and deeply impressed his students.

Sommerfeld was over seventy, and retired after forty years of academic teaching, when he committed his lectures to paper. He did it with a sense of double obligation: to preserve through a crisis the achievements that had carried physics to great triumphs and to bequeath to the young generation of physicists the valuable analytical tools that had been shaped on the classical problems. Sommerfeld had taken an active part in perfecting these tools from 1895 onwards, when he wrote his doctoral thesis on *Arbitrary Functions in Physics*. Among his earliest brilliant work was the construction of a strict solution for the diffraction of a wave by an edge; he extended the methods that Riemann used in the theory of functions, with the result that a solution of the diffraction problem by an image method in multi-valued space was obtained. The reader will find this discussed in Volume V on *Optics*. Extending from Sommerfeld's early period in Göttingen to the beginning of the quantum period in Munich, and in co-authorship with the great mathematician Felix Klein in Göttingen, the preparation of the four

volume standard work on the theory of rotating rigid bodies, *Theorie des Kreisels*, proceeded. This work was intended to demonstrate the intimate connection between "pure" and "applied" mathematics by bringing a great variety of mathematical topics, such as the theory of functions, elliptic functions, quaternions, Klein-Caley parameters, etc., to bear on this problem of dynamics of a rigid body. While holding the chair of Technical Mechanics at the Technische Hochschule in Aachen, 1899-1905, Sommerfeld became deeply interested in engineering problems. His papers on the hydrodynamics of lubrication, on the interaction between electrical generators working on the same power line, on the braking of trains, and on other topics all adopt a general approach that gives them lasting value. With the advent of wireless telegraphy a series of papers by Sommerfeld and his pupils began on the mode of emission and of propagation of radio waves. They offer excellent examples of the mathematical methods in which Sommerfeld was a master. In particular, the diffraction problem of these waves round the earth was brought down to the discussion of complex integrals, which form a strict solution (see Volume 6, Chapter 6).

It would be out of place to elaborate a full list of the achievements with which Sommerfeld enriched physical theory. The reader may be referred to some of the articles listed below. But a few words may be added on Sommerfeld as a teacher, and on the significance of the course of lectures now being published in translation.

The courses of theoretical physics held in Munich were of two kinds, general ones and specialized ones. The former were given four hours, or more precisely periods of 45-50 minutes, a week through a 13-week winter semester and an 11-week summer semester. These six courses form the subject of the present six volumes. Each served as an introduction for students who had taken the demonstration courses on experimental physics (given, in Munich, by Röntgen, later by W. Wien). In experimental physics the student acquired a factual survey of the phenomena and of their quantitative evaluation, based on a fundamentally non-mathematical treatment. In the courses on theoretical physics the elementary ground was gone over again, but with a view to developing the mathematical handling and to constructing an integrating theory which could then be extended to advanced problems. The latter might change from one series of courses to the next, and the inclusion of topical subjects in the second halves of these courses made them most interesting even to advanced students who had already gone over the subject in their previous work. In addition to the lectures, two hours a week were devoted to discussing problems.

The specialized courses were two-hour-a-week lecture courses on subjects which could be dealt with only briefly in the general course, or had topical interest. Those given by Sommerfeld were usually connected with his own current research and often contained parts which appeared a little later as

original papers. The interpretation of the Lorentz transformation as a rotation in four dimensional space (Volume 3, §26), the transition from wave optics to geometrical optics (Volume 5, §35), the discussion of the signal velocity in a dispersive medium (Volume 5, §22) are some examples. In later general courses such subjects were often included, to the exclusion of other less interesting parts of previous courses.

Besides the lecture courses, a seminar and colloquium offered instruction in advanced topics ; here the students had to review the assigned subject and to deliver the talk, which meant several weeks' intensive study.

From the student's point of view the great attraction of Sommerfeld's lectures lay in their clarity : the approach from the physical side, the formulation of the mathematical problem, the simple and yet general explanation of the mathematical methods used, and the thorough discussion of the result again in terms of physical experiment. His firm, well-distributed writing on the blackboard, and the evidence of his diagrams, helped the student to survey at the end of each period all the subjects that had been covered. Besides, the standard of the course was high enough to tax the powers of the better students and to demand vigilant cooperation. This was all the more important in a university system where there was no check on attendance and only a voluntary one on performance. In giving an original discussion of a problem in the exercises even the beginner would attract the attention of Sommerfeld or of the assistant in charge, and he would be stimulated by the appreciative understanding his effort received.

Sommerfeld had an extraordinary flair for genuine endeavor and performance, irrespective of the age of his students. That is why scientists of the rank of Debye, Pauli, Heisenberg (to name only those who now are Nobel prize men) became attached to him in their early years of study. But also the good average student was well looked after and given smaller problems or small responsibilities to exercise his forces. The indolent student soon turned away on his own account. Thus Sommerfeld's students formed in a way a select group, but their number remained large enough to create a breeze that helped the inexperienced newcomers rapidly to unfurl their own sails. May the translation of Sommerfeld's lectures carry some of this breeze afield and assist other groups in preparing to sail the ocean of discovery.

PREFACE TO THE FIRST EDITION, SEPTEMBER 1942

The encouragement of some of my former students and the repeated suggestion of the publishers decided me to publish my general course on theoretical physics which I gave regularly for thirty-two years at the University of Munich.

This was an introductory course, and was attended not only by the physics majors of the University and the Polytechnic Institute (Technische Hochschule), but also by candidates for teachers' degrees in mathematics and physics, by students of astronomy and some few of physical chemistry—all usually in their third and fourth years. The lectures were held four times a week and supplemented by a two-hour problem period. Special courses on modern physics, which were given concurrently with these, have not been included in this series of books; their subject matter found its way into my scientific papers, summarizing articles, and other books. While it is true that quantum mechanics always hovers in the background and reference is made to it now and then, the actual substance of these lectures is classical physics.

The order of the courses, which has been kept in their publication, was

1. Mechanics
2. Mechanics of Deformable Bodies
3. Electrodynamics
4. Optics
5. Thermodynamics and Statistical Mechanics
6. Partial Differential Equations in Physics

The courses on mechanics were given in alternate years by myself and by my colleagues in mathematics. Concurrent courses in hydrodynamics, electrodynamics, and thermodynamics were taught by younger members of the staff. Vector analysis was given in a separate course so that its systematic development could be omitted from my lectures.

In print, as in my classes, I will not detain myself with the mathematical foundations, but proceed as rapidly as possible to the physical problems themselves. My aim is to give the reader a vivid picture of the vast and varied material that comes within the scope of theory from a suitably chosen mathematical and physical vantage point. With this in mind I shall not be too concerned if I have left some gaps in the systematic justification and axiomatic structure of the work. In any case I do not wish to frighten the hearer of my lectures with drawn-out investigations of a mathematical or logical nature and distract his attention from what is physically interesting. It is my belief that this attitude proved its worth in my courses; it has therefore been retained in the printed lectures. Whereas the lectures of Planck are irreproachable in systematic formulation, I believe that I can claim for mine a greater variety of subject matter and a more flexible handling

of the mathematical apparatus. Moreover, I gladly refer the reader to the more complete and often more thorough treatment of Planck, especially in thermodynamics and statistical mechanics.

The problems collected at the end of each volume should be regarded as supplementary to the text. They were handed in by the students and then presented orally during the problem periods. Elementary numerical problems, to be found so prolifically in texts and collections of problems, have, in general, not been included. The problems are numbered by chapter. Sections are numbered through in each volume and equations in each section. References within each volume to earlier equations can thus be made merely by giving the section, and equation numbers. To make it simpler to find a given section the upper inside corners of every pair of pages bear the section and chapter number.

Looking back on my years of teaching I wish to acknowledge with gratitude my special indebtedness to two men, Röntgen and Felix Klein. Röntgen not only created the external conditions for my professional activity by calling me to a privileged sphere of action; he also stood by my side and actively furthered the increasing scope of my work over a period of many years. Even earlier Felix Klein had imparted to my mathematical thinking that turn of mind which is best adapted to applications; through his mastery in the art of lecturing he exerted a strong indirect influence on my own teaching. In particular let me mention that the last part of this course was announced for the first time while I was still instructor in Göttingen and imbued with the mathematical tradition of that university symbolized in the three names Riemann—Dirichlet—Klein. At that time my course was less comprehensive than the present Volume VI, but it found much resonance in the audience. When the course was repeated in later years my students often told me that only here had they really grasped the handling and application of mathematical results, e.g., Fourier methods, applications of the theory of functions, boundary value problems.

In conclusion, let me send out these volumes with the wish that they arouse the reader's interest in our beautiful science and give him as much pleasure as the courses gave to those attending them and to me during my many years of teaching activity.

Munich, September 1942

Arnold Sommerfeld

TABLE OF CONTENTS

	PAGE
FOREWORD TO SOMMERFELD'S COURSE BY P. P. EWALD.....	v
PREFACE TO THE FIRST EDITION.....	ix
INTRODUCTION	1
CHAPTER I. MECHANICS OF A PARTICLE	3
1. Newton's Axioms	3
2. Space, Time and Reference Systems	9
3. Rectilinear Motion of a Mass Point.....	16
Examples:	
(1) Free Fall Near Earth's Surface (Falling Stone)	19
(2) Free Fall From a Great Distance (Meteor)	20
(3) Free Fall in Air	21
(4) Harmonic Oscillations	22
(5) Collision of Two Particles	24
4. Variable Masses	28
5. Kinematics and Statics of a Single Mass Point in a Plane and in Space..	32
(1) Plane Kinematics	32
(2) The Concept of Moment in Plane Statics and Kinematics	34
(3) Kinematics in Space	36
(4) Statics in Space; Moment of Force About a Point and About an Axis	37
6. Dynamics (Kinetics) of the Freely Moving Mass Point; Kepler Problem;	
Concept of Potential Energy	38
(1) Kepler Problem with Fixed Sun	38
(2) Kepler Problem Including Motion of the Sun.....	44
(3) When Does a Force Field Have a Potential ?.....	45
CHAPTER II. MECHANICS OF SYSTEMS, PRINCIPLE OF VIRTUAL WORK, AND	
D'ALEMBERT'S PRINCIPLE	48
7. Degrees of Freedom and Virtual Displacements of a Mechanical System;	
Holonomic and Non-holonomic Constraints	48
8. The Principle of Virtual Work.....	51
9. Illustrations of the Principle of Virtual Work	54
(1) The Lever.....	54
(2) Inverse of the Lever: Cyclist, Bridge	55
(3) The Block and Tackle.....	56
(4) The Drive Mechanism of a Piston Engine	57
(5) Moment of a Force About an Axis and Work in a Virtual Rotation ..	58
10. D'Alembert's Principle; Introduction of Inertial Forces	59
11. Application of d'Alembert's Principle to the Simplest Problems	62
(1) Rotation of a Rigid Body About a Fixed Axis.....	62
(2) Coupling of Rotational and Translational Motion	64
(3) Sphere Rolling on Inclined Plane	64
(4) Mass Guided Along Prescribed Trajectory	65
12. Lagrange's Equations of the First Kind.....	66
13. Equations of Momentum and of Angular Momentum	69
(1) Equation of Momentum.....	70
(2) Equation of Angular Momentum	71
(3) Proof Using the Coordinate Method.....	73
(4) Examples	74
(5) Mass Balancing of Marine Engines.....	76
(6) General Rule on the Number of Integrations Feasible in a Closed	
System	79

Table of Contents

	PAGE
14. The Laws of Friction.....	81
(1) Static Friction	81
(2) Sliding Friction	83
CHAPTER III. OSCILLATION PROBLEMS	87
15. The Simple Pendulum	87
16. The Compound Pendulum.....	91
Supplement: A Rule Concerning Moments of Inertia	93
17. The Cycloidal Pendulum	94
18. The Spherical Pendulum	96
19. Various Types of Oscillations.	
Free and Forced, Damp and Undamped Oscillations	100
20. Sympathetic Oscillations	106
21. The Double Pendulum	111
CHAPTER IV. THE RIGID BODY	118
22. Kinematics of Rigid Bodies	118
23. Statics of Rigid Bodies	125
(1) The Conditions of Equilibrium	125
(2) Equipollence; the Reduction of Force Systems.....	126
(3) Change of Reference Point.....	127
(4) Comparison of Kinematics and Statics.....	127
Supplement: Wrenches and Screw Displacements	129
24. Linear and Angular Momentum of a Rigid Body.	
Their Connection with Linear and Angular Velocity	130
25. Dynamics of a Rigid Body. Survey of its Forms of Motion.....	133
(1) The Spherical Top Under No Forces	134
(2) The Symmetrical Top Under No Forces	134
(3) The Unsymmetrical Top Under No Forces	135
(4) The Heavy Symmetrical Top.....	136
(5) The Heavy Unsymmetrical Top.....	138
26. Euler's Equations. Quantitative Treatment of the Top Under No Forces	139
(1) Euler's Equations of Motion.....	139
(2) Regular Precession of the Symmetrical Top Under No Forces and Euler's Theory of Polar Fluctuations.....	142
(3) Motion of an Unsymmetrical Top Under No Forces. Examination of its Permanent Rotations as to Stability	146
27. Demonstration Experiments Illustrating the Theory of the Spinning Top; Practical Applications.....	150
(1) The Gyrostabilizer and Related Topics.....	153
(2) The Gyrocompass	154
(3) Gyroscopic Effects in Railroad Wheels and Bicycles.....	156
Supplement: The Mechanics of Billiards	158
(a) High and Low Shots, 158—(b) Follow Shots and Draw Shots, 159— (c) Trajectories with "English" Under Horizontal Impact, 160— (d) Parabolic Path Due to Shot with Vertical Component, 160	
CHAPTER V. RELATIVE MOTION	162
28. Derivation of the Coriolis Force in a Special Case	162
29. The General Differential Equations of Relative Motion	165
30. Free Fall on the Rotating Earth; Nature of the Gyroscopic Terms	167

Table of Contents

	PAGE
31. Foucault's Pendulum	171
32. Lagrange's Case of the Three-Body Problem	174
CHAPTER VI. INTEGRAL VARIATIONAL PRINCIPLES OF MECHANICS AND LAGRANGE'S	
EQUATIONS FOR GENERALIZED COORDINATES	181
33. Hamilton's Principle	181
34. Lagrange's Equations for Generalized Coordinates	185
35. Examples Illustrating the Use of Lagrange's Equations	192
(1) The Cycloidal Pendulum	192
(2) The Spherical Pendulum	193
(3) The Double Pendulum	195
(4) The Heavy Symmetrical Top	196
36. An Alternate Derivation of Lagrange's Equations	200
37. The Principle of Least Action	204
CHAPTER VII. DIFFERENTIAL VARIATIONAL PRINCIPLES OF MECHANICS	
38. Gauss' Principle of Least Constraint	210
39. Hertz's Principle of Least Curvature	212
40. A Digression on Geodesics	214
CHAPTER VIII. THE THEORY OF HAMILTON	
41. Hamilton's Equations	217
(1) Derivation of Hamilton's Equations from Lagrange's Equations	218
(2) Derivation of Hamilton's Equations from Hamilton's Principle	218
42. Routh's Equations and Cyclic Systems	222
43. The Differential Equations for Non-Holonomic Velocity Parameters	226
44. The Hamilton-Jacobi Equation	229
(1) Conservative Systems	230
(2) Dissipative Systems	231
45. Jacobi's Rule on the Integration of the Hamilton-Jacobi Equation	233
46. Classical and Quantum-Theoretical Treatment of the Kepler Problem	235
PROBLEMS	
FOR CHAPTER I	
I. 1, I. 2, I. 3. Elastic collision	240
I. 4. Inelastic collision between an electron and an atom	240
I. 5. Rocket to the moon	241
I. 6. Water drop falling through saturated atmosphere	241
I. 7. Falling chain	241
I. 8. Falling rope	241
I. 9. Acceleration of moon due to earth's attraction	241
I. 10. The torque as vector quantity	241
I. 11. The hodograph of planetary motion	242
I. 12. Parallel beam of electrons passing through the field of an ion. Envelope of the trajectories	242
I. 13. Elliptical trajectory under the influence of a central force directly proportional to the distance	242
I. 14. Nuclear disintegration of lithium	242
I. 15. Central collisions between neutrons and atomic nuclei; effect of a block of paraffin	243
I. 16. Kepler's equation	243

Table of Contents

	PAGE
FOR CHAPTER II	
II. 1. Non-holonomic conditions of a rolling wheel.....	244
II. 2. Approximate design of a flywheel for a double-acting one-cylinder steam engine	245
II. 3. Centrifugal force under increased rotation of the earth	246
II. 4. Poggendorff's experiment.....	246
II. 5. Accelerated inclined plane	246
II. 6. Products of inertia for the uniform rotation of an unsymmetrical body about an axis	246
II. 7. Theory of the Yo-yo.....	246
II. 8. Particle moving on the surface of a sphere.....	247
FOR CHAPTER III	
III. 1. Spherical pendulum under infinitesimal oscillations.....	247
III. 2. Position of the resonance peak of forced damped oscillations	247
III. 3. The galvanometer	247
III. 4. Pendulum under forced motion of its point of suspension.....	248
III. 5. Practical arrangement of coupled pendulums	248
III. 6. The oscillation quencher	250
FOR CHAPTER IV	
IV. 1. Moments of inertia of a plane mass distribution.....	250
IV. 2. Rotation of the top about its principal axes	250
IV. 3. High and low shots in a billiard game. Follow shot and draw shot..	250
IV. 4. Parabolic motion of a billiard ball	251
FOR CHAPTER V	
V. 1. Relative motion in a plane	251
V. 2. Motion of a particle on a rotating straight line	251
V. 3. The sleigh as the simplest example of a non-holonomic system.....	251
FOR CHAPTER VI	
VI. 1. Example illustrating Hamilton's principle.....	252
VI. 2. Relative motion in a plane and motion on a rotating straight line	253
VI. 3. Free fall on the rotating earth and Foucault's pendulum.....	253
VI. 4. "Wobbling" of a cylinder rolling on a plane support	254
VI. 5. Differential of an automobile	254
HINTS FOR SOLVING THE PROBLEMS	256
INDEX	283

INTRODUCTION

Mechanics is the backbone of mathematical physics. Though it is true that we no longer require physics to explain all phenomena in terms of mechanical models, as was common during the last century, we are nevertheless convinced that the principles of mechanics, such as those of momentum, energy, and least action, are of the greatest importance in all branches of physics.

We call this book "Mechanics," not "Analytical Mechanics" as the mathematicians are wont to do. The latter name has its origin in the great work of Lagrange (1788), who attempted to mold the whole system of mechanics into a consistent language of mathematical equations and was proud of the fact that "one would not find a single diagram in his work." We, on the contrary, shall draw as much as possible on illustration and comparison. The reader will find in this volume many concrete applications in astronomy, physics, and even to some degree in engineering, which should help to make the principles clearer.

The exact title of the book should be "Mechanics of Systems of a Finite Number of Degrees of Freedom"; that of the second volume would accordingly be "Mechanics of Systems with an Infinite Number of Degrees of Freedom." Since, however, the concept of degrees of freedom is not too well known and can here be explained only at the beginning of the second chapter, we shall be satisfied with the customary title "Mechanics," a title hardly subject to misunderstanding.

We commence with Newton's fundamental analysis in his "*Philosophiæ Naturalis Principia Mathematica*" (London, 1687); not that Newton lacked important predecessors, such as Archimedes, Galileo, Kepler, and Huygens, to mention only a few. It was, nevertheless, Newton who first created a firm foundation for general mechanics. Even today, apart from some changes and reinforcements, the foundation laid down by him provides us with the most natural and didactically simplest approach to general mechanics.

We shall at first investigate the mechanics of the single mass point or particle.

CHAPTER I

MECHANICS OF A PARTICLE

§ 1. Newton's Axioms

The laws of motion will be introduced in axiomatic form; they summarize in precise form the whole body of experience.

First law: *Every material body remains in its state of rest or of uniform rectilinear motion unless compelled by forces acting on it to change its state.*¹

We shall at first withhold explanation of the concept of force introduced in this law. We notice that the states of *rest* and of *uniform (rectilinear) motion* are treated on equal footing and are regarded as natural states of the body. The law postulates a tendency of the body to remain in such a natural state; this tendency is called the *inertia* of the body. One often speaks of *Galileo's law of inertia* instead of Newton's first law in referring to the above axiom. We must say in this connection that while it is perfectly true that Galileo arrived at this law long before Newton (as a limiting result of his experiments with sliding bodies on planes of vanishing inclination), we find it characteristic of Newton that the law holds top position in his system. Newton's word "body" will, for the time being, be replaced by the words "particle" or "mass point."

To formulate the first law mathematically we shall make use of definitions 1 and 2 preceding it in the "Principia."

Definition 2: *The quantity of motion is the measure of the same, arising from the velocity and the quantity of matter conjunctly.*²

The "quantity of motion" is hence the product of two factors, the velocity, whose meaning is geometrically evident,³ and the "quantity of

¹ We mention here, and in connection with what is to follow, the book *Die Mechanik in ihrer Entwicklung* (8th ed., F. A. Brockhaus, Leipzig, 1923; translated into English under the title *The Science of Mechanics*, Open Court Publishing Co., LaSalle, Ill., 1942) by Ernst Mach. The study of this excellent critical history is recommended to all students of mechanics, especially since in our book we must restrict ourselves to the concepts of mechanics in a form ready for use and cannot delve into the origin and gradual clarification of these concepts. This should not be interpreted to mean, however, that we agree with Mach's positivistic philosophy as it is developed in Chapter IV, 4, of his book, with its attendant overemphasis of the Economy Principle, the denial of atomic theory and the preference for formal continuity theories.

² *Newton's Principia*, translated by Andrew Motte.—TRANSLATOR.

³ Evident, that is, once a reference system has been chosen in which the velocity is to be measured.

matter," which is to be explained physically. Newton attempts the latter in his definition 1, in which he says that the quantity of matter is measured by its density and volume conjunctly. This is obviously only a mock definition, since density itself cannot be defined in any other way than by the amount of matter in unit volume. In the same definition 1, Newton also states that instead of "quantity of matter" he will use the word *mass*. We shall follow him in this, but shall postpone the physical definition of mass (as well as that of force) until later.

The quantity of motion accordingly becomes the product of mass and velocity. Like the latter it is a directed magnitude, a *vector*. We write⁴

$$(1) \quad \mathbf{p} = m\mathbf{v}$$

and formulate the first law of motion in its final form:

$$(2) \quad \mathbf{p} = \text{constant in the absence of forces.}$$

We shall put the law of inertia thus formulated at the head of our mechanics. It is the result of an evolution extending over many centuries, and is by no means as self-evident as it appears to us today. The philosopher Kant, for instance, says in his paper, "Thoughts on the True Estimation of Living Forces," written in 1747, long after Newton: "There exist two kinds of motions; those which have ceased after a certain time, and those which persist." The motions that in Kant's opinion cease by themselves are, according to modern ideas — and those of Newton — motions which are attenuated by frictional forces and finally destroyed.

The expression "quantity of motion" is unfortunately chosen in that it does not take into account the vector character of $m\mathbf{v}$. Thus a better term would be the word "impulse," which conveys the idea of a push of a certain magnitude in a definite direction that the given $m\mathbf{v}$ is able to impart, by collision, to some body initially at rest. Since the term "impulse" is, however, used in a somewhat different sense in mechanics, we shall have to retain the name "quantity of motion," or, in modern language, *momentum* for the vector \mathbf{p} . Instead of the law of inertia and Newton's first law of motion we can then speak of the *law of conservation of momentum*.

We shall now discuss Newton's second law, the real law of motion: *The change in motion is proportional to the force acting and takes place in the direction of the straight line along which the force acts.*

⁴ We assume that the reader is familiar with the elements of vector algebra. Since, however, vector operations originated in close association with mechanics (including the mechanics of fluids), we shall often have occasion to explain vector concepts simultaneously with mechanical concepts.

As regards notation, vectors will be designated throughout by bold-faced letters; thus ω for the angular velocity when regarded as a (axial) vector. In diagrams, overhead arrows will occasionally be used.

By "change in motion" Newton undoubtedly means the change with time of the previously defined momentum \mathbf{p} , hence the vector $\dot{\mathbf{p}}$ (the dot is Newton's notation for the "fluxion" $\dot{\mathbf{p}} = \frac{d\mathbf{p}}{dt}$). If we designate the force by the letter \mathbf{F} , our second law can then be written as

$$(3) \quad \dot{\mathbf{p}} = \mathbf{F}.$$

Since we called \mathbf{p} the momentum, this law expresses the manner in which momentum changes with time, and can, for brevity, be called simply the *law of momentum*.

Unfortunately the law is often, especially in the mathematical literature, designated as "Newton's law of acceleration." It is of course true that if we treat m as a constant, (3) combined with (1) is identical to

$$(3a) \quad m\dot{\mathbf{v}} = \mathbf{F}: \text{Mass} \cdot \text{Acceleration} = \text{Force}.$$

But mass is not always constant; it is variable in the theory of relativity for example, where Newton's formulation (3) prophetically turns out to be the correct one. We shall treat a series of examples with variable mass in § 4, where we shall have a closer look at the interrelation between formulations (3) and (3a). Incidentally, the mechanical system which is next in simplicity to that of a single mass point, namely, the rotating rigid body, leads us to an equation of motion along the lines of (3), in the form "rate of change of moment of momentum (angular momentum) = moment of force (torque)"; a description in terms of angular acceleration, similar to (3a), is not possible. An effect similar to the non-constancy of mass in relativity must be taken into account: the moment of inertia, here replacing the mass, changes with changing location of the axis of rotation in the body.

We must now seek to get a clear idea of the concept of *force*. Kirchhoff⁵ wanted to degrade it to a quantity defined by the product of mass and acceleration. Hertz⁶, too, tried to eliminate and replace it by coupling the system under consideration with other, generally hidden systems interacting with the former. Hertz carried out this program with admirable consistency. His method, however, hardly produced fruitful results; and it is especially unsuitable for the beginner.

We are of the opinion that we have at least a *qualitative* notion of "force" which we acquire quite directly through the feeling we experience when using our muscles. In addition the earth has provided us with the comparison standard of gravity, with which we can measure all other forces *quantitatively*. For this purpose we need merely balance the effect

⁵ Gustav Kirchhoff, Vol. I of his *Vorlesungen über mathematische Physik*, p. 22.

⁶ Heinrich Hertz, *Miscellaneous Papers*, Vol. III, *Principles of Mechanics*, Macmillan, New York, 1896.

of a given force by a suitable weight. (By means of a pulley and string we can let the vertical force of gravity act in a direction opposed to the given force.) If, in addition, we procure a number of equally heavy bodies, a "set of weights," we obtain a tentative scale with which to measure forces quantitatively.

The same is true for the concept of force as for all other physical concepts and names: word definitions have very little meaning; physically significant definitions are obtained as soon as we prescribe a way of measuring the quantity in question. Such a prescription need not contain the details of practical procedure, but merely state a way to measure the quantity in principle.

The above prescription, making use of gravity, has given a concrete content to the right member of our law of momentum (3); it has thereby become a real physical statement. It is true that the left member still contains the mass m , up to now undefined. This does not mean that the definition of mass is the only content of the law. For the law brings out that it is \dot{p} , not p itself or perhaps β which is determined by the force. We shall see in § 4 how the definition of mass is obtained in case it is variable, the relativistic mass serving as example.

Third law: *Action always equals reaction, or: the forces two bodies exert on each other are always equal and opposite in direction.*

This is the principle of action and reaction. It says that for every pressure there is a pressure in the opposite direction. Forces always occur paired in nature. The falling stone attracts the earth just as strongly as the earth attracts the stone.

This law makes possible the transition from the mechanics of single mass points to that of compound systems; it is therefore fundamental to the entire field of structural statics, to name but one example.

We shall call the rule of the *parallelogram of forces* our **Fourth law**, even though in Newton it appears merely as an addition or corollary to the other laws of motion. The fourth law states that two forces applied to the same mass point compound to act like the diagonal of the parallelogram formed by them: *forces add like vectors*. This seems self-evident since we equated the force F to the vector \dot{p} in the Second Law. Actually, however, the Fourth Law, as Mach emphasizes, contains the axiom that each force acting on a mass point causes it to change its motion as if this force were the only one acting there. The parallelogram of forces hence establishes axiomatically the independence of the effects of several forces acting together at the same point, or, more generally, the *principle of superposition of forces*. Of course the last statement as well as the laws of motion preceding it are nothing but an idealization and a precise formulation of our whole body of experience.

Having introduced the concept of force, we shall at this point introduce that of *work* with the definition

$$(4) \quad dW = \mathbf{F} \cdot d\mathbf{s} = F \, ds \cos(\mathbf{F}, d\mathbf{s}).$$

Thus the work does not equal "force times distance" as often stated, but "component of force along path times path length" or "force times component of path length along force."

From the statement, "forces add vectorially," follows immediately the complementary statement that "work adds algebraically." Indeed

$$\mathbf{F}_1 + \mathbf{F}_2 + \cdots = \mathbf{F}$$

leads to

$$(5) \quad \mathbf{F}_1 \cdot d\mathbf{s} + \mathbf{F}_2 \cdot d\mathbf{s} + \cdots = \mathbf{F} \cdot d\mathbf{s}$$

by scalar multiplication with the distance $d\mathbf{s}$. Here \mathbf{F} is the resultant force. The definition of the scalar product contained in (4) automatically sees to it that, for example, in the first product of (5) only ds_1 , the component of the distance in the direction of the force \mathbf{F}_1 , occurs. Hence we can also write instead of (5) that

$$(6) \quad dW_1 + dW_2 + \cdots = dW,$$

as stated above.

Related to the concept of work is that of *power*; power is the work done in unit time.

In concluding these introductory remarks we shall have to agree on how to measure the mechanical quantities that we have introduced. Here we have a choice of two systems of units, the *physical* (or *absolute*) and the *practical* (or *gravitational*) metric systems. The difference between them is that in the absolute system the gram (or kilogram) serves as unit *mass*, whereas in the gravitational system the kilogram (or gram) serves as unit *force*. In the latter case we speak of a kilogram-weight and write

$$1 \text{ kg-weight} = g \cdot \text{kg-mass}.$$

The gravitational acceleration g is, however, a function of the location on the earth, being greater at the poles than at the equator because of a smaller distance from the center of the earth as well as because of diminished centrifugal force. Hence the kg-weight is dependent on location; a kg-weight sample cannot be transported. The gravitational system is therefore unsuitable for precise measurements. The physical system has, in contrast, been distinguished by the title, "absolute system of units." We have nevertheless become so accustomed to the gravitational system that in many cases where we should really say "mass," the word "weight" has once and for all made its way into our scientific language. Thus we talk of specific

weight when we should say specific mass or density; and of atomic and molecular weights — which surely have nothing to do with the acceleration due to gravity.

Gauss, the originator of absolute measurements, decided in favor of the absolute system after some hesitation. Initially he, too, was in favor of introducing force as the basic unit, since it played a more direct role than mass in his measurements of terrestrial magnetism. On the other hand he wanted these measurements to encompass the entire surface of our globe; he therefore saw himself forced to adopt as unit a quantity whose value would not depend on location.

Below we have put the two systems next to each other and at the same time introduced the derived units dyne, erg, joule, watt, and horse power (HP):

<u>Absolute system (CGS)</u>	<u>Gravitational system (MKS)</u>
cm, g-mass, sec	kg-weight, m, sec
1 kg-weight = $9.81 \cdot 10^5$ g cm sec ⁻² = $9.81 \cdot 10^5$ dyne	1 g-mass = $\frac{1 \text{ kg}}{1000} \frac{1}{g} \text{ sec}^2 \text{ m}^{-1}$
1 erg = 1 dyne · 1 cm	1 unit of work = 1 kg · 1 m
1 joule = 10^7 erg	
1 mkg-weight = $1000 \cdot g \cdot 100$ erg = $9.81 \cdot 10^7$ erg = 9.81 joule	
1 watt = 1 joule sec ⁻¹	1 unit of power = 1 kg m sec ⁻¹
1 kilowatt = 1000 joule sec ⁻¹ = $\frac{1 \text{ HP}}{0.736} = 1.36 \text{ HP}$	1 HP = 75 kg m sec ⁻¹ = $75 \cdot 1000 \cdot 100 \cdot 981 \text{ erg sec}^{-1}$ = $75 \cdot 9.81 \text{ watt} = 0.736 \text{ kw}$

It should be noted that according to a decision of the pertinent international commissions the CGS system was to be replaced by an absolute MKS system beginning with the year 1940. In this new system the meter takes the place of the centimeter, and the kilogram that of the gram as unit of mass, while the second is retained as unit of time. This is in agreement with a proposal of G. Giorgi, which shows its advantages fully only in electrodynamics with the addition of a fourth independent electrical unit (see Vol. III of this series). In mechanics the proposed change would have the advantage that in the definition of the joule and the watt the bothersome powers of ten are eliminated. With the new larger units M and K the units of work and power become

$$1 \text{ M}^2\text{KS}^{-2} = 10^7 \text{ cm}^2 \text{ g sec}^{-2} = 1 \text{ joule},$$

$$1 \text{ M}^2\text{KS}^{-3} = 10^7 \text{ cm}^2 \text{ g sec}^{-3} = 1 \text{ watt}.$$

The unit of force in the new system, called the newton, is thus

$$1 \text{ newton} = 1 \text{ MKS}^{-2} = 10^5 \text{ cm g sec}^{-2} = 10^5 \text{ dyne.}$$

This, too, can be regarded as an advantage of the Giorgi system, since now the new unit of force is brought closer to the convenient gravitational unit, the kg-weight, whereas the old unit of force, the dyne, is inconveniently small for most practical uses.

§ 2. *Space, Time and Reference Systems*⁷

Newton's views about space and time seem to us moderns quite unrealistic and appear to contradict his declared intention to base his analysis on fact alone. He states:

"Absolute space, in its own nature, without regard to anything external, remains always similar and immovable.

"Absolute, true, and mathematical time, of itself, and from its own nature, flows equably without regard to anything external, and by another name is called duration."

From these two quotations one would conclude that Newton worried but little where absolute time was to be taken from, and how an immovable absolute space was to be distinguished from one moving uniformly with respect to it. This is all the more surprising since he put the states of rest and of uniform motion on the same footing in his first law. On the other hand Newton tried to clarify the distinction between absolute and relative motion by his famous pail experiment.⁸ In this experiment a pail is suspended from a twisted thread and filled with water. The pail is then suddenly released and as the thread untwists acquires a rotation about its axis of symmetry. The surface of the water remains at first level, although the relative velocity between pail and water is great. Gradually the water is set in motion by friction with the walls of the pail, climbs up the wall, and its surface assumes the familiar hollow paraboloidal shape. Finally a steady state is reached in which the relative motion between pail and water is zero; the "absolute" motion of the water in space has, on the other hand, increased to a maximum, and with it the curvature of the surface.

Actually the experiment only shows that the rotating pail does not furnish a suitable reference system from which the motion of the water can be understood. Is the earth such an unsuitable reference system?

⁷ The beginner to whom the following somewhat abstract considerations seem unfamiliar may postpone the study of this section and of § 4 until a later time.

⁸ "I have performed this experiment myself," says Newton, probably with reference to the natural philosophers, perhaps his compatriot Francis Bacon, who was wont to describe the results of experiments he had not performed.

It, too, rotates and furthermore describes an orbit around the sun. In general, what are the requirements that an ideal reference system has to satisfy in mechanics? By a reference system is meant a frame in space and time which will enable us to read off the position of mass points and the passage of time; we might take a Cartesian system of coordinates x, y, z , and a time scale, t .

In practice we shall have to rely on the astronomers for this choice. The fixed stars furnish sufficiently constant directions for our coordinate axes, and the sidereal day furnishes a sufficiently constant interval of time. Theoretically, on the other hand, we are forced to recognize a disagreeable tautology: that reference frame is an ideal one in which the Galilean law of inertia holds with sufficient accuracy, for a sufficiently force-free body. Thus the first law is degraded to a formal identity or to the rank of definition. The only positive, not purely formal content that the law retains is the assertion that reference systems of the required properties do exist. All our experience indicates that one such system is approximated by astronomical determinations of position and time.

We mean essentially the same thing when we say that the laws of mechanics presuppose the existence of an *inertial frame*, i.e., an imaginary structure whose axes are trajectories of bodies moving purely under inertia.

The question now arises to what extent this ideal system of reference is determined. Is there only one such system x, y, z, t , or are there perhaps infinitely many such systems? Newton's first law gives the answer at once, for it states that any two systems x, y, z, t and x', y', z', t' are equivalent if they differ only by a uniform translational motion. In mathematical form

$$(1) \quad \begin{aligned} x' &= x + \alpha_0 t \\ y' &= y + \beta_0 t \\ z' &= z + \gamma_0 t \\ t' &= t. \end{aligned}$$

We can generalize the transformation (1) by performing a rotation on the spatial system x, y, z about its origin, which amounts to replacing x, y, z in (1) by new space coordinates ξ, η, ζ such that

$$(2) \quad \xi^2 + \eta^2 + \zeta^2 = x^2 + y^2 + z^2.$$

This condition defines an arbitrary *orthogonal transformation*. With $\alpha_k, \beta_k, \gamma_k$, the direction cosines, it yields

$$(3) \quad \begin{array}{c|ccc} & x & y & z \\ \hline \xi & \alpha_1 & \alpha_2 & \alpha_3 \\ \eta & \beta_1 & \beta_2 & \beta_3 \\ \zeta & \gamma_1 & \gamma_2 & \gamma_3 \end{array}$$

This scheme can be read equally well from left to right as from top to bottom. Because of (2) the α , β , γ satisfy the well-known relations

$$(4) \quad \sum \alpha_k^2 = \sum \beta_k^2 = \sum \gamma_k^2 = 1, \quad \sum \alpha_k \beta_k = \dots = 0, \text{ etc.}$$

If now we replace the x, y, z in the right member of (1) by the ξ, η, ζ of (3), we obtain the generalized transformation scheme*

$$(5) \quad \begin{array}{c|cccc} & x & y & z & t \\ \hline x' & \alpha_1 & \alpha_2 & \alpha_3 & \alpha_0 \\ y' & \beta_1 & \beta_2 & \beta_3 & \beta_0 \\ z' & \gamma_1 & \gamma_2 & \gamma_3 & \gamma_0 \\ t' & 0 & 0 & 0 & 1 \end{array}$$

The fact that the primed system x', y', z', t' is just as good a reference frame for the purposes of classical mechanics as the unprimed system x, y, z, t is called the *principle of relativity of classical mechanics*. In what follows (5) will be called a *Galilean transformation*. It is a linear transformation in the four coordinates; it is orthogonal in the first three, and leaves the time coordinate invariant ($t' = t$). The last statement means that the principle of relativity of classical mechanics leaves intact the absolute character of time as postulated by Newton.

A new situation arises, however, in the field of electrodynamics, particularly in the electromagnetic theory of optical phenomena. Maxwell's equations, which form the basis of this field, require that the process of the propagation of light *in vacuo* with the velocity c be independent of the frame of reference from which this process is observed. The front of a spherical wave whose source is at the origin of coordinates is given by the equation

$$(6) \quad x^2 + y^2 + z^2 = c^2 t^2 \quad \text{or} \quad x'^2 + y'^2 + z'^2 = c^2 t'^2$$

respectively, depending on whether we are describing the wave front in the unprimed or the primed system. It is now convenient to change the names of the coordinates in the following manner:

$$(7) \quad x = x_1, y = x_2, z = x_3, i c t = x_4,$$

where i is the imaginary unit; we introduce a corresponding change of notation for the primed coordinates. Equations (6) then read

$$(8) \quad \sum_1^4 x_k^2 = 0, \quad \sum_1^4 x'_k{}^2 = 0,$$

* Note that this table can be read from left to right but no longer from top to bottom, since the transformation is no longer orthogonal.—TRANSLATOR.

and the fact that the propagation of light does not depend on the choice of reference frame demands that¹⁰

$$(9) \quad \sum_1^4 x_k'^2 = \sum_1^4 x_k^2.$$

Whereas Eq. (2) was an orthogonal transformation in three-dimensional space, we are dealing in (9) with an orthogonal transformation in four-dimensional space. True, the fourth coordinate is imaginary. This, however, will not affect the existence of equations analogous to (3), (4) and (5). The relation between the x_k and the x'_k arising from (5) is in general called a *Lorentz transformation*, after the great Dutch theoretical physicist Hendrik Antoon Lorentz. We write it in the form of the general scheme

$$(10) \quad \begin{array}{c|cccc} & x_1 & x_2 & x_3 & x_4 \\ \hline x'_1 & \alpha_{11} & \alpha_{12} & \alpha_{13} & \alpha_{14} \\ x'_2 & \alpha_{21} & \alpha_{22} & \alpha_{23} & \alpha_{24} \\ x'_3 & \alpha_{31} & \alpha_{32} & \alpha_{33} & \alpha_{34} \\ x'_4 & \alpha_{41} & \alpha_{42} & \alpha_{43} & \alpha_{44} \end{array}$$

This table shows at once that the time coordinate (in the imaginary form x_4) is now involved in a change of reference system to the same extent as the space coordinates. As a necessary consequence of the invariance requirement (9) the absoluteness of time is now destroyed.

More instructive than the general Lorentz transformation is the special one which we obtain when we leave two space coordinates, say x_1 and x_2 , unchanged, and transform only x_3 and x_4 .

Then all the α_{ij} of the first and second rows of columns in (10) must vanish, except for

$$\alpha_{11} = \alpha_{22} = 1,$$

because $x'_1 = x_1$, $x'_2 = x_2$ (as read from left to right as well as from top to bottom). Furthermore we have the conditions analogous to (4),

$$(11) \quad \alpha_{33}^2 + \alpha_{34}^2 = \alpha_{33}^2 + \alpha_{43}^2 = \alpha_{43}^2 + \alpha_{44}^2 = \alpha_{34}^2 + \alpha_{44}^2 = 1,$$

and therefore

$$\alpha_{33}^2 = \alpha_{44}^2, \quad \alpha_{34}^2 = \alpha_{43}^2.$$

Letting $\delta = \pm 1$, we can write

$$(11a) \quad \alpha_{34} = \delta \alpha_{43}$$

¹⁰ For one of the Eqs. (8) must be the consequence of the other. In view of the linearity of the relation between them, one of the expressions (8) must be proportional to the other. Since the relation is a reciprocal one, the factor of proportionality must be unity.

and we must then put

$$(11b) \quad \alpha_{44} = -\delta\alpha_{33}$$

because of the other orthogonality condition $\alpha_{33}\alpha_{34} + \alpha_{43}\alpha_{44} = 0$. We now make use of (11a, b) to solve for the primed coordinates in terms of the unprimed. At the same time, with the help of (7), we go back to our original coordinates z, t, z', t' to obtain

$$(12) \quad \begin{aligned} z' &= \alpha_{33} \left(z + i\delta c \frac{\alpha_{43}}{\alpha_{33}} t \right), \\ t' &= -\delta \alpha_{33} \left(t + i \frac{\delta}{c} \frac{\alpha_{43}}{\alpha_{33}} z \right). \end{aligned}$$

The first of these equations shows that

$$(12a) \quad -i\delta c \frac{\alpha_{43}}{\alpha_{33}} = v$$

must be identified with the velocity with which the z' -axis moves parallel to the z -axis in the positive direction of the latter, as observed from the unprimed system. With the help of (12a) Eqs. (12) become

$$(13) \quad \begin{aligned} z' &= \alpha_{33} (z - vt), \\ t' &= -\delta \alpha_{33} \left(t - \frac{v}{c^2} z \right). \end{aligned}$$

Finally we must determine α_{33} . To this end we use Eq. (9) which, in the original coordinates, now simplifies to $z'^2 - c^2 t'^2 = z^2 - c^2 t^2$. Let us introduce here the values of z' and t' from (13). The factor of $2vzt$ vanishes on the left. Comparison of the factors of z^2 and t^2 on the left and right yields

$$\alpha_{33}^2 = \frac{1}{1 - v^2/c^2}.$$

In the limit $c \rightarrow \infty$ (13) must of course reduce to the Galilean transformation (1) with $\alpha_0 = \beta_0 = 0$ and $\gamma_0 = -v$. To this end we must put $\delta = -1$ and must choose the positive sign of α_{33} . We then obtain the characteristic two-dimensional Lorentz transformation

$$(14) \quad \begin{aligned} z' &= \frac{z - vt}{(1 - \beta^2)^{\frac{1}{2}}}, \\ t' &= \frac{t - \frac{v}{c^2} z}{(1 - \beta^2)^{\frac{1}{2}}}, \end{aligned}$$

where $\beta = \frac{v}{c}$, $(1 - \beta^2)^{\frac{1}{2}} > 0$.

The relativization of the time in (14) and the change of scale of the space coordinate z , as embodied in the denominator $(1 - \frac{v^2}{c^2})^{\frac{1}{2}}$, are, as we

have seen, a result of the fact that the velocity of light c is finite, a fact with which the principle of relativity of classical mechanics is incompatible.

If it be true that all electrodynamic effects are propagated with finite velocity c , it follows that for such effects the Galilean transformation must always be replaced by a Lorentz transformation, either in the general form (10), or the specialized form (14). We call this fact the *principle of relativity of electrodynamics*. It is evident, however, that mechanics too has to adapt itself to the fact of the finite propagation velocity of light. Now all velocities occurring in ordinary mechanics are quite small compared to c . This is the reason why for the purposes of mechanics we can, as a rule, neglect the change of scale of the space and time coordinates indicated by (14).

The wealth of physical facts embodied in the Lorentz transformation will be discussed in the third volume of this series. Here we shall only investigate the changes that we have to make in the concept of the fundamental quantity p , the momentum, as a result of our new relativity principle.

We have called p a vector. This means that the three components of p transform just like the coordinates themselves [i.e., the components of the radius vector $r = (x, y, z)$] in a change of the system of coordinates. We therefore say that p is covariant to r .

This is valid only from the viewpoint of the Galilean transformation, where the time is regarded as absolute. From the viewpoint of the Lorentz transformation the radius vector is a four-component quantity, a *four-vector*

$$(15) \quad \mathbf{x} = (x_1, x_2, x_3, x_4).$$

Our relativistic momentum will similarly have to be a four-vector, i.e., must be covariant to \mathbf{x} , if it is to have a meaning in relativity theory. We arrive at this four-vector in the following manner:

(a) (15) being a four-vector, the coordinate distance between two neighboring points

$$(16) \quad d\mathbf{x} = (dx_1, dx_2, dx_3, dx_4) = (dx_1, dx_2, dx_3, icdt)$$

is also a four-vector.

(b) The magnitude of this distance is certainly invariant under a Lorentz transformation. Apart from a factor ic , it is given by

$$(17) \quad d\tau = \left[dt^2 - \frac{1}{c^2} (dx_1^2 + dx_2^2 + dx_3^2) \right]^{\frac{1}{2}}$$

We follow Minkowski in calling $d\tau$ the element of *proper time*; in contrast to dt it is relativistically invariant. We shall factor out dt in (17) and introduce the ordinary velocity v of three dimensions, to obtain

$$(17a) \quad d\tau = dt \left(1 - \frac{v^2}{c^2}\right)^{\frac{1}{2}} = dt (1 - \beta^2)^{\frac{1}{2}}.$$

(c) Division of the four-vector (16) by the invariant (17a) yields another four-vector; we call it the four-vector velocity

$$(18) \quad \frac{1}{(1 - \beta^2)^{\frac{1}{2}}} \left(\frac{dx_1}{dt}, \frac{dx_2}{dt}, \frac{dx_3}{dt}, ic \right).$$

(d) Earlier we derived the momentum vector \mathbf{p} by multiplying the velocity three-vector by a mass m independent of the reference frame. We shall similarly deduce the momentum four-vector \mathbf{p} from the four-vector (18) by multiplication by a mass factor independent of the frame of reference. We shall call this mass factor the *rest mass* m_0 and obtain

$$(19) \quad \mathbf{p} = \frac{m_0}{(1 - \beta^2)^{\frac{1}{2}}} \left(\frac{dx_1}{dt}, \frac{dx_2}{dt}, \frac{dx_3}{dt}, ic \right).$$

It is proper to call the quantity in front of the parenthesis the moving mass (since it reduces to the rest mass for $\beta=0$), or simply the mass. We therefore assert that

$$(20) \quad m = \frac{m_0}{(1 - \beta^2)^{\frac{1}{2}}}.$$

This expression was first derived by Lorentz in 1904 under very special assumptions (deformable electron). The derivation from the principle of relativity makes such special assumptions unnecessary. Eq. (20) has been confirmed by many precision experiments with fast electrons. Together with optical experiments, notably that of Michelson and Morley, it forms the basis of the theory of relativity. Here we have proceeded in inverse order and deduced Eq. (20) from the principle of relativity in what appears to be a very formal procedure. This is not only logically admissible, but especially serviceable in view of the brevity of these introductory explanations. In § 4 we shall discuss what changes in the further application of Newton's laws of motion will have to be made as a result of the velocity-dependence of mass.

At this point we should, if only sketchily, bring to a conclusion the question of the permissible frames of reference; to this end we must pass from the *special theory of relativity* treated so far to the *general theory of relativity* (Einstein, 1915). In special relativity there are allowed reference systems which are obtained from one another by Lorentz transformations, and forbidden ones, such as, for example, those that are accelerated with respect to the former. In general relativity all possible frames of reference are admitted. Transformations between them need no longer be linear and orthogonal as in (10), but can instead be given by arbitrary functions $x'_k = f_k(x_1, x_2, x_3, x_4)$. Hence we are dealing with systems which are moving

and are being deformed with respect to each other in any way desired. As a result space and time lose any vestiges of the absolute character which they held in Newton's fundamental analysis. They become merely classification schemes for physical events. Euclidean geometry no longer suffices for this classification and must be replaced by the much more general metric geometry advanced by Riemann. The task then arises to give such a form to physical laws that they will remain valid in all frames of reference here considered, i.e., a form that remains invariant under arbitrary point transformations $x'_A = f_A(x_1 \cdots x_4)$ of four-dimensional space. The positive content of the general theory of relativity is precisely the possibility of this task. We cannot in this volume delve into the mathematically very involved form which the laws of mechanics take on in their invariant formulation. Suffice it to say that the general theory leads to a derivation and a more precise formulation of Newtonian gravitation.

We conclude with a remark about the name, theory of relativity. The positive achievement of the theory is not so much the complete relativization of space and time, but the proof that the laws of nature are independent of the choice of reference system, i.e., that events in nature are invariant under any change in the observer's view point. The names, "theory of the invariance of natural events," or, as occasionally proposed, "view-point theory," would be more appropriate than the customary name, general theory of relativity.

§ 3. Rectilinear Motion of a Mass Point

Let the motion of the particle take place along the x -axis. Only the x -components of any forces present will have any effect. Let X denote the resultant of these components.

We have $v = v = \frac{dx}{dt}$ and $p = m \frac{dx}{dt}$. Then

$$(1) \quad \dot{p} = X$$

and, with constant m ,

$$(2) \quad m \frac{d^2x}{dt^2} = X.$$

We wish to study the integration of this equation of motion for the three cases: X is given as a pure function of the time, [$X = X(t)$], of the position, [$X = X(x)$], or of the velocity, [$X = X(v)$].

(a) $X = X(t)$.

Immediate integration yields

$$(3) \quad v - v_0 = \frac{1}{m} \int_{t_0}^t X(t) dt = \frac{1}{m} Z(t).$$

Here $Z(t)$ is by definition the time integral of the force and equals the change in momentum during the time from t_0 to t .

A second integration leads to the equation of the trajectory,

$$(4) \quad x - x_0 = v_0(t - t_0) + \frac{1}{m} \int_{t_0}^t Z(t) dt.$$

(b) $X = X(x)$.

This is the typical case of the *force field* given as a function of position. Integration is achieved by use of the principle of the conservation of energy.

We multiply (2) on both sides by $\frac{dx}{dt}$,

$$(5) \quad m \frac{dx}{dt} \frac{d^2x}{dt^2} = X \frac{dx}{dt}.$$

The left member is now a complete differential,

$$\frac{d}{dt} \left\{ \frac{m}{2} \left(\frac{dx}{dt} \right)^2 \right\}.$$

In agreement with the general definition of (1.4) we write for the right member $dW = X dx$ and call dW the work done over the path dx . The equation thus arising says that *the change in kinetic energy equals the work done*.

For we define

$$(6) \quad T = E_{\text{kin}} = \frac{m}{2} v^2$$

as the *kinetic energy* or energy of motion of the mass point; the older name, live force (Leibniz), shows the ambiguity of the word force (he distinguished live force, *vis viva*, i.e., kinetic energy, and motor force, *vis motrix*, our present-day force; even Helmholtz, as late as 1847, entitled a treatise dealing with the conservation of energy "Concerning the Conservation of Force").

To the definition of the kinetic energy we add that of the potential energy V ,

$$(7) \quad dV = -dW = -X dx, \quad V = E_{\text{pot}} = - \int X dx.$$

In one-dimensional particle mechanics this definition suffices; in the case of two- or three-dimensional force fields the existence of V depends on the character of the fields (cf. § 6, Part 3). According to (7) V is determined only to within an additive constant.

With these definitions the integrated Eq. (5) yields the law of the conservation of energy,

$$(8) \quad T + V = \text{constant} = E.$$

Here E is the energy constant or *total energy*.

The principle of the conservation of energy possesses not only an exceedingly great physical importance, but also remarkable mathematical power. For it performs, as we have seen, not only the first integration of the equation of motion (hence its alternate name, "integral of energy"), but at once makes possible — at least in the present case (b) — a second integration as well. If we write (8) in the form

$$\left(\frac{dx}{dt}\right)^2 = \frac{2}{m} [E - V(x)],$$

we can solve for dt ,

$$dt = \left[\frac{m}{2(E - V)} \right]^{\frac{1}{2}} dx,$$

so that

$$(9) \quad t - t_0 = \left(\frac{m}{2}\right)^{\frac{1}{2}} \int_{x_0}^x \frac{dx}{(E - V)^{\frac{1}{2}}}.$$

Thus t is a known function of x , and therefore x can also be expressed in terms of t . (9) is then the completely integrated equation of motion.

(c) $X = X(v)$.

Now the equation of motion reads

$$m \frac{dv}{dt} = X(v)$$

which we rewrite as

$$dt = \frac{m dv}{X}$$

thereby at once obtaining

$$(10) \quad t - t_0 = m \int_{v_0}^v \frac{dv}{X} = F(v).$$

This also allows us to solve for v in terms of t , $v = f(t)$, so that

$$\frac{dx}{dt} = f(t),$$

from which we conclude that

$$x - x_0 = \int_{t_0}^t f(t) dt.$$

Examples

1. FREE FALL NEAR EARTH'S SURFACE (Falling Stone)

We take the positive x -direction as vertically upward. The force is constant,

$$(11) \quad X = -mg,$$

i.e., independent of t , x , and v . Here all three methods of integration (a), (b), (c) can be applied.

We shall carry out (a) and (b), and postulate explicitly that the "gravitational mass" and the "inertial mass" be equal,

$$(12) \quad m_{\text{inert}} = m_{\text{grav}}.$$

m_{inert} is the mass defined by the Second Law; m_{grav} is the mass occurring in the law of gravitation and hence also in our force equation (11).

Bessel recognized the necessity for testing Eq. (12) experimentally, by means of pendulum experiments.¹¹ A much more precise experimental proof was furnished by Eötvös with his torsion balance. Later on, Eq. (12) gave the first impulse to Einstein's theory of gravitation.

(a) $\ddot{x} = -g$. With suitable choice of the integration constants ($v=0$ and $x=h$ for $t=0$) we end up with

$$\dot{x} = -gt, \quad x = h - \frac{g}{2}t^2.$$

(b) Since $dW = -mgdx$, $V = mgx$ and $T + mgx = E$. If $v=0$ at $x=h$, we must have $E = mgh$; therefore

$$\frac{m}{2}v^2 + mgx = mgh.$$

From this we get for the particular value $x=0$ that $v^2 = 2gh$, or

$$(13) \quad v = (2gh)^{\frac{1}{2}}.$$

Inverting this equation we obtain

$$(13a) \quad h = \frac{v^2}{2g},$$

which is the height to which an arbitrary mass must be raised in order to attain, falling through this height in the gravitational field, a specified velocity v . The introduction of this height h instead of the velocity v is convenient, especially in certain engineering problems, such as the

¹¹ Incidentally we would like to direct the reader's attention to an interesting sentence occurring in Newton's *Mechanics*. At the beginning of this work, under Definition 1, Newton says: "Through very carefully performed experiments with pendula I have verified that mass and weight are proportional."

height to which water rises in a Pitot tube,¹² the pressure head in a centrifuge, etc. The height to which the water surface climbs in Newton's pail experiment is similarly given by (13a).

2. FREE FALL FROM A GREAT DISTANCE (Meteor)

Now the force of attraction is no longer constant. Instead we must use the law of gravitation

$$(14) \quad m \frac{d^2 r}{dt^2} = - \frac{mMG}{r^2},$$

where m is the mass of the meteor, M that of the earth, G the gravitational constant. Instead of the coordinate x we have introduced the distance r of the meteor from the center of the earth. Since the force is now a function of r , method of integration (b) should be used.

In particular, for the surface of the earth, with a the earth's radius, (14) yields

$$mg = \frac{mMG}{a^2},$$

so that mMG can be eliminated from (14),

$$\frac{d^2 r}{dt^2} = -g \frac{a^2}{r^2}.$$

With this notation (7) yields

$$dV = -dW = mga^2 \frac{dr}{r^3},$$

so that the potential energy, with zero level at infinity, becomes

$$(15) \quad V(r) = -mg \frac{a^2}{r}.$$

Eq. (8) therefore gives

$$\frac{m}{2} \left(\frac{dr}{dt} \right)^2 - \frac{mga^2}{r} = W = - \frac{mga^2}{R},$$

where R is some hypothetical initial distance from the earth's center at which the falling mass was in a state of rest. We thus obtain

$$(16) \quad \frac{dr}{dt} = a \left[2g \left(\frac{1}{r} - \frac{1}{R} \right) \right]^{\frac{1}{2}}$$

and, corresponding to (9),

$$(16a) \quad t = \frac{1}{a(2g)^{\frac{1}{2}}} \int \frac{dr}{\left(\frac{1}{r} - \frac{1}{R} \right)^{\frac{1}{2}}}.$$

¹² A hollow tube used in fluid flow to measure the dynamic pressure. It is often used on airplanes as an airspeed indicator. Cf. Glazebrook, *Dictionary of Applied Physics* V, p. 2.—TRANSLATOR.

We need not do the integration indicated in (16a) in detail, since only two special cases of (16) are of interest to us:

$$(a) \quad R = \infty, r = a.$$

The meteor reaches the earth with the velocity

$$\frac{dr}{dt} = (2ga)^{\frac{1}{2}},$$

i.e., a free fall in the earth's gravitational field from infinity results in the same velocity at the surface of the earth which would be achieved by a free fall from a height $h=a$ equal to the earth's radius under a constant acceleration due to gravity g [cf. Eq. (13)].

$$(b) \quad R = a + h, \quad h \ll a, \quad r = a.$$

Here we are concerned with a first order correction to the velocity of fall (13), taking into consideration the decreasing gravitational acceleration, but assuming that the meteor falls from not too great a height. From (16) we derive

$$\begin{aligned} \frac{dr}{dt} &= \left[2ga \left(1 - \frac{1}{1 + \frac{h}{a}} \right) \right]^{\frac{1}{2}} = (2ga)^{\frac{1}{2}} \left(\frac{h}{a} - \frac{h^2}{a^2} + \dots \right)^{\frac{1}{2}} \\ &= (2ga)^{\frac{1}{2}} \left(\frac{h}{a} \right)^{\frac{1}{2}} \left(1 - \frac{1}{2} \frac{h}{a} + \dots \right) = (2gh)^{\frac{1}{2}} \left(1 - \frac{1}{2} \frac{h}{a} + \dots \right). \end{aligned}$$

3. FREE FALL IN AIR

We shall assume that the air resistance is proportional to the square of the velocity. This assumption, introduced by Newton, agrees quite well with experience if the falling body is not too small and its velocity is neither comparable to that of sound, nor vanishingly small. The resultant force is then

$$X(v) = -mg + av^2,$$

where the signs indicate that the air resistance opposes the force of gravitation. Here method (c) of p. 18 applies, and the equation of motion becomes

$$(17) \quad \frac{dv}{dt} = -g + \frac{a}{m} v^2.$$

If we put $\frac{a}{mg} = b^2$, it goes over into

$$\frac{dv}{dt} = -g(1 - b^2 v^2).$$

From this we obtain the analogue of (10) with $t_0=0$,

$$-g dt = \frac{dv}{2} \left(\frac{1}{1-bv} + \frac{1}{1+bv} \right), \quad -gt = \frac{1}{2b} \cdot \ln \left(\frac{1+bv}{1-bv} \right),$$

so that

$$\frac{1+bv}{1-bv} = e^{-2bgt}$$

and

$$(18) \quad bv = \frac{e^{-2bgt} - 1}{e^{-2bgt} + 1} = -\frac{\sinh bgt}{\cosh bgt} = -\tanh bgt,$$

where \sinh , \cosh , and \tanh are the hyperbolic functions. $|bv|$ hence grows monotonically from 0 at $t=0$, and approaches the value 1 as $t \rightarrow \infty$. The limiting value of v itself is

$$|v| = \frac{1}{b} = \left(\frac{mg}{a} \right)^{\frac{1}{2}}.$$

This can also be read at once out of Eq. (17), since for the above limiting value $\frac{dv}{dt}$ becomes equal to zero.

We make use of Eq. (18) to obtain the first order correction due to air resistance which must be added to the formula derived for a free fall *in vacuo*. From the series expansion

$$\tanh \alpha = \frac{\sinh \alpha}{\cosh \alpha} = \frac{\alpha + \frac{\alpha^3}{6}}{1 + \frac{\alpha^2}{2}} = \alpha \left(1 - \frac{\alpha^2}{3} \right)$$

we obtain, according to (18), with $\alpha = bgt$,

$$v = -gt \left(1 - \frac{(bgt)^2}{3} \right).$$

4. HARMONIC OSCILLATIONS

Harmonic oscillations occur whenever a restoring force X proportional to the displacement x acts on a mass point m . We call the proportionality factor k , so that

$$X = -kx$$

and the equation of motion with constant m is

$$(19) \quad m \frac{d^2x}{dt^2} = -kx.$$

Since the force is a given function of the coordinate [case (b) of p. 17], we make use of the rule given there and apply the integral of energy.

We must therefore first determine the potential energy of the harmonic binding force. We have

$$dW = X dx = -\frac{k}{2} d(x^2),$$

so that, according to (7), with a suitable choice of the zero of V ,

$$V = - \int_0^x dW = \frac{k}{2} x^2.$$

The equation of energy is then

$$mv^2 + kx^2 = 2E.$$

As our initial conditions we may choose

$$(19a) \quad \text{at } t=0: \begin{cases} x=a \\ v=\dot{x}=0. \end{cases}$$

As a result $2E$ takes the value ka^2 , and

$$\begin{aligned} \left(\frac{dx}{dt}\right)^2 &= \frac{k}{m} (a^2 - x^2), \\ \left(\frac{k}{m}\right)^{\frac{1}{2}} dt &= \frac{dx}{(a^2 - x^2)^{\frac{1}{2}}}. \end{aligned}$$

A quadrature, incorporating the initial conditions (19a), yields

$$(20) \quad \omega t = \sin^{-1}\left(\frac{x}{a} - \frac{\pi}{2}\right) \text{ with } \omega = \left(\frac{k}{m}\right)^{\frac{1}{2}}.$$

An inversion finally gives

$$(21) \quad x = a \sin\left(\omega t + \frac{\pi}{2}\right) = a \cos \omega t.$$

The physical meaning of the abbreviation ω is therefore clear. It is the circular frequency, i.e., the number of vibrations in 2π units of time; T being the period of oscillation, ν the frequency¹², we have the relation

$$(22) \quad \omega = \frac{2\pi}{T} = 2\pi\nu.$$

With the help of this abbreviation (19) can also be written

$$(23) \quad \ddot{x} + \omega^2 x = 0.$$

The equation of energy has the advantage that it always leads to the desired end, no matter how the force X depends on x . In our case, however, where X is linear in x , another much more elegant method exists. It is

¹² As opposed to ω , ν is the frequency, the number of vibrations in *unit* time.

based on the immediately plausible rule that a homogeneous linear differential equation with constant coefficients of any order (x being the dependent, t the independent variable) can always be solved by putting

$$(24) \quad x = C e^{\lambda t},$$

provided λ is chosen to be one of the roots of an algebraic equation obtained from our differential equation. This furnishes a *particular* solution. The *general* solution is obtained by a superposition of all such particular solutions in the form

$$(24a) \quad x = \sum C_j e^{\lambda_j t}.$$

The algebraic equation in λ is obtained by substitution of (24) in (23), and is here of second degree,

$$\lambda^2 + \omega^2 = 0 \text{ with the roots } \lambda = \pm i\omega.$$

The general solution is therefore

$$(24b) \quad x = C_1 e^{i\omega t} + C_2 e^{-i\omega t}.$$

Constants C_1, C_2 are determined by the boundary conditions (19a):

$$\dot{x} = 0 \quad , \quad C_1 i\omega - C_2 \omega i = 0: \quad C_1 = C_2.$$

$$x = a \quad , \quad a = C_1 + C_2 = 2C_1: \quad C_1 = \frac{a}{2}.$$

The final solution of the problem is, in agreement with (21),

$$x = a \cos \omega t.$$

We shall later (Chapter III, § 19) make extensive use of this method for damped, forced, coupled, etc., oscillations, provided these can be described by linear differential equations. The title, "harmonic oscillations," which we have given to this part, calls attention to the fact that the restoring force is linear in the coordinate, so that the resulting motion can be represented by a single constant frequency ω . The method fails in case the binding force is anharmonic, i.e., non-linear; in that event one has to resort to the less elegant method of the energy integral.

5. COLLISION OF TWO PARTICLES

Before the collision (cf. Fig. 1) let the masses m and M have velocities v_0 and V_0 respectively; after the collision they proceed with velocities v and V .

FIG. 1. Collision of two masses M and m ; velocities before collision v_0 and V_0 , after collision V and v .

No matter what the nature of the collision, whether elastic or inelastic, Newton's axiom "action=reaction" must be valid for the forces transmitted between m and M , and also for the time integral Z of these forces. Therefore, according to Eq. (3),

$$(25) \quad m(v - v_0) = Z = -M(V - V_0),$$

and hence also

$$(25a) \quad mv + MV = mv_0 + MV_0.$$

This equation states that the total momentum of the system is conserved.

Let us now introduce in (25a) the coordinate of the center of mass of the system,

$$(25b) \quad \xi = \frac{mx + MX}{m + M}.$$

We obtain

$$\dot{\xi} = \dot{\xi}_0.$$

This result says that the collision has no effect on the velocity of the center of mass.

Thus the center of mass of a shell fired *in vacuo* continues undisturbed in its parabolic path, even if at some point along the path the shell bursts into splinters each of which seems to follow an independent trajectory of its own.

So far we have two unknowns, v and V , and only one equation (25a). In order to find the complete solution of the collision problem a second relation is evidently necessary. We define an *elastic collision* as an interaction in which the kinetic energy as well as the momentum is conserved. We then require

$$(26) \quad \frac{m}{2}v^2 + \frac{M}{2}V^2 = \frac{m}{2}v_0^2 + \frac{M}{2}V_0^2,$$

or

$$m(v^2 - v_0^2) = M(V_0^2 - V^2).$$

But from (25)

$$m(v - v_0) = M(V_0 - V).$$

Division of these two equations yields

$$v + v_0 = V_0 + V,$$

or

$$(26a) \quad V - v = -(V_0 - v_0).$$

This equation states that the relative velocity of one mass with respect to the other after the collision is equal and opposite to that before the collision.

The combination of Eqs. (25a) and (26a),

$$mv + MV = mv_0 + MV_0$$

$$v - V = -v_0 + V_0$$

now completely determines the velocities after the collision,

$$(27) \quad \begin{aligned} v &= \frac{m-M}{m+M}v_0 + \frac{2M}{m+M}V_0 \\ V &= \frac{M-m}{m+M}V_0 + \frac{2m}{m+M}v_0. \end{aligned}$$

Notice that the determinant Δ of this "transformation" from initial values v_0, V_0 to final values v, V has the absolute value 1. For

$$\Delta = \begin{vmatrix} \frac{m-M}{m+M} & \frac{2M}{m+M} \\ \frac{2m}{m+M} & \frac{M-m}{m+M} \end{vmatrix} = -\left(\frac{M-m}{m+M}\right)^2 - \frac{4mM}{(m+M)^2} = -1.$$

This means that if we allow the initial velocities to have a certain range of values, the transformed surface element in v - V space has the same area as the initial surface element; the transformation is *area-preserving* (cf. Fig. 2a). This law is important in collision processes in the kinetic theory of gases and is related to Liouville's theorem (cf. Vol. V, this series).

FIG. 2a. Velocity domains before and after collision. The mapping is area-preserving.

FIG. 2b. In the case of two equal masses, $m=M$, the mapping is not only area-preserving, but also angle-preserving.

Let us consider the case of two equal masses such as two billiard balls, $m=M$. Eqs. (27) become

$$(27a) \quad v = V_0, \quad V = v_0.$$

Now the transformation is not only area-preserving, but angle-preserving as well; cf. Fig. 2b, in which the transformed rectangle is obtained from the initial one by interchange of its sides. In particular, if, in a central collision (head-on collision), in a billiard game, one ball is initially at rest, then the other one transmits all its velocity to the former and thereby comes to rest [cf. (27a) with $V_0=0$].

If, on the other hand, one mass is very great compared to the other, $M \gg m$, the large mass retains practically all its original velocity after the collision, while the small mass follows the large one with a velocity equal to that of the large one minus the original relative velocity. For with $m \ll M$ the Eqs. (27) can be simplified to

$$(27b) \quad v = -v_0 + 2V_0 = V_0 - (v_0 - V_0), \quad V = V_0.$$

To complete the discussion of collisions we shall briefly go into inelastic collisions. In atomic physics one investigates inelastic collisions ("collisions of the second kind"), in which the colliding particle, say an electron, loses part of its energy in order to "excite" the atom with which it collides; such an excited atom has been raised from its ground state to a level of higher energy. Since in this type of process part of the initial energy is lost as far as the motion after collision is concerned, this motion can no longer be calculated using the formulas of elastic collisions. (Cf. problems I.1 to I.4.)

We shall here limit ourselves to the "completely inelastic collision," which is often considered in engineering problems. Such a collision is defined by the condition

$$v = V,$$

i.e., after the collision both masses m and M proceed at the same velocity, as if rigidly coupled together. The equation of momentum, as emphasized earlier, retains its validity under all circumstances; it becomes

$$(28) \quad (m+M)v = mv_0 + MV_0$$

and alone is sufficient to determine the sole unknown v . We would like to know the energy lost in this collision, which is

$$\frac{m}{2}v_0^2 + \frac{M}{2}V_0^2 - \frac{m+M}{2}v^2,$$

or, after a simple elimination of v with the help of (28),

$$(28a) \quad \frac{\mu}{2}(v_0 - V_0)^2.$$

The loss of energy equals the kinetic energy of a certain *reduced mass* μ which moves with the original relative velocity. μ is defined by

$$(28b) \quad \frac{1}{\mu} = \frac{1}{m} + \frac{1}{M}, \text{ therefore } \mu = \frac{mM}{m+M}.$$

The theorem contained in Eqs. (28a, b) was first advanced by General Lazarus Carnot. (General Carnot was a mathematician and the organizer of universal military service during the French Revolution, as well as the father of Sadi Carnot, whose name has become famous in thermodynamics.)

§ 4. Variable Masses

The illustrations cited below will aid us in a critical evaluation of Newton's second law. We put this law in the form (1.3), "change of momentum equals force," rather than in the less general one (1.3a), "mass · acceleration equals force." We shall now learn how the rate of change of momentum is to be understood. We shall show that even in the case of variable mass the general form (1.3) may under certain circumstances reduce to (1.3a).

Let us consider a familiar example: a sprinkler wagon wets the asphalt on a hot summer day. The power of the motor is barely great enough to overcome the combined friction of the ground and wheels, of the air, and in the axle bearings. The vehicle therefore behaves as if under no forces. Let m be the mass of water in the tank at any instant + the constant mass of the empty vehicle. Let the amount of water squirted out per unit time be $\mu = -\dot{m}$, its exit velocity toward the rear, q as seen from the wagon, or $v - q$ as seen from the street, v being the speed of the vehicle.

If we were to use the formula (1.3) mechanically, we would obtain

$$(1) \quad \dot{\mathbf{p}} = \dot{\mathbf{p}} = \frac{d}{dt}(mv) = 0$$

from which would follow

$$(1a) \quad m\dot{v} = \mu v.$$

The acceleration of the wagon would then be independent of the exit velocity q . This is paradoxical, since one would expect the recoil (cf. gun) from the outgoing water jet to have some effect.

Actually we have not used the correct expression for the rate of change of momentum meant in (1.3), for it should consist not only of the member taken into account in (1), but also of a term giving the momentum contained in the water jets. This latter is $\mu(v - q)$ per unit time. Explicitly,

$$p_t = mv_t, \quad p_{t+dt} = (m + dm)(v + dv) + \mu dt(v - q)$$

so that the corrected rate of change of momentum becomes

$$(2) \quad \dot{\mathbf{p}} = \frac{d}{dt}(mv) + \mu(v - q) = 0,$$

or, remembering $\mu = -\dot{m}$ and simplifying,

$$(3) \quad m\dot{v} = \mu q.$$

From the viewpoint of (1.3a), the recoil of the water leaving the vehicle acts as an accelerating force on the latter, just as in the reaction water wheel used in rotary lawn sprinklers.

Instead of the sprinkler wagon we could have chosen as our example the interplanetary rocket, with which one might reach the moon. The rocket would be propelled by the expulsion of explosive gases. See problem I.5.

We generalize this result in two statements which are equivalent to Eqs. (2) and (3), respectively, of our illustrative example:

Either we take the viewpoint of (1.3), where we must then add to the change in momentum contained in the body in question the momentum convectively given off or added per unit time. The latter is to be calculated in the same frame of reference as the momentum of the body under investigation; the sign of \dot{m} takes care of the correct sign for this term. The equation of motion then becomes

$$(4) \quad \frac{d}{dt}(m\mathbf{v}) - \dot{m}\mathbf{v}' = \mathbf{F},$$

where \mathbf{v}' is the convective velocity. In our case we had $-\dot{m} = \mu$ and $|\mathbf{v}'| = |\mathbf{v}| - q$.

Or we take the viewpoint of (1.3a), in which case we must, however, add the recoil momentum gained or lost per unit time as a kind of external force. We then obtain the equation of motion in a form analogous to (3),

$$(5) \quad m\dot{\mathbf{v}} = \mathbf{F} + \dot{m}\mathbf{v}_{\text{rel}}.$$

\mathbf{v}_{rel} is the relative velocity of the convective momentum with respect to the body under observation, measured positive in the same sense as \mathbf{v} . In our example we had $|\mathbf{v}_{\text{rel}}| = -q$ and again $-\dot{m} = \mu$.

Two special cases deserve our attention:

(a) $\mathbf{v}' = 0$. The elements of mass gained or lost have zero velocity and therefore do not carry any momentum. In that case the equation of motion has the Newtonian form $\dot{\mathbf{p}} = \mathbf{F}$. Examples: water drop, chain, problems I.6 and I.7.

(b) $\mathbf{v}' = \mathbf{v}$ or, equivalently, $\mathbf{v}_{\text{rel}} = 0$. The equation of motion has the form, mass \cdot acceleration = force, in spite of the fact that the mass involved is variable. Example: rope hanging over the edge of a table, problem I.8.

In case (b) the Carnot energy loss, Eq. (3.28a), is zero; therefore the equation of energy applies in the usual form. In case (a) the form of the energy conservation law valid for a given problem is not obvious and must first be investigated.

We conclude these instructive remarks with the problem of the relativistic variation of mass. We shall talk specifically about the electron, even though equation (2.20) is of course valid not only for it, but for all masses. Here the variation of mass is a purely internal affair of the electron; there is no question of any momentum gained from or lost to the surroundings. As in case (a) the equation of motion is therefore $\dot{\mathbf{p}} = \mathbf{F}$, i.e., in view of (2.20),

$$(6) \quad \frac{d}{dt} \left(\frac{m_0 \mathbf{v}}{(1 - \beta^2)^{\frac{1}{2}}} \right) = \mathbf{F}.$$

Let us first consider the rectilinear motion of an electron; \mathbf{F} acts longitudinally, that is, in the direction of \mathbf{v} , so that $\mathbf{F} = F_{\text{long}}$ and $\mathbf{v} = v$.

We shall change Eq. (6) to the form "mass · acceleration = force," a customary procedure in the early part of the century, though unnecessarily complicated. To this end we carry out the differentiation on the left,

$$(6a) \quad \frac{m_0 \dot{v}}{(1 - \beta^2)^{\frac{1}{2}}} + m_0 v \frac{d}{dt} (1 - \beta^2)^{-\frac{1}{2}} = \frac{m_0}{(1 - \beta^2)^{\frac{1}{2}}} \left(\dot{v} + \frac{v \beta \dot{\beta}}{1 - \beta^2} \right).$$

Now $\beta = v/c$ so that

$$\dot{\beta} = \frac{\dot{v}}{c} \quad \text{and hence} \quad v \beta \dot{\beta} = \beta^2 v.$$

Consequently Eq. (6a) becomes

$$(6b) \quad \frac{m_0 \dot{v}}{(1 - \beta^2)^{\frac{1}{2}}} \left(1 + \frac{\beta^2}{1 - \beta^2} \right) = \frac{m_0}{(1 - \beta^2)^{\frac{1}{2}}} \dot{v} = F_{\text{long}}.$$

The *longitudinal mass* multiplying the acceleration \dot{v} is therefore

$$(7) \quad m_{\text{long}} = \frac{m_0}{(1 - \beta^2)^{\frac{3}{2}}}.$$

If, on the other hand, \mathbf{F} acts transversely, i.e., normal to the trajectory, only the direction, not the magnitude of the velocity is altered. In that case $\dot{\beta}$ is zero; (6) simply yields

$$\frac{m_0}{(1 - \beta^2)^{\frac{1}{2}}} \dot{v} = F_{\text{trans}}.$$

For this reason one introduced at the time a *transverse mass* different from the longitudinal mass and given by

$$(8) \quad m_{\text{trans}} = \frac{m_0}{(1 - \beta^2)^{\frac{1}{2}}}.$$

In view of these complications we emphasize that the above distinction between two kinds of masses becomes unnecessary if we use only the rational form (6) of the equation of motion.

Next we wish to determine the form of the equation of energy in relativity theory. Let us therefore multiply (6) by $\frac{dx}{dt} = v = \beta c$. In the right member we obtain

$$(9) \quad F \frac{dx}{dt} = \frac{dW}{dt} = \text{work done, or power.}$$

In the left member we have

$$m_0 c^2 \beta \frac{d}{dt} \left(\frac{\beta}{[1 - \beta^2]^{\frac{1}{2}}} \right) = m_0 c^2 \beta \dot{\beta} (1 - \beta^2)^{-\frac{1}{2}}.$$

We can at once convince ourselves that this is a total derivative in t , viz.,

$$(10) \quad m_0 c^2 \frac{d}{dt} \frac{1}{(1 - \beta^2)^{\frac{1}{2}}}.$$

Since (10) must be equal to (9), the rate of doing work, (10) must be the time rate of change of the kinetic energy T . We therefore have

$$T = m_0 c^2 \left(\frac{1}{[1 - \beta^2]^{\frac{1}{2}}} + \text{const.} \right).$$

We must put the constant equal to -1 , because T , by its nature, must vanish as β vanishes. Hence the *relativistic kinetic energy* is

$$(11) \quad T = m_0 c^2 \left(\frac{1}{[1 - \beta^2]^{\frac{1}{2}}} - 1 \right).$$

In view of (2.20) we can also write this as

$$(12) \quad T = c^2 (m - m_0).$$

In words: *the difference in energy between a moving electron and one at rest (which is nothing but the kinetic energy or "live force") equals the difference between the masses of the electron in motion and at rest, multiplied by c^2 .* Thus we have verified for the simplest case the law of the equivalence of mass and energy (law of the "inertia of energy"). This important law is fundamental to the whole field of atomic weight determinations and to nuclear physics and its applications to cosmology.

For the sake of completeness we point out that for small β , (11) can be expanded in a series which yields to a first approximation the elementary expression for T ,

$$T = m_0 c^2 \left(\frac{1}{2} \beta^2 + \frac{3}{8} \beta^4 + \dots \right) = \frac{m_0}{2} c^2 \beta^2 \left(1 + \frac{3}{4} \beta^2 + \dots \right) \rightarrow \frac{m_0}{2} v^2,$$

as is to be expected.

§ 5. Kinematics and Statics of a Single Mass Point in a Plane and in Space

Kinematics deals with the geometry of motions regardless of their physical realization. Statics¹⁴ is concerned with forces, their composition and equivalence, without regard to the motions caused by them.

(1) Plane Kinematics

We shall begin by writing down the formulas for the decomposition and composition of velocity and acceleration in Cartesian coordinates.

FIG. 3. Decomposition and composition of velocities in a plane; intrinsic coordinates s and n .

Velocity:

$$(1) \quad \mathbf{v} = (v_x, v_y) = \left(\frac{dx}{dt}, \frac{dy}{dt} \right) = (\dot{x}, \dot{y});$$

$$(2) \quad |\mathbf{v}| = (\dot{x}^2 + \dot{y}^2)^{\frac{1}{2}} = v.$$

Acceleration:

$$(3) \quad \dot{\mathbf{v}} = (\dot{v}_x, \dot{v}_y) = \left(\frac{d^2x}{dt^2}, \frac{d^2y}{dt^2} \right) = (\ddot{x}, \ddot{y});$$

$$(4) \quad |\dot{\mathbf{v}}| = (\ddot{x}^2 + \ddot{y}^2)^{\frac{1}{2}}.$$

Instead of decomposing velocity and acceleration in Cartesian coordinates we can also decompose them in terms of the *intrinsic coordinates* of the curve described by our mass point. Let s be the length of arc, subscript s denoting the path direction varying from point to point along the curve,

¹⁴ The name statics is actually not appropriate, for it refers only to equilibrium, whereas the content of statics applies to problems of motion as well as of equilibrium. The correct name would be dynamics. This term has been in historical usage for the study of motions caused by forces, and is therefore not available for the field which its name implies, i.e., the analysis of forces.

subscript n denoting the direction normal to s at any point of the curve. We then have

$$(5) \quad v_s = \pm v, v_n = 0.$$

This is trivial. The decomposition of $\dot{\mathbf{v}}$ into $\dot{\mathbf{v}}_s$ and $\dot{\mathbf{v}}_n$ is, however, significant. If we let α be the angle between the tangent to the path and the x -direction, we have

$$(6) \quad \dot{v}_s = \dot{v}_x \cos \alpha + \dot{v}_y \sin \alpha$$

for the tangential acceleration, and

$$(7) \quad \dot{v}_n = -\dot{v}_x \sin \alpha + \dot{v}_y \cos \alpha$$

for the normal acceleration.

Now

$$\cos \alpha = \frac{dx}{ds} = \frac{\dot{x}}{\dot{s}} = \frac{v_x}{v}, \quad \sin \alpha = \frac{dy}{ds} = \frac{\dot{y}}{\dot{s}} = \frac{v_y}{v},$$

so that

$$(8) \quad \begin{aligned} \dot{v}_s &= \frac{1}{v} (v_x \dot{v}_x + v_y \dot{v}_y) = \frac{1}{2v} \frac{d}{dt} (v_x^2 + v_y^2) \\ &= \frac{1}{2v} \frac{d}{dt} v^2 = \frac{dv}{dt} = |\dot{\mathbf{v}}|. \end{aligned}$$

This equation states that the tangential acceleration is the change in magnitude of the velocity, no matter what its change in direction may be.

Eq. (7), on the other hand, yields

$$(9) \quad \dot{v}_n = \frac{1}{v} (v_x \dot{v}_y - v_y \dot{v}_x) = \frac{1}{v} (\dot{x}\dot{y} - \dot{y}\dot{x}) = v^2 \cdot \frac{\dot{x}\ddot{y} - \dot{y}\ddot{x}}{(\dot{x}^2 + \dot{y}^2)^{3/2}} = \frac{v^3}{\rho},$$

where $\frac{1}{\rho}$ is the curvature of the path.¹⁵

The normal acceleration therefore does not depend on the change of velocity, but only on the velocity itself and on the shape of the trajectory. If, in particular, $\frac{dv}{dt} = 0$, the acceleration is normal to the velocity and hence to the path.

We shall now derive the same relations in a direct, differential-geometrical fashion by means of the *hodograph*¹⁶ introduced by Hamilton.

¹⁵ Cf., for example, Franklin, *Treatise on Advanced Calculus*, p. 295.—TRANSLATOR.

¹⁶ The name hodograph= path writer is misleading; it should really be called velocity writer, or better, polar diagram of velocity.

FIG. 4a. Hodograph of motion in a plane. Velocities v_1 and v_2 are laid off from the pole O in the polar diagram.

FIG. 4b. Trajectory and radius of curvature of motion in a plane.

The meaning of the hodograph becomes clear when we compare Figs. 4a and 4b. Fig. 4b shows the trajectory in the xy -plane. The velocities at two of its neighboring points, Δs apart, are indicated as tangents to the path; their included angle is $\Delta\epsilon$. The same angle $\Delta\epsilon$ also occurs at the center of curvature M . ρ being the radius of curvature,

$$(10) \quad \Delta s = \rho \Delta\epsilon.$$

The same two velocities are plotted in Fig. 4a from a common origin O , with directions preserved. Consider the two neighboring vectors $\vec{O1}$ and $\vec{O2}$ with $\Delta\epsilon$ as their included angle. Projection of 1 on $\vec{O2}$ gives point 3. $\Delta v = \vec{12}$ is decomposed into $\Delta v_n = \vec{32}$ and $\Delta v_s = \vec{13}$. We therefore obtain, in agreement with (8) and (9),

$$\begin{aligned} \dot{v}_s &= \frac{\vec{32}}{\Delta t} = \frac{v_2 - v_1}{\Delta t} = \frac{\Delta v}{\Delta t} = \frac{dv}{dt}, \\ \dot{v}_n &= \frac{\vec{13}}{\Delta t} = \frac{\Delta\epsilon \cdot v}{\Delta t} = \frac{\Delta\epsilon}{\Delta s} v^2 = \frac{v^2}{\rho}, \end{aligned}$$

the latter by recalling (10). Cf. problem I.9.

(2) The Concept of Moment in Plane Statics and Kinematics

The moment of a vector quantity \mathbf{E} about a given point of reference O is defined as the *vector product* of the radius vector \mathbf{r} from O to the point of application P of the vector \mathbf{E} by the vector \mathbf{E} itself, i.e.,

$$(11) \quad \mathbf{N} = \mathbf{r} \times \mathbf{E}.$$

FIG. 5. Moment of an arbitrary vector quantity \vec{E} about an arbitrary point O .

N is therefore represented by the area of the parallelogram formed by \vec{r} and \vec{E} together with the sense of rotation of \vec{r} into \vec{E} as indicated by an arrow in Fig. 5. In magnitude,

$$(11a) \quad |N| = l|\vec{E}| = r|\vec{E}|\sin \alpha,$$

where l is the "lever arm" of \vec{E} about O . If we take for \vec{E} a force \vec{F} , we obtain the *moment of the force \vec{F} , or torque*

$$(12) \quad \vec{L} = \vec{r} \times \vec{F}.$$

The moment of a force \vec{F} is a fundamental concept of statics, whose discovery goes back to Archimedes himself. Let us denote the Cartesian components of \vec{F} by X and Y . Elementary vector algebra readily gives

$$(12a) \quad L_z = xY - yX.$$

The concept of moment is of importance in kinematics and kinetics as well. Let us still restrict ourselves to problems in a plane, and form

the moment of velocity $= \vec{r} \times \vec{v}$

the moment of acceleration $= \vec{r} \times \dot{\vec{v}}$

the moment of momentum $=$ angular momentum $= \vec{r} \times \vec{p} = m(\vec{r} \times \vec{v})$

In Cartesian coordinates, with (12a) as a model, we have

$$(13) \quad \vec{r} \times \vec{v} = x\dot{y} - y\dot{x}, \quad \vec{r} \times \dot{\vec{v}} = x\ddot{y} - y\ddot{x}.$$

Between the moments of velocity and acceleration, there exists the relation

$$(14) \quad \vec{r} \times \dot{\vec{v}} = \frac{d}{dt}(\vec{r} \times \vec{v}).$$

It derives from the fact that $\frac{d\vec{r}}{dt} = \vec{v}$ and $\vec{v} \times \vec{v} = 0$, so that

$$(14a) \quad \frac{d}{dt}(\vec{r} \times \vec{v}) = \vec{r} \times \frac{d\vec{v}}{dt} + \vec{v} \times \vec{v} = \vec{r} \times \dot{\vec{v}}.$$

The customary proof by means of decomposition into coordinates runs exactly parallel to Eq. (14a):

$$(14b) \quad \frac{d}{dt}(xy - yx) = x\dot{y} + \dot{x}y - y\dot{x} - \dot{y}x = x\dot{y} - y\dot{x}.$$

If in Fig. 5 one thinks of the velocity \mathbf{v} of point P replacing the arbitrary vector \mathbf{E} , with P describing an arbitrary path, one can read off another simple relation, now between angular momentum and the so-called *areal velocity*. Indeed the infinitesimal element of area dS swept out by the radius vector \mathbf{r} with origin at O is equal to one half the area of the parallelogram $\mathbf{r} \times d\mathbf{s}$, so that the areal velocity

$$\frac{dS}{dt} = \frac{1}{2}(\mathbf{r} \times \mathbf{v}).$$

We therefore obtain the relation between areal velocity and angular momentum

$$(15) \quad \mathbf{r} \times \mathbf{p} = 2m \frac{dS}{dt}.$$

(3) Kinematics in Space

We decompose vectors along the three directions s (tangent), n (principal normal) and b (binormal) of the three-dimensional trajectory to obtain the following components:

$$\mathbf{v} = (v, 0, 0),$$

$$\dot{\mathbf{v}} = (\dot{v}, \frac{v^2}{\rho}, 0).$$

ρ is the radius of curvature introduced in (9) or (10), now constructed so as to lie in the osculating plane of the trajectory.

If we pass to the moments of velocity and acceleration, we keep the definitions $\mathbf{r} \times \mathbf{v}$ and $\mathbf{r} \times \dot{\mathbf{v}}$, but note that Fig. 5 must now be thought of as three-dimensional. In addition to magnitude and sense of rotation the parallelogram drawn there also has position in space. Because it is helpful in visualizing this point it has become customary to indicate the position by a normal to the plane of the parallelogram. By convention that side of the normal is chosen which points in the direction of advance of a right-handed screw rotated in the sense of rotation of the moment (from \mathbf{r} to \mathbf{v} or $\dot{\mathbf{v}}$ through an angle less than π). The vector picture of the moment then becomes an arrow pointing along this normal, its length being equal to the magnitude of the moment. In Fig. 5 one should, therefore, think of the moment as directed out of and perpendicular to the plane of the paper. We shall postpone a thorough investigation of this procedure and of the difference between axial and polar vectors to Chapter IV, § 23.

So far we have described the moment about an arbitrarily chosen point of reference O . In the following subsection we shall explain what is meant by the moment about a given axis.

(4) Statics in Space; Moment of Force About a Point and About an Axis

The moment of a force F about a reference point O is completely defined by

$$(16) \quad \mathbf{L} = \mathbf{r} \times \mathbf{F},$$

where \mathbf{r} is the radius vector from O to the point of application P of F ,

$$(16a) \quad \mathbf{r} = (x, y, z)$$

if O is taken as origin of coordinates. \mathbf{L} can be represented as a vector by the rule just given for moments (rule of the right-hand screw, with length of vector equal to $|\mathbf{L}|$). We now ask: what are the components of \mathbf{L} along the coordinate axes? We can define them as the projections of the moment vector on these three axes; for instance,

$$(17) \quad L_z = |\mathbf{L}| \cos(\mathbf{L}, z)$$

But $|\mathbf{L}|$ is the area of the parallelogram having sides \mathbf{r} and \mathbf{F} . The right member of (17) is therefore at the same time the projection of the area of the parallelogram on the x - y -plane. The latter has sides

$$\mathbf{r}_{\text{proj}} = (x, y); \quad \mathbf{F}_{\text{proj}} = (X, Y),$$

so that, with the help of (17), we obtain as in (12a)

$$(17a) \quad L_z = xY - yX,$$

and similarly

$$(17b) \quad L_x = yZ - zY, \quad L_y = zX - xZ.$$

The components L_x, L_y, L_z of \mathbf{L} can be called the moments of the force F about axes x, y, z . Cf. problem I.10.

What has been said of the coordinate axes also applies to any arbitrary axis a . The moment of a force F about an axis a is defined, just as in (17), by taking the moment about a point O located on a and projecting the corresponding moment vector on a . Or it can be formed as in (17a, b) by projecting the area of the moment about O on a plane perpendicular to a . A third method consists in finding the shortest distance from the point of application of the force to a , which we shall call the lever arm l . In this case F is decomposed into three components, F_a parallel to a , F_l in the

direction of l , and F_n in a direction perpendicular to both a and l . We then have

$$(18) \quad L_a(F) = L_a(F_a) + L_a(F_l) + L_a(F_n).$$

The first two terms on the right must vanish; for there can arise no moment of force about an axis a if the force is either parallel to a or if it intersects a .

There remains the third term which results from a force perpendicular to a acting with a lever arm l . Instead of (18) we have, therefore,

$$(18a) \quad L_a(F) = L_a(F_n) = F_n \cdot l.$$

At this point it may be well to say a few words about the different notations for the products of two vectors. The following list shows that unfortunately these notations vary widely, both in historical and national usage.

Name of product	This book	German Ed. SOMMERFELD	GIBBS	HEAVISIDE	ITALIANS	GRASSMANN
Scalar or inner ..	$A \cdot B$	$(\mathfrak{A} \mathfrak{B})$	$\mathfrak{A} \mathfrak{B}$	$\mathfrak{A} \mathfrak{B}$	$\mathfrak{A} \times \mathfrak{B}$	$\mathfrak{A} \mathfrak{B}$
Vector or outer ..	$A \times B$	$[\mathfrak{A} \mathfrak{B}]$	$\mathfrak{A} \times \mathfrak{B}$	$\nabla \mathfrak{A} \mathfrak{B}$	$\mathfrak{A} \wedge \mathfrak{B}$	$\mathfrak{A} \mathfrak{B}$ or $ \mathfrak{A} \mathfrak{B}$

Some explanatory remarks follow. The great thermodynamicist Willard Gibbs made a short summary of vector analysis, then still little known, for the use of his students. His notation is still followed (with slight variations) by many American and British authors. Heaviside's notation for the vector product, in which ∇ stands for vector, was thereupon generally abandoned. The Italian notation originated with Marcolongo. Hermann Grassmann, in his "Ausdehnungslehre" (Extension Analysis, 1844 and 1862), had developed a logical system of calculation with segments and points. According to him the simplest relation between two directed segments a and b , is the "planar magnitude" (*Plangrösse*), i.e., the parallelogram formed by a and b , which he therefore denotes by ab (though occasionally also by $[ab]$). The vertical line in Grassmann's notation for the vector product means "complement" (*Ergänzung*), that is, denotes passing to the vector arrow perpendicular to the planar magnitude.

§ 6. Dynamics (Kinetics) of the Freely Moving Mass Point; Kepler Problem; Concept of Potential Energy

(1) Kepler Problem with Fixed Sun

The simplest example we can think of in connection with a freely moving mass point is, at the same time, the most important for our picture

of the universe, namely, the motion of the planets. It is a two-dimensional problem, and motion takes place in the ecliptic if the planet in question is the earth. We assume the sun to be fixed in position and justify this by its large relative mass,

$$\text{Sun } 330000, \text{ Jupiter } 320, \text{ Earth } 1, \text{ Moon } \frac{1}{81}.$$

We shall deal with the problem including the sun's motion in Part 2 of this section. Let M be the mass of the sun, m that of the planet. The Newtonian attraction is

$$|F| = G \frac{mM}{r^2}, \quad G = \text{gravitational constant},$$

or, vectorially,

$$(1) \quad \mathbf{F} = -G \frac{mM}{r^2} \frac{\mathbf{r}}{r}.$$

It passes through the fixed point O at the center of the sun, which serves as origin for the radius vector \mathbf{r} .

It follows that $\mathbf{r} \times \mathbf{F} = 0$ and therefore, by the Second Law,

$$\mathbf{r} \times \dot{\mathbf{p}} = 0 \text{ and in view of (5.14), } \mathbf{r} \times \mathbf{p} = \text{const.}$$

The angular momentum about the sun is constant, therefore also the areal velocity of Eq. (5.15) is constant. This is the second Kepler law:

The radius vector from the sun to the planet sweeps over equal areas in equal times.

Let the constant areal velocity multiplied by two be called the "areal velocity constant" C ,

$$(2) \quad 2 \frac{dS}{dt} = C.$$

FIG. 6. Polar coordinates for the Kepler problem with sun as origin; area swept out by the radius vector.

We now introduce the polar angle ϕ , the *true anomaly*¹⁷ of the astronomers (cf. Fig. 6), and obtain

$$dS = \frac{1}{2} r^2 d\phi, \quad 2 \frac{dS}{dt} = r^2 \dot{\phi} = C$$

¹⁷ True anomaly is here defined as the angular distance of a planet from its aphelion, as seen from the sun.—TRANSLATOR.

so that

$$(3) \quad \dot{\phi} = \frac{C}{r^2}.$$

In order to derive the first Kepler law, the equation of the trajectory, we decompose the forces along Cartesian coordinates. After division by m the equation of motion becomes

$$(4) \quad \begin{aligned} \frac{dx}{dt} &= -\frac{GM}{r^2} \cos \phi \\ \frac{dy}{dt} &= -\frac{GM}{r^2} \sin \phi. \end{aligned}$$

If we multiply both sides of both equations by $\frac{1}{\dot{\phi}}$ and recall (3), we obtain

$$\begin{aligned} \frac{dx}{d\phi} &= -\frac{GM}{C} \cos \phi \\ \frac{dy}{d\phi} &= -\frac{GM}{C} \sin \phi. \end{aligned}$$

These can now be integrated. Let A and B be constants of integration. The result is

$$(5) \quad \begin{aligned} x &= -\frac{GM}{C} \sin \phi + A \\ y &= \frac{GM}{C} \cos \phi + B. \end{aligned}$$

This means that the hodograph of planetary motion is a circle,

$$(5a) \quad (x-A)^2 + (y-B)^2 = \left(\frac{GM}{C}\right)^2.$$

We shall return to this point in problem I.11. Let us transform the left members of (5) into polar coordinates,

$$x = r \cos \phi, \quad y = r \sin \phi,$$

so that

$$\begin{aligned} \dot{x} &= \dot{r} \cos \phi - r \dot{\phi} \sin \phi = -\frac{GM}{C} \sin \phi + A \\ \dot{y} &= \dot{r} \sin \phi + r \dot{\phi} \cos \phi = \frac{GM}{C} \cos \phi + B. \end{aligned}$$

We now eliminate \dot{r} by multiplication of the first equation by $-\sin \phi$, the second by $\cos \phi$, and subsequent addition. We obtain

$$r \dot{\phi} = \frac{GM}{C} - A \sin \phi + B \cos \phi$$

or, recalling (3),

$$(6) \quad \frac{1}{r} = \frac{GM}{O^2} - \frac{A}{O} \sin \phi + \frac{B}{O} \cos \phi.$$

This is the equation of a conic section in polar coordinates whose origin coincides with one of the foci of the conic section. We therefore obtain the first Kepler law: *The planet describes an ellipse with the sun at one focus.* In this connection we note that two equally possible trajectories, the hyperbola and the parabola, evidently do not apply to the planets, but only to comets. We shall not discuss them here, but refer the reader to problem I.12.

The derivation of the first Kepler law given here differs from that offered in most texts. The latter starts out with the equation of energy, which we shall now derive. We turn back to Eq. (4), where we replace $\cos \phi$ by $\frac{x}{r}$, $\sin \phi$ by $\frac{y}{r}$ in the right members. We then multiply the first of Eqs. (4) by \dot{x} , the second by \dot{y} , add the two, and get

$$\frac{d}{dt} \frac{1}{2} (\dot{x}^2 + \dot{y}^2) = -\frac{1}{2} \frac{GM}{r^3} \frac{d}{dt} (x^2 + y^2) = -\frac{GM}{r^3} \frac{dr}{dt}.$$

An integration with respect to t yields

$$(7) \quad \frac{1}{2} (\dot{x}^2 + \dot{y}^2) = \frac{GM}{r} + E.$$

The left member is the kinetic energy divided by m ; the first term on the right is, apart from sign, the potential energy divided by m (cf. Part 3 of this section); E is therefore the total energy divided by m . Our Eq. (7) has the same form as the equation of energy of one-dimensional motion, (3.8).

In order to pass from (7) to the equation of the path (6) in the simplest possible manner, we recall that in polar coordinates the square of the element of line is

$$dx^2 + dy^2 = dr^2 + r^2 d\phi^2.$$

We therefore have

$$\dot{x}^2 + \dot{y}^2 = \left(\frac{dr}{dt}\right)^2 + r^2 \left(\frac{d\phi}{dt}\right)^2 = \left(\frac{d\phi}{dt}\right)^2 \left\{ \left(\frac{dr}{d\phi}\right)^2 + r^2 \right\},$$

or, in view of (3),

$$O^2 \left\{ \left(\frac{1}{r^2} \frac{dr}{d\phi} \right)^2 + \frac{1}{r^2} \right\}$$

If we put $s = \frac{1}{r}$, this becomes

$$O^2 \left\{ \left(\frac{ds}{d\phi} \right)^2 + s^2 \right\},$$

so that our equation of energy (7) is transformed into

$$\frac{1}{2}C^2 \left\{ \left(\frac{ds}{d\phi} \right)^2 + s^2 \right\} - GMs = E.$$

Differentiation with respect to ϕ gives

$$\frac{ds}{d\phi} \left\{ C^2 \left(\frac{d^2s}{d\phi^2} + s \right) - GM \right\} = 0.$$

Since $\frac{ds}{d\phi} \neq 0$, the bracket must vanish. Thus we obtain a linear homogeneous differential equation with constant coefficients of second order in s ,

$$\frac{d^2s}{d\phi^2} + s = \frac{GM}{C^2}.$$

The general solution of such an equation consists of a particular solution of the inhomogeneous equation plus the general solution of the homogeneous equation. Evidently

$$s = \text{constant} = \frac{GM}{C^2}$$

is a particular integral of the inhomogeneous equation. The general solution of the homogeneous equation is the sum of $\sin \phi$ and $\cos \phi$. We can now take A/C and B/C as our constants of integration and finally obtain

$$s = \frac{GM}{C^2} - \frac{A}{C} \sin \phi + \frac{B}{C} \cos \phi,$$

which is precisely the previously obtained Eq. (6).

FIG. 7. Kepler ellipse with major and minor axes; perihelion, aphelion, eccentricity.

We shall now specialize this equation in such a way that the line $\phi=0$, which starts out from one focus, passes through the other focus as well, i.e., that it forms, together with the line $\phi=\pi$, the major axis of the ellipse (cf. Fig. 7). On this axis are located the points P, "perihelion" (closest

to the sun) and A , "aphelion" (farthest from the sun), at which r must be a minimum and a maximum respectively. We therefore impose the condition

$$\frac{dr}{d\phi} = 0 \text{ for } \phi = \begin{cases} 0 \\ \pi \end{cases}$$

which, from (6), requires $A=0$.

If, in addition, e is the eccentricity of the ellipse, Fig. 7 shows that at

$$\text{perihelion, } r=SP=a(1-e), \phi=\pi,$$

$$\text{aphelion, } r=SA=a(1+e), \phi=0.$$

According to (6) we then have at

$$\text{perihelion, } \frac{1}{a(1-e)} = \frac{GM}{C^2} - \frac{B}{C},$$

$$\text{aphelion, } \frac{1}{a(1+e)} = \frac{GM}{C^2} + \frac{B}{C}.$$

From these we obtain by addition and subtraction

$$(8) \quad \frac{GM}{C^2} = \frac{1}{a(1-e^2)}, \quad \frac{B}{C} = -\frac{e}{a(1-e^2)},$$

respectively.

We shall finally express the areal velocity constant C in terms of the period T . From (2) we immediately obtain

$$C = \frac{2S}{T} \text{ with } S = \pi ab = \pi a^2(1-e^2)^{\frac{1}{2}}$$

as the total area swept out by the radius vector. It follows that

$$(9) \quad C^2 = \frac{4\pi^2 a^4 (1-e^2)}{T^2}.$$

If we introduce this in the first of Eqs. (8), we have

$$(10) \quad \frac{T^2}{a^3} = \frac{4\pi^2}{GM}.$$

Since G and M are the same for all planetary trajectories, (10) is the expression of the third Kepler law: *the squares of the periodic times are proportional to the cubes of the major axes.*

Kepler greeted the discovery of this law with the enthusiastic statement¹⁸: "Finally I have brought to light and verified beyond all my hopes and

¹⁸ *Harmonices mundi*, 1619. The two first Kepler laws had been published in the *Astronomia Nova*, 1609.

expectations that the whole Nature of Harmonies permeates to the fullest extent, and in all its details, the motion of the heavenly bodies; not, it is true, in the manner in which I had earlier thought, but in a totally different, altogether complete way."

Actually the third Kepler law in the form (10) is not yet quite exact. It is valid only as long as one can neglect the planetary mass m in comparison with the mass M of the sun. We shall now drop this assumption, thereby passing to the two-body problem proper of astronomy. This problem is not significantly more difficult than the one-body problem treated so far.

(2) Kepler Problem Including Motion of the Sun

Let x_1, y_1 be the coordinates of the sun S ; x_2, y_2 those of the planet P .

According to Newton's third law the force on S must be equal and opposite to that on P , so that the complete equations of motion are

$$\begin{array}{ll} \text{for the sun,} & \text{for the planet,} \\ M \frac{d^2 x_1}{dt^2} = \frac{mMG}{r^3} \cos \phi; & m \frac{d^2 x_2}{dt^2} = -\frac{mMG}{r^3} \cos \phi; \\ M \frac{d^2 y_1}{dt^2} = \frac{mMG}{r^3} \sin \phi; & m \frac{d^2 y_2}{dt^2} = -\frac{mMG}{r^3} \sin \phi. \end{array}$$

We now introduce the relative position coordinates

$$(11a) \quad x_2 - x_1 = x, \quad y_2 - y_1 = y,$$

and furthermore the center of mass coordinates

$$(11b) \quad \frac{mx_2 + Mx_1}{m+M} = \xi, \quad \frac{my_2 + My_1}{m+M} = \eta.$$

FIG. 8. Kepler problem with motion of sun taken into account.

Subtraction of the equations of motion gives

$$(12) \quad \begin{aligned} \frac{d^2 x}{dt^2} &= -\frac{(M+m)G}{r^3} \cos \phi, \\ \frac{d^2 y}{dt^2} &= -\frac{(M+m)G}{r^3} \sin \phi; \end{aligned}$$

whereas addition yields

$$(13) \quad \frac{d^2\xi}{dt^2} = 0, \quad \frac{d^2\eta}{dt^2} = 0.$$

Comparison of (12) with the earlier Eqs. (4) shows at once that the first two laws of Kepler remain intact, i.e., are valid for the relative motion as well. The third law takes the form

$$(14) \quad \frac{T^2}{a^3} = \frac{4\pi^2}{G(M+m)}.$$

The ratio T^2/a^3 is therefore no longer a universal constant, but in principle is somewhat different for every planet. Because of the preponderance of the sun's mass the deviations from (10) are, however, exceedingly slight.

Eqs. (13) further show that the mass center of sun and planet moves with constant velocity. If we do our calculations in terms of a coordinate system in which the mass center is fixed at the origin, this velocity must be put equal to 0; the same applies to the coordinates ξ, η of the center of mass themselves.

Eqs. (11b) are simplified accordingly. With their help and that of Eqs. (11a) the coordinates x_1, y_1 of the sun and the coordinates x_2, y_2 of the planet can now be expressed separately in terms of the relative position coordinates x, y :

$$x_1, y_1 = -\frac{m}{M+m}(x, y),$$

$$x_2, y_2 = \frac{M}{M+m}(x, y).$$

It follows that in the center of mass system the trajectories of the sun and planet are also ellipses; that of the planet is almost identical to the ellipse considered in Part I of this section. That of the sun is a very dwarfed ellipse, traversed in the same sense, but π out of phase with the planet's trajectory.

If we change the law of gravitation to

$$(15) \quad F = kr^n \cdot \frac{\mathbf{r}}{r}, \quad n \text{ arbitrary},$$

the second Kepler law will hold unchanged; the trajectories, however, become transcendental curves which are, in general, not closed. It is only in the case $n=1$ that we obtain ellipses just as in the case of gravitation, $n=-2$. (Cf. problem I.13).

(3) When Does a Force Field Have a Potential?

In one-dimensional motion we were able to define a potential energy V connected with a force X without any difficulty—see Eq. (3.7). As

mentioned at that time, this is possible for two- or three-dimensional motions only if certain conditions are met. If X , Y , Z are the Cartesian components of the force \mathbf{F} the definition of potential energy for the three-dimensional case analogous to (3.7) would be

$$(16) \quad V = - \int_{\text{sys}} (X \, dx + Y \, dy + Z \, dz).$$

If V is to be a quantity independent of the path of integration and dependent only on its endpoint (the choice of the initial point merely gives rise to an additive constant which remains arbitrary in any case), the expression

$$X \, dx + Y \, dy + Z \, dz$$

must be a *perfect differential*; i.e., X , Y , Z must be the derivatives with respect to x , y , z of a "field function." In our case the function is just $-V$, and we say that \mathbf{F} is "derivable from the potential V ." The well-known conditions for this are that

$$(17) \quad \frac{\partial Y}{\partial x} = \frac{\partial X}{\partial y}, \quad \frac{\partial Z}{\partial y} = \frac{\partial Y}{\partial z}, \quad \frac{\partial X}{\partial z} = \frac{\partial Z}{\partial x}.$$

It is only if these conditions are fulfilled that a field function $V(x, y, z)$ can be defined for each point x, y, z ; V is called the potential energy or simply the potential.

In the two-dimensional case, where $Z=0$ and X , Y are independent of z , the three Eqs. (17) are reduced to the first one of these.

Vector analysis (which has been relegated to Vol. II of this series since we need only vector algebra in this volume) shows that the conditions (17) have an invariant meaning, i.e. are independent of the choice of coordinates. In Vol. II these conditions will be summarized in the vector equation, $\text{curl } \mathbf{F} = 0$ (this is often expressed by saying that the vector field \mathbf{F} is *irrotational*).

Evidently one can without difficulty write down expressions for X , Y , Z in terms of x , y , z which do not satisfy conditions (17). On the other hand we see that these conditions are satisfied for the gravitational field

$$X = Y = 0, \quad Z = -mg$$

and lead to

$$(18) \quad V = mgz.$$

The same is true of the general gravitational fields based on Newton's law and the mathematically similar fields of electrostatics and magnetostatics. As a matter of fact fields that are irrotational and simultaneously time-independent ("potential fields") occupy a unique position in nature.

They will play a special role in the general developments of Chapters VI and VIII.

A mechanical system in which only forces derivable from potentials act is called a *conservative system* because its energy is conserved; otherwise we speak of non-conservative or *dissipative systems*.

MECHANICS OF SYSTEMS, PRINCIPLE OF VIRTUAL WORK, AND D'ALEMBERT'S PRINCIPLE

§ 7. *Degrees of Freedom and Virtual Displacements of a Mechanical System; Holonomic and Non-holonomic Constraints*

The single mass point has one degree of freedom if its motion is restricted to a straight line or a curve, two degrees of freedom if it is made to move in a plane or on a curved surface; the mass point moving freely in space has three degrees of freedom.

Two mass points connected by a weightless, rigid rod have five degrees of freedom; for the first point can be regarded as freely moving, in which case the second is restricted to the surface of a sphere described about the first, its radius equal to the length of the rod.

The number of degrees of freedom for n mass points which are coupled by r relations between their coordinates is

$$(1) \quad f = 3n - r.$$

If there is an infinity of mass points connected by infinitely many conditions such an enumeration is of course not feasible. The procedure to be used in that case will now be shown, the rigid body serving as example.

(a) *Freely Moving Rigid Body*

We single out a point of the rigid body. It has three degrees of freedom. A second point, at a constant distance from the first (definition of "rigid"), can move only on a spherical surface about the first point as center. This gives two more degrees of freedom. Finally a third point can describe a circle about the axis connecting the first two points, thus contributing one more degree of freedom. Once the motions of these three points have been specified, the paths of all other points of the rigid body are uniquely determined. It follows that

$$f = 3 + 2 + 1 = 6.$$

(b) *Top on a Plane Surface*

We assume that the bottom of the spinning top terminates in a point, and take this as the first point of our enumeration; it has two degrees of

freedom. A second point can move on a hemisphere about the first, and a third one on a circle about a line connecting the first two. Thus

$$f=2+2+1=5.$$

(c) *Top with Fixed Point*

Now the two degrees of freedom of the first point are lost, so that

$$f=2+1=3.$$

(d) *Rigid Body with Fixed Axis—Pendulum*

Here

$$f=1.$$

If the center of mass of the body does not lie on the axis we speak of a physical or *compound pendulum*. From this we obtain a mathematical or *simple pendulum* if the body shrinks to a point. The *spherical pendulum* — a mass point restricted in its motion to the surface of a sphere — has

$$f=2.$$

(e) *Infinitely Many Degrees of Freedom*

For a deformable solid body or a liquid

$$f=\infty.$$

In that case the equations of motion become partial differential equations. By contrast a system with a finite number of degrees of freedom n is determined by an equal number n of ordinary differential equations of second order.

(f) *Machine with One Degree of Freedom*

Such a machine consists of a series of nearly rigid bodies coupled to each other either by links or by means of guides of various types. The classical example of such a machine is the drive mechanism of a piston engine (Fig. 9). If the machine is provided with a centrifugal governor (also called Watt governor because it was first proposed by the inventor of the steam engine), it acquires a second degree of freedom.

In the aforementioned examples the number of degrees of freedom equals the number of independent coordinates which are necessary to determine the position of the system. The coordinates need not be Cartesian. In case of the drive mechanism we can equally well specify either the coordinate x determining the position of the piston or the angle ϕ giving the position of the crank pin on the shaft. In general we shall call the independent coordinates of a system of f degrees of freedom

$$(2) \quad q_1, q_2, \dots, q_f.$$

They can, within certain limits, be chosen arbitrarily. The r conditions among the coordinates referred to in Eq. (1) can be satisfied identically by suitable choice of the q , so that they drop out of the subsequent treatment of our system.

The mechanics of Hertz mentioned on p. 5 has the important merit of having called attention to *conditions of differential form*, to which the foregoing cannot be applied. Such a condition can be written as

$$(3) \quad \sum_{k=1}^f F_k(q_1 \dots q_f) dq_k = 0.$$

Here we assume that the F_k do not all have the form $\frac{\partial \Phi}{\partial q_k}$, so that (3) is not the total differential of some function $\Phi(q_1 \dots q_f)$, and we assume, moreover, that it cannot be converted into a total differential by means of an integrating factor.

In agreement with Hertz we shall call conditions of the form $\Phi(q_1 \dots q_f) = \text{const.}$ *holonomic* (*holos* in Greek = *integer* in Latin = whole = integrable); conditions of the form (3) which cannot formally be integrated will be called *non-holonomic*.¹ The simplest example of a non-holonomic condition is furnished by a sharp-edged wheel rolling on a horizontal plane, cf. problem II.1 (the sleigh and the flexible coupling mechanism of a bicycle also belong in this category). Such a wheel is restricted to move always in the direction it may have at any given instant. Nevertheless it is able to reach all points of its supporting plane, even if at times only by pivoting about its sharp point of contact. It therefore possesses more degrees of freedom in finite than in infinitesimal motion. In general, if a system subject to r non-holonomic conditions has f degrees of freedom in finite motion, it has only $f-r$ degrees of freedom in infinitesimal motion. This point will be investigated in problem II.1.

The foregoing distinction is important for the concept of virtual displacements. A *virtual displacement* is an arbitrary, instantaneous, infinitesimal change of the position of the system compatible with the conditions of constraint. Whereas we shall denote real displacements due to given forces under given conditions by

$$dq_1, dq_2 \dots dq_f,$$

the symbols

$$\delta q_1, \delta q_2 \dots \delta q_f$$

will be used to denote virtual displacements. The δq have nothing to do

¹ A. Voss made a general study of such conditions in 1884, long before Hertz; cf. *Math. Ann.* 25.

with the actual motion. They are introduced, so to speak, as test quantities, whose function it is to make the system reveal something about its internal connections and about the forces acting on it.

For purely holonomic constraints the δq are independent of each other, one δq corresponding to each degree of freedom. A larger number of δq must be introduced for non-holonomic constraints; in that case the δq are related by differential conditions of the form (3), or, for virtual displacements,

$$(4) \quad \sum_{k=1}^f F_k(q_1 \dots q_f) \delta q_k = 0.$$

Here f is the number of degrees of freedom for finite motion. As previously emphasized, this number is greater than that for infinitesimal motion.

§ 8. The Principle of Virtual Work

Let us consider a mechanical system in equilibrium under applied forces. The forces may have any desired direction, may act on various parts of the system, and need not have the positions required for the equilibrium of a simple rigid body. Whether the forces lead to the equilibrium of the system under investigation depends as much on the system as on the forces.

FIG. 9. Schematic diagram of the drive mechanism of a piston engine.

In the spirit of elementary particle mechanics we would ask for the *reactions* which are exerted by one part of the system on another due to the applied forces. This procedure would, for instance, be used by a mechanical engineer in the analysis of the crank mechanism (Fig. 9). The steam pressure P acting on the piston is transmitted by the piston rod to the crosshead K , whence it is passed on as longitudinal compression to the connecting rod of length l . The connecting rod acts on the crank pin Z with a thrust which has the direction of the rod. In order that the system be in equilibrium only that part U of the thrust which is perpendicular to the crank, therefore tangential to the crank circle, need be opposed by an equal applied force. The component in the direction of the crank,

i.e., toward the center of the crank shaft, is absorbed by the rigidly fixed shaft bearing, O . It only puts a stress on the bearing and is irrelevant to the question of the equilibrium of the system.

It is therefore the reactions within the system which make equilibrium possible. To investigate them individually is possible in simple cases, but tedious in general. We can, however, assert without knowing them in detail that *they do no work on the system*. In our case the guide pressure at the guide rails is perpendicular to the motion of the crosshead, and that part of the force acting on the crank pin which is transmitted to the crank shaft acts through the fixed point O of the crank shaft bearing. We establish this assertion in the general case by giving the system a tentative virtual displacement from its position of equilibrium. The "virtual work" of the reactions in such a displacement is found to be zero.

Let us verify the principle in detail on the simple rigid body. We must imagine that every point i is related to every point k of the body by means of reactions R_{ki} and R_{ik} acting on i and k respectively. If we single out two such points, we have the system of two mass points mentioned at the beginning of § 7, the two masses being connected by a weightless, rigid rod. The reactions acting in this rod must satisfy Newton's third law,

$$(1) \quad R_{ik} = -R_{ki}.$$

Just as in § 7, in the enumeration of the degrees of freedom, we shall now decompose the virtual displacement into a translation δs_i common to both points and a rotation δs_n of point k about the already displaced point i , this rotation being a motion normal to the rod. Then

$$\delta s_k = \delta s_i + \delta s_n$$

For the virtual work of translation we therefore obtain, in view of (1),

$$\delta W_{tr} = R_{ik} \cdot \delta s_i + R_{ki} \cdot \delta s_i = 0;$$

for that of rotation, for which i remains fixed and k is displaced normal to the rod,

$$\delta W_{rot} = R_{ik} \cdot \delta s_n = 0.$$

This example illustrates that Newton's law of action and reaction is the salient point in the transition from particle mechanics to the mechanics of systems.

We shall now expand what we have learned with the help of the foregoing examples into a general postulate: *in any mechanical system the virtual work of the reactions equals zero*. Far be it from us to want to give

a general proof of this postulate.² Rather we regard it practically as definition of a "mechanical system."

It is now only a small step to the general formulation of the principle of virtual work. We argue as follows: every physically given force acting on a system in equilibrium is in equilibrium with the reactions induced at its point of application; the work done by such an applied force plus that done by its reactions in any virtual displacement of the point of application is therefore zero. The same is true of the sum of all applied forces and the sum of all the reactions induced by them. Now the reactions, taken by themselves, do no virtual work (by the previous paragraph). *Therefore the virtual work done by the applied forces keeping a system in equilibrium must equal zero as well.* The tedious investigation of the reactions is thereby eliminated.

This is the principle of virtual work, often called *Prinzip der virtuellen Verrückungen oder Verschiebungen* (principle of virtual displacements) in the German literature. This name is not as fortunate as the one used in English-speaking countries, which was taken over from the Italian *principio dei lavori virtuali*. The term, principle of virtual velocities, which is often used in the mathematical literature and was first proposed by Jean Bernoulli, seems unsuited to us.

Historically the principle was already sketched by Galileo. It was further developed by Stevin, Jacques and Jean Bernoulli and d'Alembert. It achieved its dominating position as the most general equilibrium principle only with the "Mécanique analytique" of Lagrange.

Whether the constraints of the system are of the holonomic or the non-holonomic variety affects the application of the principle of virtual work but little. Indeed, a condition of the form (7.4) can be introduced in the expression for the virtual work by elimination of one of the δq , regardless of whether this condition is integrable or not.

Instead of forces of reaction we can use the more descriptive term, forces of geometric origin. For they are given by the geometric relations between the various parts of the system, or, as in the case of the rigid body, between its individual mass points.

Antonymous to forces of geometric origin are the "forces of physical origin" or *applied forces*. The commonly used term "external forces" is less clear and will not be used here in this sense. Applied forces are caused by physical effects, such as gravity, steam pressure, cable tensions acting on the system from the outside, etc. They betray their physical origin by the fact that their mathematical expressions contain specific

² Lagrange attempts this in the introduction of his *Mécanique Analytique* (cf. p. 1) by means of certain block and tackle constructions.

constants (gravitational constant, readings of the scale of a manometer or barometer, etc.) which can be determined only experimentally. In § 14 we shall talk about the force of friction, which must sometimes be counted among the forces of reaction, sometimes among the applied forces. It is a force of reaction if it occurs as static friction; an applied force if it occurs as sliding or kinetic friction. Static friction is automatically eliminated by the principle of virtual work; kinetic friction must be introduced as an applied force. An external indication of this is the occurrence of the experimental constant μ in the law of sliding friction (14.4).

§ 9. Illustrations of the Principle of Virtual Work

(1) The Lever (Archimedes)

The lever possesses one degree of freedom, $f=1$, therefore only one displacement δq which corresponds to the virtual angular displacement $\delta\phi$.

Equilibrium exists if, and only if, the virtual work done in a rotation $\delta\phi$ of the lever is zero. Let δs_A , δs_B be the virtual displacements of the points of application P and Q of the forces A and B respectively. We then demand that

$$A \delta s_A + B \delta s_B = 0.$$

But from Fig. 10a $\delta s_A = a \delta\phi$, $\delta s_B = -b \delta\phi$. Therefore

$$(Aa - Bb) \delta\phi = 0$$

and consequently

$$Aa = Bb.$$

The moments of the forces about the fulcrum O are equal, i.e., their algebraic sum is zero.

FIG. 10a. Lever with arms a and b under vertical loads A and B .

FIG. 10b. Lever under oblique load, showing the reaction of the fulcrum on the beam.

If, as in Fig. 10b, the force A is not perpendicular to the lever arm, we can decompose it into a component A_1 in the direction of the arm, and A_2 perpendicular to it. With point O fixed, A_1 has no effect, so that we have

$$A_2 a = |B| b.$$

In order to obtain the load at O , we must introduce an opposing force acting on the arm; in Fig. 10a it is directed vertically upward and has magnitude $Q = A + B$; the load on the fulcrum is equal and opposite to this force Q . In the case of Fig. 10b we have the vector equation $Q = A + B$; here, too, the force on O is the opposite (i.e., "equilibrant") of Q . In posing these questions, we actually transgress the limits of the principle of virtual work. The fixed position of the pivot O is characteristic of the mechanical system of the lever. Its virtual displacement, and the virtual work done on it, are therefore zero. In order to obtain Q or Q by means of our principle we should have to consider an altogether different mechanical system: we should have to provide O with two degrees of freedom and ask for the condition of equilibrium when we add a virtual translation of the whole lever parallel to itself to the rotation so far considered.

(2) Inverse of the Lever: Cyclist, Bridge

Consider the bicycle of Fig. 11a. The earth opposes the weight in the two points R (rear wheel) and F (front wheel). The rear wheel is exposed to the greater pressure, since the weight Q of bicycle and rider lies closer to R than to F . Accordingly a cyclist pumps his rear wheel to a higher

FIG. 11a. Distribution of weight on front and rear wheels of a bicycle with rider.

FIG. 11b. Distribution of load on the two supports of a schematic bridge.

pressure than his front wheel. The load on the rear wheel is $A = \frac{b}{a+b} Q$, that on the front wheel, $B = \frac{a}{a+b} Q$.

The same situation obtains with a bridge loaded off center (Fig. 11b).

(3) The Block and Tackle (also known to the Greeks)

Let n be the number of pulleys at both the upper and the lower end of the tackle. Q is the load to be lifted, P the force required at the loose end of the rope. In a virtual displacement of the system let

P move a distance δp ,

Q move a distance δq ,

the positive direction of motion being indicated by the arrows of Fig. 12. Equilibrium exists if

$$(1) \quad P \delta p - Q \delta q = 0.$$

If now Q is lifted an amount δq , the $2n$ rope lengths between the upper and lower pulleys are shortened by δq each, the total shortening therefore being $2n\delta q$. The loosely hanging rope at P must lengthen by precisely the same amount. Thus

$$\delta p = 2n\delta q$$

and, in view of (1),

$$(Q - 2nP) \delta q = 0.$$

We then obtain

$$(2) \quad P = \frac{Q}{2n}.$$

We have here treated the block and tackle as an "ideal" mechanical system, i.e., we have neglected the friction between ropes and pulleys and the friction in the pulley bearings.

This simple example can of course also be treated by the elementary method of rope tension, which in this case affords perhaps a more concrete picture of the interplay of forces.

Let S be the tension in the rope, taken over its total cross-section. If we neglect all frictional effects, the tension must be the same at every point of the rope; no matter where the rope is cut, one encounters the same tension S , which in both severed ends acts away from the point of severance. Let us cut the rope once on the left side, above P . The severed piece, in which P

FIG. 12. Block and tackle. Virtual displacements of load and force.

acts downward and S upward, gives

$$P=S.$$

Next we cut all the ropes in the right part of the figure, thereby exposing $2n$ cross-sections on each side of the cut. The equilibrium of the forces acting on the severed lower right part demands

$$Q=2nS.$$

We therefore have again

$$P=\frac{Q}{2n}.$$

In addition, a consideration of the upper part of the system yields the loading of the beam from which the block is suspended. Evidently it amounts to $P+Q$.

(4) The Drive Mechanism of a Piston Engine

As in Fig. 9, P is the total force due to the steam pressure exerted on the piston, so that the virtual work done on the piston is $P\delta x$. Let Q be the equilibrant of the peripheral force U on the crank, i.e., the force causing P to be in equilibrium. The virtual work done by Q is $-Qr\delta\phi$. Our principle requires

$$(3) \quad Qr\delta\phi = P\delta x, \quad Q = P \frac{\delta x}{r\delta\phi}.$$

The calculation of Q therefore reduces to the purely kinematic task of determining the relation between δx and $\delta\phi$.

According to Fig. 9 (projection on the x -direction),

$$(4) \quad r \cos \phi + l \cos \psi = \text{const} - x,$$

so that, differentiating,

$$(4a) \quad r \sin \phi \delta\phi + l \sin \psi \delta\psi = \delta x.$$

The triangle OZK gives

$$(4b) \quad \sin \psi = \frac{r}{l} \sin \phi, \quad \delta\psi = \frac{r \cos \phi}{l \cos \psi} \delta\phi = \frac{r}{l} \frac{\cos \phi}{\left[1 - \left(\frac{r}{l}\right)^2 \sin^2 \phi\right]^{\frac{1}{2}}} \delta\phi$$

If we introduce this in (4a), we obtain

$$(4c) \quad r \sin \phi \delta\phi \left(1 + \frac{r}{l} \frac{\cos \phi}{\left[1 - \left(\frac{r}{l}\right)^2 \sin^2 \phi\right]^{\frac{1}{2}}}\right) = \delta x.$$

This relation furnishes the kinematic quantity $\frac{\delta x}{r \delta \phi}$. Substitution in (3) now gives

$$(5) \quad Q = P \sin \phi \left(1 + \frac{r}{l} \frac{\cos \phi}{\left[1 - \left(\frac{r}{l} \right)^2 \sin^2 \phi \right]^{\frac{1}{2}}} \right).$$

Thus the peripheral force $U = Q$ transmitted by the crank pin Z is determined for every crank position ϕ . Its precise knowledge is essential for an evaluation of the amount of cyclic fluctuation of the machine, and hence for the determination of the flywheel required. Since r/l is a small proper fraction, (5) can be expanded into a rapidly converging series in r/l . Cf. also problem II.2.

Finally, for the sake of a later application we shall calculate the piston position x as a power series in r/l . According to (4) and (4b) we have

$$(6) \quad x + r \left(\cos \phi - \frac{1}{2} \frac{r}{l} \sin^2 \phi + \dots \right) = \text{const.}$$

(5) Moment of a Force About an Axis and Work in a Virtual Rotation

Let a point P be at a distance l from an axis a . Let a force \mathbf{F} of arbitrary direction act at P . In a virtual rotation $\delta \phi$ about the axis a , P is displaced by

$$\delta s_P = l \delta \phi.$$

What is the work δW done by \mathbf{F} in this displacement?

We decompose \mathbf{F} into the mutually perpendicular components F_a , F_t , F_n , just as for Eq. (5.18). The work done depends only on F_n , for

$$\delta W = F_n \delta s_P = F_n l \delta \phi.$$

A comparison with (5.18a) will allow us to make a general statement:

The moment of a force about an axis can be regarded as the virtual work of the force in a rotation $\delta \phi$ of its point of application about the axis, divided by $\delta \phi$,

$$(7) \quad L_a(\mathbf{F}) = \frac{\delta W}{\delta \phi} = l F_n.$$

The concept of moment, basic to statics, is thereby brought into relation with the concept of virtual work basic to all questions of equilibrium.

Let us remark in this connection that the dimensions of moment (force-lever arm) are the same as those of work (force · distance). This is in agreement with (7) if, as is customary, we regard the angle measured in radians as dimensionless,

§ 10. *D'Alembert's Principle ; Introduction of Inertial Forces*

As we have seen, all bodies have the tendency to remain in a state of rest or of uniform rectilinear motion. We can think of this tendency as a resistance to changes in the motion, an inertial resistance, or, for brevity, as an *inertial force*. The definition of inertial force F^* for the single mass point is therefore

$$(1) \quad F^* \equiv -\dot{\mathbf{p}}$$

and the fundamental law $\dot{\mathbf{p}} = \mathbf{F}$ takes on the form

$$(2) \quad F^* + F = 0.$$

The inertial force is in vectorial equilibrium with the applied force.

While F is a force given by the physical situation, F^* is a fictitious force. We introduce it in order to reduce problems of motion to problems involving equilibrium, a procedure that is often convenient.

Inertial forces are familiar to us from everyday life. When we set the heavy revolving door of an hotel in motion, it is not the force of gravity or friction, but the inertia of the door that has to be overcome. A similar example is that of the sliding doors of street cars and trolleys.* On the forward platform the door opens in the direction of travel. When the car brakes, the door tends to move forward and can therefore be opened easily. When the car accelerates after a stop, the open door seeks to retain its position of rest; it therefore tends to move to the rear and can be closed without effort. It is easier to get on and off at the front platform than at the rear, where the door opens in the reverse manner.

The best-known form of an inertial force is the *centrifugal force*, which is noticeable in any curved motion. It, too, is a fictitious force. It corresponds to the acceleration $\dot{\mathbf{v}}_n$ normal to the curve, which is a *centripetal* acceleration, i.e., directed toward the center of curvature. According to (5.9) the centrifugal force is given by

$$(3) \quad \mathbf{C} = -m\dot{\mathbf{v}}_n, \quad |\mathbf{C}| = m|\dot{\mathbf{v}}_n| = m\frac{v^2}{\rho},$$

where the minus sign refers to the outward direction.

The *Coriolis force* (cf. § 28) and the various gyroscopic effects (cf. § 27) also come under the heading of inertial forces.

Incidentally the operation of railroads furnishes a very vivid example of the fact that the "fictitious" centrifugal force has a very real existence.

* The translator does not guarantee that the following is applicable to trolleys in the United States. It applies at least in part to the streetcars of San Francisco, which belong, however, to a breed rapidly approaching extinction.

On a curve the rail bed is banked in such a way that the outer rail is higher than the inner. The difference in height is always such that for some mean velocity of the train the resultant of gravity and centrifugal force is perpendicular to the rail bed. This procedure eliminates not only the danger of overturning about the outer rail, but also a harmful unequal loading of the rails.

Strangely enough, the great Heinrich Hertz raises objections to the introduction of the centrifugal force in the unusually beautiful and beautifully written introduction to his "Mechanics" (Collected Works, Vol. III, p. 6):

"We swing a stone attached to a string in a circle; we thereby consciously exert a force on the stone; this force constantly deviates the stone from a straight path, and if we alter this force, the mass of the stone or the length of the string, we discover that indeed the motion of the stone occurs at all times in agreement with Newton's second law. Now the third law demands a force opposing that which is exerted by our hand on the stone. If we ask for this force, we obtain the answer familiar to everybody, that the stone reacts on the hand by virtue of the centrifugal force, and that this centrifugal force is indeed equal and opposite to the force exerted by us on the stone. Is this mode of expression admissible? Is that which we now call centrifugal force anything but the inertia of the stone?"

We answer this question with a flat no; indeed the centrifugal force, by virtue of our definition (3), is identical to the inertia of the stone. But the force opposing that which we exert on the stone, i.e., really on the string, is the pull which the string exerts on our hand. Hertz further remarks that "we are forced to the conclusion that the classification of the centrifugal force as a force is not suitable; its name, just like that of live force, is to be regarded as a heritage passed down from former times; and from the point of view of usefulness the retention of this name is easier to excuse than to justify." In regard to this we would like to say that the name centrifugal force needs no justification, for it rests, like the more general term, inertial force, on a clear definition.

Incidentally, it is precisely this alleged lack of clarity of the force concept which induced Hertz, in an interesting but not very fruitful attempt, to construct his mechanics entirely without the notion of force (cf. § 1, p. 5).

We now come to the achievement of d'Alembert (mathematician, philosopher, astronomer, physicist, encyclopedist; "Traité de Dynamique," 1758).

If a mass point k , part of an arbitrary mechanical system, is acted on by an applied force F , Eq. (2) must be changed to read

$$(4) \quad \mathbf{F}_k^* + \mathbf{F}_k + \sum_i \mathbf{R}_{ik} = 0.$$

Here \mathbf{R}_{ik} is the reaction which the mass point i connected with k exerts on k . According to our general postulate of p. 52, the \mathbf{R}_{ik} , taken together, do no work in an arbitrary virtual displacement compatible with the (here internal) constraints. It follows that the virtual work of the sum of all the $\mathbf{F}^* + \mathbf{F}$ is zero as well,

$$(5) \quad \sum_k (\mathbf{F}_k^* + \mathbf{F}_k) \cdot \delta \mathbf{s}_k = 0.$$

Recalling now the principle of virtual work, we can express Eq. (5) by saying that *the inertial forces of a system are in equilibrium with the forces applied to the system*. A knowledge of the reactions is not required.

This is *d'Alembert's principle* in its simplest and most natural form. In order to obtain another interesting formulation of the principle, let us look at the quantity

$$\mathbf{F}_k + \mathbf{F}_k^* = \mathbf{F}_k - \dot{\mathbf{p}}_k.$$

It is that part of the force \mathbf{F}_k that cannot be converted into motion of the point k . We can call this part the "lost force" and can therefore re-frame (5) by stating that *the lost forces of a system are in equilibrium*.

A formulation of d'Alembert's principle widely used in textbooks is that expressed in Cartesian coordinates. We call the components of \mathbf{F}_k , X_k, Y_k, Z_k and those of $\delta \mathbf{s}_k$, $\delta x_k, \delta y_k, \delta z_k$. Furthermore, we stipulate that the masses m_k involved are constant; for a system consisting of n mass points we can then replace (5) by

$$(6) \quad \sum_{k=1}^n \{ (X_k - m_k \ddot{x}_k) \delta x_k + (Y_k - m_k \ddot{y}_k) \delta y_k + (Z_k - m_k \ddot{z}_k) \delta z_k \} = 0.$$

It is here required that the $\delta x_k, \delta y_k, \delta z_k$ be compatible with the constraints of the system. Let us at once consider the general case of non-holonomic constraints. There relations of type (7.4) exist; if we replace the general coordinates q of (7.4) by Cartesian coordinates, these relations become

$$(6a) \quad \sum_{\mu=1}^n [F_{\mu}(x_1 \dots x_n) \delta x_{\mu} + G_{\mu}(x_1 \dots x_n) \delta y_{\mu} + H_{\mu}(x_1 \dots x_n) \delta z_{\mu}] = 0.$$

If f is the number of degrees of freedom for infinitesimal motion, there must be $3n - f$ such relations for the $\delta x, \delta y, \delta z$ (cf. p. 50). In the case of holonomic constraints the $F_{\mu}, G_{\mu}, H_{\mu}$ are derivatives of one and the same function with respect to $x_{\mu}, y_{\mu}, z_{\mu}$.

Let the reader be warned emphatically not to look for the true content of d'Alembert's principle in the clumsy formulation (6), (6a). Equation (5) or the statement of equilibrium equivalent to it is not only more readily useful, but also, by virtue of its invariant form, more natural.

§ 11. Application of d'Alembert's Principle to the Simplest Problems

(1) Rotation of a Rigid Body About a Fixed Axis

Here we are dealing with a single degree of freedom, viz., the angle of rotation ϕ . We let $\dot{\phi} = \omega$ be the angular velocity, $\ddot{\phi} = \dot{\omega}$ the angular acceleration. For the present we are not interested in the axle bearings.

We suppose that arbitrary applied forces F act on the body. According to § 9, Eq. (7), their virtual work is given by the sum of their moments about the axis of rotation, i.e., by

$$(1) \quad \delta W = L \cdot \delta\phi = L_a \delta\phi$$

where L_a is the sum of the moments of the F about the axis of rotation a . We also wish to know the work done by the inertial forces F^* . For this purpose we subdivide the body into mass elements dm . In view of (10.3) the inertial force acting on dm directed normal to the path is the centrifugal force $dm \frac{v^2}{r} = dm \omega v$. (In circular motion the radius of curvature ρ is of course equal to the distance r from the rotation axis, the velocity v of each element of mass therefore becomes $r\omega$, and its acceleration \dot{v} along the path is $r\dot{\omega}$). But the centrifugal force does no work. Along the path direction, on the other hand, the inertial force is

$$-dm\dot{v} = -dmr\dot{\omega}.$$

The total virtual work of the inertial forces is therefore

$$(2) \quad \sum (-dm\dot{v})\delta s = \sum -dmr\dot{\omega}r\delta\phi = -\delta\phi\dot{\omega} \int r^2 dm = -\delta\phi\dot{\omega}I,$$

where

$$(3) \quad I = \int r^2 dm$$

is the *moment of inertia* of the body. The dimensions of I are ML^2 , therefore g cm^2 in the absolute system, g cm sec^2 in the gravitational system.

By virtue of (1) and (2) d'Alembert's principle takes the form

$$\delta\phi(L_a - I\dot{\omega}) = 0$$

so that we obtain the basic equation of rotational motion

$$(4) \quad I\dot{\omega} = L_a.$$

Let us compare this equation with the basic equation of translational motion of one degree of freedom, say in the x -direction,

$$m\ddot{x} = F_x.$$

We see that in rotational motion I takes the place of m .

The same substitution holds in the expression for the kinetic energy. The kinetic energy of rotation of a rigid body is

$$(5) \quad E_{\text{kin}} = T = \int \frac{dm}{2} v^2 = \int \frac{dm}{2} r^2 \omega^2 = \frac{\omega^2}{2} \int r^2 dm = \frac{\omega^2}{2} I$$

and therefore corresponds exactly to the elementary expression of particle mechanics,

$$(5a) \quad E_{\text{kin}} = T = \frac{\dot{x}^2}{2} m.$$

In the case of a rigid body with fixed axis, I is time-independent; in mechanisms with flexible joints and in living beings it is, however, variable in a characteristic manner. In § 13 we shall see that all athletic activities, in particular apparatus gymnastics, are based primarily on the ability of the human body to change its moment of inertia.

An investigation of the manner in which the moment of inertia of a rigid body depends on the position of the axis of rotation will be deferred to § 22.

Finally we shall turn to the connection of the kinetic energy with the basic equation of motion. Just as, in the case of constant mass, we can obtain the equation of motion $m\ddot{x} = F_x$ from the law of kinetic energy in particle mechanics, i.e.,

$$\frac{dT}{dt} = \frac{dW}{dt} \quad \text{with} \quad dW = F_x dx,$$

we obtain, in the case of constant I , the equation of motion (4) for rotation. We need merely make use of (5) in

$$\frac{dT}{dt} = \frac{dW}{dt} \quad \text{with} \quad dW = L_a d\phi \quad [\text{Eq. (9.7)}].$$

The moment of inertia occurs also in the expression for the *moment of momentum* or *angular momentum* of the rotating body. If we let M be the angular momentum of the body, we evidently have

$$(6) \quad M = \sum dm \, vr = \omega \sum dm \, r^2 = \omega I.$$

(2) Coupling of Rotational and Translational Motion

Think of the coal basket in a mine, or of an elevator. The cable carrying the elevator is wound around a drum and driven by a force P . Let r be the drum radius. The two virtual displacements that take place (cf. Fig. 13) are related by

$$(7) \quad \delta z = r \delta \phi.$$

d'Alembert's principle requires

$$(7a) \quad (-Q - M\ddot{z})\delta z + (rP - I\dot{\omega})\delta \phi = 0.$$

It is convenient to "reduce" the mass of the drum, so to speak, to the periphery of the drum, i.e., to replace I by a "reduced mass" defined by

$$(8) \quad I = M_{\text{red}} r^2.$$

By virtue of (7), Eq. (7a) can then be rewritten in the form

$$(P - Q - M\ddot{z} - M_{\text{red}} r \dot{\omega}) \delta z = 0.$$

Since $r\omega = \dot{z}$, $r\dot{\omega} = \ddot{z}$, we then obtain the equation of motion

$$(9) \quad (M + M_{\text{red}})\ddot{z} = P - Q.$$

The inertia of the drum therefore adds a term M_{red} to the mass of the elevator.

(3) Sphere Rolling on Inclined Plane

Here again we are dealing with the coupling of translation (motion down the incline) and rotation (about an axis through the center of the sphere perpendicular to the plane of the paper in Fig. 14). The component of gravity effective in this case is $P = Mg \sin \alpha$; the static friction F indicated on the diagram does not enter d'Alembert's principle, since it acts at the point of contact which is instantaneously at rest. The condition for pure rolling motion is

$$(10) \quad \dot{z} = r\omega, \text{ or, written for virtual motion, } \delta z = r \delta \phi.$$

With d'Alembert we now require that

$$(11) \quad \delta z (Mg \sin \alpha - M\ddot{z}) + \delta \phi (-I\dot{\omega}) = 0.$$

The calculation of I is a problem of integral calculus. We shall state without proof that the moment of inertia of a homogeneous ellipsoid of

FIG. 13. Coupling of translational and rotational motion (elevator, coal basket).

semi-axes a , b , c about axis c (and correspondingly about a and b) is

$$(12) \quad I_c = \frac{M}{5} (a^2 + b^2).$$

As a special case we obtain for the moment of inertia of a sphere

$$(12a) \quad I = \frac{2}{5} Mr^2.$$

As in (8) we introduce a mass reduced to the distance r , which by virtue of (12a) becomes

$$(12b) \quad M_{\text{red}} = \frac{2}{5} M.$$

If we substitute this in (11) and also take (10) into account, we easily obtain

$$(13) \quad \ddot{z} = \frac{5}{7} g \sin \alpha.$$

The factor $\frac{5}{7}$ shows how the "fall" on an inclined plane is delayed by the angular acceleration of the sphere and the increased inertia due to it.

Whereas from (3.13) the final velocity in a free fall was found to be

$$v = (2gh)^{\frac{1}{2}}, \quad h = \text{height of fall},$$

equation (13) now gives the final velocity

$$v = (2 \cdot \frac{5}{7} gh)^{\frac{1}{2}}.$$

The difference is due to the fact that now the gravitational potential energy is converted not only into kinetic energy of descent, but also into rotational energy of the rolling sphere.

(4) Mass Guided Along Prescribed Trajectory

If we assume the guide ways to be frictionless, d'Alembert's principle applied to the one degree of freedom here present (displacement along the guide) simply says that

$$\delta s (F_s^* + F_s) = 0,$$

i.e., according to (5.8),

$$(14) \quad m\dot{v}_s = m|\dot{v}| = F_s$$

with arbitrary direction of the applied force F . The component F_s of F

FIG. 14. Sphere on inclined plane. The static friction F causes pure rolling, but does not enter d'Alembert's principle.

normal to the guide, which we may take positive in the centripetal direction, must then add to the reaction R_n (counted positive in the same direction) to give the equilibrant of the centrifugal force C ; i.e.,

$$(15) \quad R_n + F_n = C = m \frac{v^2}{\rho}.$$

In general, especially if the guiding action is achieved by a material device such as a rail, we are compelled to take into account also a tangential component R_s of the reaction, the *friction*. If we count the friction positive in the negative direction of δs , Eq. (14) is therefore enlarged to

$$(16) \quad m\dot{v} = F_s - R_s.$$

Whereas R_n is determined by Eq. (15), R_s in (16), on the other hand, remains "statically and dynamically indeterminate" and can be determined only from experiment. In § 14 we shall discuss how such experiments are carried out.

§ 12. Lagrange's Equations of the First Kind

Let us consider a system of discrete mass points m_1, m_2, \dots, m_n , connected with each other by r holonomic conditions

$$(1) \quad F_1 = 0, F_2 = 0, \dots, F_r = 0.$$

The number of degrees of freedom is then $f = 3n - r$. We operate in Cartesian coordinates and make use of the formulation (10.6) of d'Alembert's principle. In order to write the clumsy sums occurring there in a more convenient way, we number the coordinates $x_1, y_1, z_1, \dots, x_n, y_n, z_n$ consecutively as

$$x_1, x_2, x_3, x_4, \dots, x_{3n-1}, x_{3n},$$

and likewise the components of force X, Y, Z . The mass belonging to x_k , X_k will be denoted by m_k ; evidently the m_k will be equal in groups of three. Eq. (10.6) now becomes

$$(2) \quad \sum_{k=1}^{3n} (X_k - m_k \ddot{x}_k) \delta x_k = 0.$$

By virtue of the r conditions of constraint (1), the δx_k are subject to the restrictions

$$(3) \quad \delta F_i = 0, \quad i = 1, 2, \dots, r,$$

which can also be written

$$(4) \quad \sum_{k=1}^{3n} \frac{\partial F_i}{\partial x_k} \delta x_k = 0, \quad i = 1, 2, \dots, r.$$

Let us multiply each of the δF_i by an arbitrary numerical factor λ_i (Lagrange multiplier) and add it to the d'Alembert equation (2), giving

$$(5) \quad \sum_{k=1}^{3n} \left(X_k - m_k \ddot{x}_k + \sum_{i=1}^r \lambda_i \frac{\partial F_i}{\partial x_k} \right) \delta x_k = 0.$$

Only f of the $3n$ displacements δx are independent of each other. The remaining r are functions of these independent ones. Let these r displacements be given by the quantities $\delta x_1, \delta x_2, \dots, \delta x_r$. Now we have precisely r quantities $\lambda_1, \lambda_2, \dots, \lambda_r$ over which we can dispose freely. We choose them so as to make

$$(6) \quad X_k - m_k \ddot{x}_k + \sum_{i=1}^r \lambda_i \frac{\partial F_i}{\partial x_k} = 0; \quad k=1, 2, \dots, r.$$

Eq. (5), with the numbers λ_i now determined, reduces to

$$(7) \quad \sum_{k=r+1}^{3n} \left(X_k - m_k \ddot{x}_k + \sum_{i=1}^r \lambda_i \frac{\partial F_i}{\partial x_k} \right) \delta x_k = 0$$

where the δx_k are completely independent, there being indeed $f=3n-r$ of these. If, for example, we choose

$$(8) \quad \delta x_{r+v} \neq 0; \delta x_{r+1} = \delta x_{r+2} = \dots = \delta x_{r+v-1} = \delta x_{r+v+1} = \dots = \delta x_{3n} = 0,$$

we see that the factor of δx_{r+v} must vanish. Letting v run through all values $1, 2, \dots, f$, we conclude that all expressions in parentheses have to be $=0$,

$$X_k - m_k \ddot{x}_k + \sum_{i=1}^r \lambda_i \frac{\partial F_i}{\partial x_k} = 0; \quad k=r+1, r+2, \dots, 3n.$$

Together with the Eqs. (6) these form $3n$ differential equations

$$(9) \quad m_k \ddot{x}_k = X_k + \sum_{i=1}^{i=r} \lambda_i \frac{\partial F_i}{\partial x_k}; \quad k=1, 2, \dots, 3n,$$

which are called the *Lagrange equations of the first kind*. Of course the m_k are equal in groups of three; thus $m_1=m_2=m_3$, since we are dealing with the same mass point m_1 having the three coordinates $x_1=x_1, x_2=y_1, x_3=z_1$.

So far we have assumed that the conditions (1) are holonomic; we can easily convince ourselves that all of the preceding can be carried over to the case of non-holonomic constraints with only slight modification. The only difference is that the factors $\frac{\partial F_i}{\partial x_k}$ in (4) must be replaced by general

functions of the coordinates, F_{ik} , which cannot be written in the form of partial derivatives of a function. If we make this replacement in Eqs. (9), we at once obtain Lagrange's equations of the first kind for non-holonomic systems,

$$(9a) \quad m_k \ddot{x}_k = X_k + \sum_{i=1}^{i=r} \lambda_i F_{ik}.$$

Let us make a more interesting generalization by assuming that the conditions (1) vary with time. Then the F_i depend explicitly not only on the x_k but also on t . We must now demand that in forming (4) the time be held constant, a stipulation which is not only permissible but also plausible since our virtual displacement has nothing to do with the passage of time. The derivation of (9) is not affected by this requirement. But we obtain an important consequence regarding the form of the equation of energy.

If we want to derive this equation in the case of time-independent constraints, we proceed as follows: we multiply (9) by dx_k and sum over k . On the left we obtain

$$(9b) \quad dt \sum m_k \dot{x}_k \ddot{x}_k = dt \frac{d}{dt} \sum \frac{m_k}{2} \dot{x}_k^2 = dt \frac{dT}{dt} = dT.$$

The first term of the right member gives the work done by the applied forces in time dt ,

$$(9c) \quad \sum dx_k X_k = dW.$$

The second term on the right vanishes. For

$$(9d) \quad \sum_{i=1}^r \lambda_i \sum_{k=1}^{3n} \frac{\partial F_i}{\partial x_k} dx_k = \sum_{i=1}^r \lambda_i dF_i = 0$$

by virtue of the fact that the F_i depend only on the x_k , so that $F_i = 0$ implies

$$(9e) \quad dF_i = \sum \frac{\partial F_i}{\partial x_k} dx_k = 0.$$

From (9b, c) we then have

$$(10) \quad dT = dW.$$

This is no longer so if the F_i also depend on t . Then the zero in (9d, e) is to be replaced by

$$-\sum_{i=1}^r \lambda_i \frac{\partial F_i}{\partial t} dt \quad \text{and} \quad -\frac{\partial F_i}{\partial t} dt$$

respectively. For time-dependent constraints the equation of energy is then

$$(10a) \quad dT = dW - dt \sum_{i=1}^r \lambda_i \frac{\partial F_i}{\partial t}.$$

This means that *time-dependent constraints do work on the system*.

To make this principle more concrete, let us think of a tennis racquet. If the racquet is kept fixed, it reflects the ball with unchanged energy. If instead it yields backward or swings toward the ball, it takes energy away from or gives energy to the ball.

In non-holonomic systems an explicit dependence on t of the F_{ik} occurring in (9a) would be compatible with an equation of energy of the form (10). If, however, the non-holonomic conditions had the form

$$\sum F_{ik} dx_k + G_i dt = 0$$

instead of (7.4), it would be necessary to add members in G_i to (10) which would then take on a form analogous to (10a), i.e.,

$$(10b) \quad dT = dW - dt \sum_{i=1}^r \lambda_i G_i.$$

We shall learn from the example of the spherical pendulum in the following chapter that the λ_i can be regarded as the reactions of the system against the constraint exerted by the holonomic or non-holonomic conditions. There we shall also see that the determination of the λ cannot be effected by means of r Lagrange equations arbitrarily singled out, even though this was a permissible assumption for purposes of our derivation. Instead the λ must be determined from all $3n$ of the Lagrange equations taken together. It should be emphasized that the method of Lagrange multipliers plays an important role not only in the Lagrange equations of the first kind, but also (cf. Ch. VI, § 34) in types of equations of a much more general nature. Apart from their use in mechanics, the Lagrange multipliers are encountered in the elementary theory of maxima and minima.

§ 13. Equations of Momentum and of Angular Momentum

We derive these equations for a system of discrete mass points which can be translated and rotated as a whole in space. Through a limiting process they can, however, be applied equally well to a freely moving rigid body or to an arbitrary mechanical system whose motion is not restricted by external constraints.

We divide the forces acting into *external* and *internal forces*. This classification says nothing about the origin of the forces and is therefore by no means identical with the classification of p. 53 into applied forces and forces of reaction. Our present distinction is strictly based on the criterion of whether the law of action and reaction is or is not satisfied within the system itself. In the first case we speak of internal forces, in the second of external forces. The internal forces of the solar system, for instance, are applied forces because they are gravitational, whereas the external force which drives a railroad train forward is a force of reaction (as we shall see on p. 84), viz., the static friction at the rolling wheels.

We call F_k the external force acting at the point k ; the internal forces will be called F_{ik} to remind us that they act between two points contained in the system and therefore within the system satisfy Newton's third law,

$$(1) \quad F_{ik} = -F_{ki}.$$

(1) Equation of Momentum

Let us now make use of d'Alembert's principle in the form (10.5). We replace F_k by $F_k + \sum_i F_{ik}$, F_k^* by $-\dot{p}_k$ in agreement with definition, and make all the δs_k equal to each other. We therefore impart the same virtual displacement to all the mass points of the system. The F_{ik} drop out because of (1) once we sum over i and k , and we are left with

$$(2) \quad \delta s \cdot \left(\sum_k F_k - \sum_k \dot{p}_k \right) = 0.$$

Let us indicate the summation over k by means of a bar. From (2) we conclude that

$$(3) \quad \dot{\bar{p}} = \bar{F}.$$

\bar{p} is the total momentum of the system, equal to the vector sum of the individual momenta. We define the center of mass velocity V by

$$MV = \bar{m}V = \bar{p}, \quad M = \bar{m}$$

and have, in lieu of (3),

$$(3a) \quad M\dot{V} = \bar{F}.$$

We now choose an arbitrary but fixed point of reference O . We measure the distance r_k of the points of the system from O and define the position R of the center of mass with respect to O by the equation

$$(3b) \quad MR = \bar{mr}.$$

The content of equations (3a, b) can be summed thus: *the center of mass of a freely moving mechanical system moves like a single mass point, having a mass M equal to the total mass of the system, and acted on by the resultant $\bar{\mathbf{F}}$ of all the external forces acting on the system.*

(2) Equation of Angular Momentum

Suppose we impart to the system a virtual rotation $\delta\phi$ about an arbitrary axis passing through a point O . The displacements $\delta\mathbf{s}_k$ of the various points m_k of the system are then unequal; for

$$(4) \quad \delta\mathbf{s}_k = \delta\phi \times \mathbf{r}_k.$$

FIG. 15. The virtual displacement $\delta\mathbf{s}$ resulting from a virtual rotation $\delta\phi$.

FIG. 16. The moments of internal forces cancel in pairs.

To prove this, let us look at Fig. 15. $\delta\phi$ is there drawn as a vector along the axis of rotation and at the same time as a curved arrow about this axis in agreement with the rule of the right-handed screw. By virtue of the definition of the vector product the magnitude δs_k of $\delta\mathbf{s}_k$ is

$$\delta s_k = \delta\phi |\mathbf{r}_k| \sin\alpha = \delta\phi \rho_k,$$

as must be the case for the rotation in question. The direction and sense of $\delta\mathbf{s}_k$ are likewise correctly given by (4). $\delta\mathbf{s}_k$ is directed normal to the plane of the drawing, into the paper.

We introduce (4) in (10.5), while replacing \mathbf{F}^* and \mathbf{F} as in subsec. 1, and immediately obtain

$$(5) \quad \sum_k \left\{ (\mathbf{F}_k + \sum_i \mathbf{F}_{ik} - \dot{\mathbf{p}}_k) \cdot (\delta\phi \times \mathbf{r}_k) \right\} = 0.$$

Next we use a rule of elementary vector algebra,

$$(6) \quad \mathbf{A} \cdot \mathbf{B} \times \mathbf{C} = \mathbf{B} \cdot \mathbf{C} \times \mathbf{A} = \mathbf{C} \cdot \mathbf{A} \times \mathbf{B}$$

which says that the parallelepiped formed by any three vectors \mathbf{A} , \mathbf{B} , \mathbf{C} has a volume which is independent of cyclic permutation of the labels of its three edges.

Instead of (5) we can therefore write

$$(7) \quad \delta\phi \cdot \left\{ \sum_k (\mathbf{r}_k \times \mathbf{F}_k) + \sum_i \sum_k (\mathbf{r}_k \times \mathbf{F}_{ik}) - \sum_k (\mathbf{r}_k \times \dot{\mathbf{p}}_k) \right\} = 0.$$

In this fashion the connection between $\delta\phi$ and \mathbf{r} is severed, so that, with $\delta\phi$ arbitrary, the factor in brackets $\{ \}$ must itself vanish. In order to write this factor more simply we introduce the following notation:

$$(7a) \quad \mathbf{L}_k = \mathbf{r}_k \times \mathbf{F}_k \text{ as in (5.12), } \bar{\mathbf{L}} = \sum \mathbf{L}_k;$$

$$(7b) \quad \mathbf{M}_k = \mathbf{r}_k \times \mathbf{p}_k, \quad \mathbf{r}_k \times \dot{\mathbf{p}}_k = \frac{d}{dt}(\mathbf{r}_k \times \mathbf{p}_k) = \dot{\mathbf{M}}_k \text{ as in (5.14);}$$

$$(7c) \quad \bar{\mathbf{M}} = \sum \mathbf{M}_k, \quad \dot{\bar{\mathbf{M}}} = \sum \dot{\mathbf{M}}_k.$$

$\bar{\mathbf{L}}$ is therefore the vector sum of all moments of the external forces about the common point of reference O , $\bar{\mathbf{M}}$ is the vector sum of the angular momenta of all the mass points of the system about the same point of reference, or, more briefly, the total angular momentum of the system about O .

Moreover we show with the help of Fig. 16 that in the double sum of Eq. (7) all the terms cancel in pairs, viz., that

$$(8) \quad \mathbf{r}_k \times \mathbf{F}_{ik} + \mathbf{r}_i \times \mathbf{F}_{ki} = 0.$$

We see that in this expression the Third Law, Eq. (1), acts essentially as the definition of internal force.

From (8) it follows that the double sum in (7) vanishes. Recalling (7a, b, c) we therefore conclude from (7) that

$$(9) \quad \dot{\bar{\mathbf{M}}} = \bar{\mathbf{L}}.$$

This equation is the exact counterpart of Eq. (3). It states that *the time rate of change of the total angular momentum of the system is equal to the resultant moment of the external forces*, just as Eq. (3) stated that *the time rate of change of the total momentum of the system is equal to the resultant of all the external forces*.

These two laws will be called the equations (or principles) of angular momentum and (linear) momentum respectively.

Formerly it was the custom in the German literature to call basic equation (9) the principle of areas (Flächensatz). This name had its origin in the Kepler problem. There we found that in the case of *one* planet the areal velocity was proportional to the angular momentum, and the direction of the angular momentum was normal to the orbital plane of the planet. This is no longer the case for the planetary many-body problem, where we have instead

$$(10) \quad \bar{\mathbf{M}} = \sum 2m_k \frac{d\mathbf{A}_k}{dt},$$

so that not only the different planetary masses occur as factors, but the individual areal velocities corresponding to the planets must be added vectorially. The areal velocity thus arising for a complete planetary system is defined, as is well known, by the *invariable plane* (plane normal to $\bar{\mathbf{M}}$). It is invariable because in a planetary system external forces are absent, so that $\bar{\mathbf{L}}=0$ and, according to (9),

$$(10a) \qquad \bar{\mathbf{M}} = \text{const.}$$

In general for $\bar{\mathbf{L}}=0$ we obtain the special *principle of the conservation of angular momentum*. The notion of areal velocity is even more difficult to visualize, hence less useful, for a system of infinitely many particles such as a rigid body, so that the term "Flächensatz" should be abandoned for general use.

(3) Proof Using the Coordinate Method

We shall now sketch the proof of our principles by an alternate method, that of decomposition into Cartesian coordinates, because the use of these coordinates is so widespread and has been so greatly favored by older texts that we wish to defer to usage in some measure.

We begin with the equations

$$(11) \qquad \begin{aligned} m_k \ddot{x}_k &= X_k + \sum_i X_{ik} \\ m_k \ddot{y}_k &= Y_k + \sum_i Y_{ik} \end{aligned}$$

which are written in easily understandable form. Summation of the first of these equations over k , with $X_{ik} = -X_{ki}$, at once yields the x -component of the equation of momentum,

$$(12) \qquad \frac{d^2}{dt^2} \sum_k m_k x_k = \sum_k X_k.$$

Multiplication of the first equation by $-y_k$, the second by x_k , yields as their sum

$$(13) \qquad \sum_k m_k (x_k \ddot{y}_k - y_k \ddot{x}_k) = \sum_k (x_k Y_k - y_k X_k) + \dots$$

We group together in pairs ik and ki the terms...not written down, thereby bringing out the direction of the internal forces, $i \rightarrow k$ and $k \rightarrow i$. We then obtain

$$\begin{aligned} x_k Y_{ki} - y_k X_{ki} + x_i Y_{ik} - y_i X_{ik} \\ = \frac{F_{ik}}{r_{ik}} [x_k (y_i - y_k) - y_k (x_i - x_k) + x_i (y_k - y_i) - y_i (x_k - x_i)]. \end{aligned}$$

Simplification shows this to equal zero, in agreement with Fig. 16. With the help of (5.17a) the right member of (13) reduces to

$$\sum_k L_{kz} = L_z.$$

The left member of (13) is, in view of (5.14b),

$$(13a) \quad \frac{d}{dt} \sum_k m_k (x_k \dot{y}_k - y_k \dot{x}_k) = \sum_k \dot{M}_{kz} = \dot{\bar{M}}_z.$$

Equation (13) is then identical with the z -component of our equation of angular momentum (9).

(4) Examples

There exists a profound difference between the principles of linear and of angular momentum which we shall explain with the help of the special case in which no external forces act on the system.

According to Eq. (3a) in this case the velocity of the mass center remains constant; for the total mass M occurring as factor is constant, even for a system with internal motion. If, then, the mass center is initially at rest, it remains at rest. *Internal forces are unable to impart motion to the center of mass, even in a mechanism with flexible joints or in a living body.* In order to move one's center of mass, one must be able to push against a support; therefore an *external force* is necessary.

It is evident that in the absence of external forces $\mathbf{L}=0$, so that (9) yields

$$(14) \quad \bar{\mathbf{M}} = \text{const.}$$

If the moment of momentum is initially zero, it remains zero, even for a system with internal motion. From this it does not follow, however, that the angular position of the system is conserved permanently. Rather, this angular position can be varied *ad libitum* with the help of internal forces alone, and without a push against some outside object.

An example of this is the cat, which always manages to fall on its feet. It achieves this by suitable rotation of the anterior extremities coupled with opposite rotation of the posterior ones. This action is illustrated by the rapid exposure photographs published in the "Comptes Rendus of the Paris Academy," 1894, p. 714.

The essential points of this process can conveniently be followed by means of an experiment with a turning stool. Such a stool consists of a horizontal disc which revolves with as little friction as possible about

a vertical axis. The victim of the experiment is seated on the disc, initially at rest:

$$M_0 = 0.$$

He lifts his right arm forward and describes with it a backward rotation. The "area swept out" in this process must be compensated by a counter-rotation of the remainder of the body including the disc of the stool. More precisely, the moment of momentum M_1 of the moving arm induces a moment of momentum of torso and disc M_2 such that

$$M_2 = -M_1.$$

The experimental subject now lowers his arm; this causes no change in M . Now the initial position of the body is restored, and the process can be repeated. With each repetition the same counter-rotation M_2 takes place. After n repetitions the subject notices that he is facing in a direction opposite to the initial one. In contrast to the position of the center of mass, the angular position is not fixed by the initial state of rest.

One can strengthen the effect by making the subject hold a heavy weight in the right hand. The "area swept out" is thereby, so to speak, multiplied, so that the counter-rotation is also visibly increased.

Let us perform two more experiments: the subject stands on the stool with lowered arms and is given an angular momentum M_0 ; he now raises his arms (with weights in his hands if desired) sideways; the rotation suddenly decreases. Instead, we can set the person spinning with outstretched arms; he next lowers his arms and usually falls off the stool because the rotation, especially when weights are used, is suddenly increased considerably.

In both foregoing cases

$$M_2 = M_1 \text{ and therefore } I_0\omega_0 = I_1\omega_1 \text{ from Eq. (11.6).}$$

In the first case, however, we have

$$I_0 \ll I_1 \text{ and hence } \omega_1 \ll \omega_0,$$

whereas in the second case

$$I_0 \gg I_1 \text{ so that } \omega_1 \gg \omega_0.$$

The changeability of the moment of inertia under conservation of angular momentum is used extensively in all athletic feats, especially in exercises on the horizontal bar. Consider, for example, the "forward upswing." In the initial act of acquiring swing the body is stretched, its moment of inertia great, and its angular velocity about the bar moderate. As he swings forward, shortly before reaching the highest point, the performer pulls in his legs, reduces his moment of inertia about the bar and

his angular velocity becomes high. His mass center swings over the bar and the performer achieves an upright position on the bar. Notice that the reactions produced by the grasp of the hands on the bar do not influence the angular momentum to any noticeable degree since the bar is so thin that the forces of reaction have a vanishingly small lever arm.

The same principles are used in the "circles," (backward hip circle, knee circle, etc.). Gymnastics, ice skating and skiing are, in a way, practical lessons in experimental and theoretical mechanics.

(5) Mass Balancing of Marine Engines

Let us finally consider an illustration on a large scale, the Schlick method for balancing the reciprocating masses of marine engines.

In the transition period leading to the modern express steamers, toward the end of the last century, the shipbuilding industry went through a crisis. For technical reasons the speed of revolution of the propellor shaft is fixed at approximately 100 per min. The inertial effects of the piston engines, which have to be absorbed by the ship's body, change in this same rhythm. As the length of ships was increased more and more, the "proper frequency" of the vessel was continually depressed, so that this frequency came dangerously near to the rhythm of the inertial effects. Let us anticipate by using the word "resonance," a phenomenon with which we shall deal at great length in the next chapter. The word originated in acoustics, where resonance phenomena are most immediate and where they were studied first.

For lack of space the steam cylinders of fast steamers have to be arranged vertically. Let us assume, to make things specific, that we are dealing with four pistons (cf. Fig. 17), which are all connected to the same crank shaft oriented lengthwise, along the z -direction in our diagram. We shall see that for a smaller number of pistons a mass balance even to first order (to which we shall restrict ourselves here) is impossible. With the choice of coordinates of Fig. 17, the inertial forces are directed along the z -axis; they give rise to moments only about the y -axis. The inertial effects must be absorbed by the reactions of the body of the ship, in which they induce rhythmic countervibrations.

This is beautifully illustrated by the models which Consul Otto Schlick donated to the German Museum in Munich at the time of his invention. The ship's hull is here idealized as an elongated beam; it is suspended by spiral springs which represent the buoyancy of the water and enable the ship to oscillate. When the engine models carried by the beam are set in motion, the beam starts oscillating with slight amplitude. If the speed of revolution of the engines is increased, the vibrations of the beam grow larger the more the rotation frequency approaches the fundamental proper

frequency of the beam (cf. Fig. 18). Great amplitudes of oscillation would have disastrous effects on the safety of the ship—and also on the wellbeing of the passengers. The idea of mass balancing is to bring about a cancellation of the inertial forces and torques of the reciprocating masses of the marine engine in order to protect the ship's body from their harmful effects.

If we pass at once from accelerations to position coordinates, the balancing of the inertial forces, which are all in the x -direction, demands that

$$(15) \quad \sum M_k x_k = 0.$$

The masses M_k include not only those of the pistons and piston rods, but to first approximation also those of the connecting rods and portions of the eccentric parts of the crank shaft.

Just as important is the balancing of the moments of the inertial forces. It is mentioned above and made plausible by Fig. 17 that only the moments about the y -axis play any role here. Again we immediately pass from the accelerations to the position coordinates, which is permissible since the lever arms, i.e., the a of our Fig. 17, are constant. We then require

$$(16) \quad \sum M_k a_k x_k = 0.$$

We now express the piston coordinates x_k in terms of the crank pin

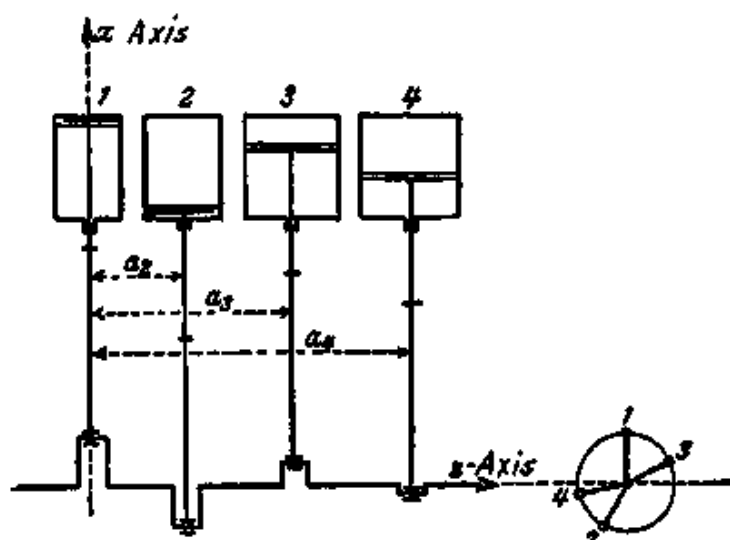

FIG. 17. Schlick mass balance of a vertically arranged four-cylinder piston engine. Diagram at lower right shows the position of the four crank pins relative to each other.

FIG. 18. Proper frequency of a freely vibrating beam as a model for the fundamental frequency of a ship.

coordinates ϕ_k . From Fig. 9 and Eq. (9.6) we have, to a *first approximation*,

$$(17) \quad x_k + r_k \cos \phi_k = \text{const.}$$

First approximation⁴ here means that we pass to the limit of an infinitely long connecting rod, or $r/l \rightarrow 0$. We shall not go into the calculation to second order where the first power of r/l is retained, as in Eqs. (9.5) and (9.6). Since all the pistons work on the same shaft, the ϕ_k are equal to each other apart from a phase shift α_k constant in time;

$$(18) \quad \phi_k = \phi_1 + \alpha_k,$$

where $\alpha_1 = 0$ and $\alpha_2, \alpha_3, \alpha_4$ can be chosen at will. By virtue of (17) and (18), the variable part of the conditions (15) and (16), which alone concerns us, gives

$$(19) \quad \sum M_k r_k \cos(\phi_1 + \alpha_k) = 0, \quad \sum M_k r_k a_k \cos(\phi_1 + \alpha_k) = 0.$$

If we expand the trigonometric functions, we see that with ϕ_1 arbitrary the factors of $\cos \phi_1$ and $\sin \phi_1$ must vanish separately. We then obtain four equations between the parameters α_k and a_k .

$$(20) \quad \begin{aligned} \sum M_k r_k \cos \alpha_k &= 0, & \sum M_k r_k \sin \alpha_k &= 0, \\ \sum M_k r_k a_k \cos \alpha_k &= 0, & \sum M_k r_k a_k \sin \alpha_k &= 0. \end{aligned}$$

The M_k and r_k are fixed by construction. The quantities at our disposal are the three phase displacements $\alpha_2, \alpha_3, \alpha_4$, and the two lever arm ratios $a_3: a_4$ [the absolute magnitudes of the a do not enter in Eq. (20)], altogether therefore five parameters; they allow a certain freedom of choice in fulfilling conditions (20). This freedom in turn makes it possible to avoid solutions which are technically objectionable. The preceding shows that the mass balancing can be carried through to first order in four-cylinder engines; it also shows that for lack of enough parameters it cannot be effected in engines with a smaller number of cylinders, as asserted above. The external characteristic of the Schlick mass balancing method is that the pistons of a four-cylinder engine are not equidistant and that their crank pins are not arranged at equal angles to each other. The latter feature is illustrated in the lower right-hand corner of Fig. 17.

The Schlick method proved its worth in the first modern steamers of the Hamburg-America Line; it eliminated the danger of resonance. It is true, however, that it had only a transient importance in the practices of ship-building, since piston engines were soon to be displaced by turbines, where there are no reciprocating masses. Even nowadays, however, mass balancing is important in automobile and airplane engines as well as in the Diesel engines of submarines.

⁴ This first approximation defines the mass balancing to first order (i.e., the "balancing for primary forces and primary couples," as it is called). Since we want to restrict ourselves to the latter, we need not carry out the second approximation.

(6) General Rule on the Number of Integrations Feasible in a Closed System

A mechanical system is called closed if no external forces, but only internal ones, act on it.⁵ In that case the equations of linear and angular momentum become principles of conservation. The conservation of momentum introduces $2 \cdot 3$ constants, that of angular momentum 3 constants of integration.⁶ The equation of energy yields one additional constant. We therefore have a total number of

$$(21) \qquad 2 \cdot 3 + 3 + 1 = 10$$

integrals of the equations of motion.

So much for the three-dimensional case. In the case of two dimensions, such as the two-body problem of astronomy, we have only one component of angular momentum (directed perpendicular to the plane containing the trajectories of the two bodies), so that we obtain, together with the integral of energy,

$$(22) \qquad 2 \cdot 2 + 1 + 1 = 6$$

generally feasible integrals.

In the one-dimensional case this number evidently reduces to

$$(23) \qquad 2 \cdot 1 + 0 + 1 = 3.$$

The general expression for n dimensions is

$$(24) \qquad n + 1 + \frac{1}{2}n(n+1).$$

The best method of clarifying this expression is to appeal to the concepts of relativity: we put $n=3$ and add the time as the fourth coordinate. We must then form the four-vector momentum which is obtained from Eq. (2.19) by summing over all the particles of the system. The basic equations of relativistic mechanics now tell us that for a closed system this four-vector remains constant; incidentally its time component is, apart from a factor $-ic$ and an additive constant, equal to the kinetic energy. The four integrals thus obtained (conservation of momentum and energy) are represented in (24) by the term $n+1$. The second term of the expression is the result of the combination of two axes at a time in the formation of moments. Evidently the combination of two space axes yields the equations of angular momentum in the ordinary sense. The combination of the time axis with one of the space axes, on the other hand, gives the second

⁵ Every system becomes closed, of course, if one makes it large enough, i.e., if one includes the sources of the external forces in the system.

⁶ The $2 \cdot 3$ constants arising from the equation of the straight line described by the center of mass, and the three areal velocity constants.

integrals of motion of the mass center which express the rectilinearity of this motion. For according to (2.19), if we indicate summation over all mass points by a bar as on p. 70 and replace $(1-\beta^2)^{\frac{1}{2}}$ by unity from the start, we calculate

$$x_k p_k - x_k p_k = ic(\overline{m_k x_k} - t \overline{m_k \dot{x}_k}), \quad k=1, 2, 3.$$

From the principle of conservation of angular momenta this quantity must be equal to a constant, which we may call icA_k . In three-dimensional vector notation and with the symbols of (3a, b) we then have

$$(25) \quad \mathbf{R} - t\mathbf{V} = \mathbf{A}.$$

With \mathbf{A} and \mathbf{V} constant this means that indeed the mass center moves in a straight line with constant speed. The foregoing should be sufficient explanation for the origin of (24); the use of the four-dimensional space-time symmetry has lent additional clarity to it.

We wish finally to make a remark concerning the enumeration of (21) and (22) pertaining to the field of astronomy. The famous three-body problem would need for its complete integration, i.e., for a determination of its $3 \cdot 3$ coordinates and $3 \cdot 3$ components of velocity,

$$(26) \quad 2 \cdot 3 \cdot 3 = 18$$

first integrals. Each of these, as exemplified by Eq. (25), would give one relation between the position and velocity coordinates involving one constant of integration. But a comparison of (26) with (21) shows that we are lacking eight integrals for the complete integration; above and beyond this the unrelenting efforts of the greatest mathematicians from Lagrange to Poincaré have shown that the missing integrals cannot be obtained in algebraic form; a conclusive proof of this was given by H. Bruns.

A similar enumeration for the two-body problem, plane by its very nature, requires only

$$2 \cdot 2 \cdot 2 = 8$$

instead of $2 \cdot 3 \cdot 3 = 18$ constants of integration for its complete integration. Thus only two constants are required beyond those which according to (22) are in all cases available for a two-dimensional problem. As a matter of fact these two integrals with their corresponding arbitrary constants can be found here, as shown by the transition from Eqs. (6.4) to (6.5). Hence the two-body problem can be solved exactly; the three-body problem is in general insoluble, i.e., it can be solved only by analytical approximation methods. It is only under very special assumptions about the type of motion that we shall be able to find a solution in closed form for the latter problem in § 32.

§ 14. The Laws of Friction

As already emphasized in § 11, subsec. 4, the guiding of a mass on a prescribed path introduces a component of reaction along the path direction which cannot be obtained from general principles of mechanics, but must be determined experimentally. Apart from some preliminary work of other investigators this determination was carried out for the first time in 1785 in the famous, and for those times very accurate, experiments of Ch. A. Coulomb, whose name, we recall, is permanently linked with the basic laws of electrostatics and magnetostatics.

With Coulomb we distinguish

- (a) Static friction
- (b) Kinetic or sliding friction.

FIG. 19. Static friction on plane support.

FIG. 20. Construction of the angle of friction and the cone of friction.

(1) Static Friction

Consider a body resting on a horizontal support. If we exert a gradually increasing pull P on the body parallel to the support, no motion will occur at first. We must therefore assume that a force of friction F balances the pull P . If, however, P exceeds a very definite limit, acceleration takes place.

This limit F_{\max} is, according to Coulomb (and his predecessors), proportional to the normal pressure N , which in the case of rest on a horizontal support is simply equal to the weight G of the body. We have

$$(1) \quad F_{\max} = \mu_0 N.$$

μ_0 is the *coefficient of static friction*; it depends on the nature and the state of the surfaces of the two materials in contact. If the two materials are the same, μ_0 is especially great (interpenetration).

By means of

$$(2) \quad \mu_0 = \tan \phi$$

one can introduce an angle ϕ which can be thought of as the vertex angle of a "cone of friction." As long as the resultant of the two forces F and N

falls inside this cone, no motion takes place, cf. Fig. 20. Motion occurs when their resultant lies in the surface of the cone or outside it.

The significance of the angle of friction is illustrated by experiments with the inclined plane (Fig. 21) which go back to Galileo. We write down without further explanation

$$N = G \cos \alpha, \quad P = G \sin \alpha = -F.$$

From

$$F < F_{\max} = \mu_0 N = N \tan \phi$$

we therefore obtain as the condition of rest

$$G \sin \alpha < \tan \phi \cos \alpha \cdot G$$

so that

$$\tan \alpha < \tan \phi$$

or

$$\alpha < \phi.$$

The body remains in a state of rest on the inclined plane as long as $\alpha < \phi$. The angle of friction ϕ is therefore that inclination of a plane at which sliding will set in.

The following is a less trivial example. An oblique arm is attached to a vertical axle at an angle $\frac{\pi}{2} - \alpha$. This arm carries a movable sleeve or bead (cf. Fig. 22). When the axle does not rotate the bead is at rest or in motion depending on whether $\alpha < \phi$ or $\alpha > \phi$. If now the axle is set rotating, the centrifugal force $mr\omega^2$ is added vectorially to the force of gravity mg . The normal force N resulting from these two and the pull P along the guiding rod are, from the diagram,

$$N = m(g \cos \alpha + r\omega^2 \sin \alpha), \quad P = \pm m(g \sin \alpha - r\omega^2 \cos \alpha).$$

The double sign in front of P means that we count the pull positive downward as well as upward, so that we can take into consideration a downward as well as an upward sliding of the bead.

FIG. 21. Equilibrium on an inclined plane.

FIG. 22. Movable sleeve or bead on an oblique rotating rod. Equilibrium under friction.

From (1) and (2) the bead is in equilibrium if

$$\pm(g \sin \alpha - r\omega^2 \cos \alpha) < \tan \phi (g \cos \alpha + r\omega^2 \sin \alpha).$$

We now replace the $<$ sign by an $=$ sign, thereby obtaining the condition for "just sliding," i.e., the limit of equilibrium. By trigonometric transformation we carry out a separate calculation for the two cases \pm .

$$+ \text{ sign, downward sliding: } g \sin (\alpha + \phi) = r_2 \omega^2 \cos (\alpha + \phi),$$

$$- \text{ sign, upward sliding: } g \sin (\alpha - \phi) = r_1 \omega^2 \cos (\alpha - \phi),$$

or, collected together,

$$\left. \begin{matrix} r_1 \\ r_2 \end{matrix} \right\} = \frac{g}{\omega^2} \tan (\alpha \mp \phi).$$

The force of friction hence results in a finite interval

$$r_1 < r < r_2$$

of r in which the bead is in equilibrium.

For $\alpha > \phi$ (the bead slides down as $\omega \rightarrow 0$) both r are positive; the smaller ω , the greater the interval between them. With $\alpha < \phi$ (the bead is in equilibrium under static friction for $\omega \rightarrow 0$) $r_1 = 0$ (even negative according to the equation) and only r_2 is positive; with increasing ω , r_2 approaches zero as well.

(2) Sliding Friction

Here the law of friction

$$(4) \quad F = \mu N$$

applies.

The coefficient of sliding friction μ is roughly independent⁷ of the velocity, and, like μ_0 , a constant depending on the nature of the materials and conditions of the surfaces. It is universally true that

$$(5) \quad \mu < \mu_0.$$

If the path along which the body slides is rectilinear, N equals the force of gravity (or its component perpendicular to the path); if the path is curved, we must, according to Eq. (II.15), add the effect of the centrifugal force.

We illustrate Eq. (5) by means of an extremely primitive experiment which is, however, very surprising in its result. Let us put a smooth cane

⁷ Experience in railroad operation (sliding friction between wheel and brakehoe) indicates that for high velocities v the factor μ decreases monotonically with increasing v .

or walking stick over the forefingers of the right and left hand, held some distance apart. From Fig. 11a the distribution of forces is

$$A = \frac{b}{a+b}G, \quad B = \frac{a}{a+b}G.$$

We now let the two fingers approach each other. Sliding occurs alternately on the right and left fingers, until the fingers meet. Where on the stick do they meet?

Let $A > B$ initially. The sliding therefore begins at B . B remains in motion not only until $a=b$, but slides to the point $b_1 < a$ where the sliding friction of B equals the static friction of A . In general we have

$$F_{B,s} = \mu a \frac{G}{a+b}, \quad F_{A,s} = \mu_0 b \frac{G}{a+b}.$$

Putting these two expressions equal for $b=b_1$, we obtain

$$\mu a = \mu_0 b_1, \quad \frac{a}{b_1} = \frac{\mu_0}{\mu} > 1.$$

At this instant the stick must begin to move over A . At once the friction $F_{A,s}$ falls to $F_{A,s} < F_{A,s}$ so that in b_1 the friction $F_{B,s}$ exceeds that in A ; i.e., B comes to rest, and $F_{B,s}$ changes to $F_{B,s}$.

This process is now repeated at each turning point. A and B thereby approach in geometric progression (since the quotient $\frac{\mu_0}{\mu}$ occurs each time) the center of mass of the stick for which $a=b=0$. In the final state the stick balances in equilibrium over the juxtaposed fingers.

We now return to static friction, which plays a decisive role in pure rolling motion. Paradoxical as it may sound, it is the static friction which drives a railroad train forward. (The same is true of an automobile; a pedestrian on slippery ground likewise propels himself only by means of static friction.) The steam pressure is an internal force, and as such could never set the mass center of the locomotive in motion. To do this an external force is needed. This external force is the reaction between rail and wheel, i.e., just the static friction.

Consider one of the driven wheels of the locomotive (Fig. 23). By means of the connecting rod the engine transmits a torque L to the wheel; its primary action would be to impart a rotational acceleration to the

FIG. 23. Reaction between wheel and rail in a locomotive. For the case of pure rolling the static friction provides the driving force of the train.

wheel. This is incompatible with the condition of pure rolling, Eq. (11.10),

$$(6) \quad \dot{z} = r\omega.$$

Let M be the mass of the train per actuated wheel, R the resistance to motion (air resistance, frictional losses in the axle bearings, etc.), I the moment of inertia of the wheel, and F the force of static friction. The equations of motion become

$$(7) \quad \begin{aligned} M\ddot{z} &= F - R; \\ I\ddot{\phi} &= L - Fr. \end{aligned}$$

The static friction F cannot be determined *a priori*; it can, however, be obtained from the foregoing equations as follows. Let us at first eliminate F from the equations

$$(8) \quad \begin{aligned} M\ddot{z} &= F - R; \\ M_{\text{red}}\ddot{z} &= P - F. \end{aligned}$$

equivalent to (7). P is the peripheral force corresponding to the torque L , and M_{red} , as in (11.8), is the reduced mass corresponding to the moment of inertia I , i.e.,

$$L = Pr, \quad I = M_{\text{red}}r^2.$$

From (8) one obtains

$$(9) \quad (M + M_{\text{red}})\ddot{z} = P - R$$

and, by virtue of the first Eq. (8),

$$(10) \quad F = R + \frac{M}{M + M_{\text{red}}}(P - R) = \frac{MP + M_{\text{red}}R}{M + M_{\text{red}}}.$$

D'Alembert's principle could have furnished equation (9) directly. The first Eq. (8) contains the quantitative proof of our assertion that the static friction F is the driving force in the operation of a train. For in the case of uniform motion it gives

$$R = F.$$

As the second Eq. (8) shows, the peripheral force P resulting from the steam pressure has merely the function of calling into play the static friction at the rails.

Another evidence of this is the fact that as trains have become faster or the freight per train greater, locomotives have become constantly heavier. This circumstance points directly to Coulomb's law of friction, Eq. (1), which states that the limit of static friction available is proportional to

the normal pressure N . The well-known fact that static friction fails and sliding occurs when the rails are too smooth (due to ice, or, for instance, to lubrication from run-over migrating caterpillars) points to the other factor μ_0 in Eq. (1), which, as emphasized, depends on the state of the surface of the rails. When the rails are too smooth, the factor μ_0 must be artificially increased; the sander serves this end.

CHAPTER III

OSCILLATION PROBLEMS

The investigations that are to follow will teach us nothing new about the principles of mechanics. So great, however, is the significance of oscillation processes for physics and engineering that their separate systematic treatment is deemed essential.

§ 15. The Simple Pendulum

The oscillating body is a particle of mass m which is attached to a fixed point O by means of a weightless rigid rod of length l ; l is called the length of the pendulum. We may neglect friction at the point of suspension and air resistance, so that the only force acting is that of gravity, with a component $-mg \sin \phi$ in the direction of increasing ϕ (cf. Fig. 24). The general equation (11.14) for the guided motion along an arbitrary path gives us, with $v = l\dot{\phi}$ (circular path), the exact equation

$$(1) \quad ml \frac{d^2\phi}{dt^2} = -mg \sin \phi.$$

For sufficiently small oscillations, $\phi \ll 1$, we can put $\sin \phi = \phi$. With the abbreviation

$$(2) \quad \frac{g}{l} = \omega^2$$

we then obtain the linear pendulum equation

$$(3) \quad \frac{d^2\phi}{dt^2} + \omega^2\phi = 0.$$

This is the differential equation of "harmonic oscillations" as treated in § 3 (4). Apart from the designation for the dependent variable it is identical with Eq. (3.23). The circular frequency ω defined in (3.22) is now given by Eq. (2) above. We therefore have

$$(4) \quad \omega = \frac{2\pi}{T} = \left(\frac{g}{l}\right)^{\frac{1}{2}}, \quad T = 2\pi \left(\frac{l}{g}\right)^{\frac{1}{2}}.$$

FIG. 24. Simple pendulum. Component of gravity along the direction of motion.

Notice that T is independent of the mass m , which dropped out already in (1). Thus different masses have the same period if the pendulum length l is the same. T is the full period, covering a complete swing to and fro. Sometimes one half of this time is designated as the period of oscillation. Thus one speaks of a "seconds pendulum" for which $\frac{1}{2}T$ equals one second. Its length is calculated from (4) to be

$$l = \frac{g}{\pi^2} \cong 1 \text{ meter.}$$

To the extent to which Eq. (3) is valid the period of oscillation is independent also of the amplitude of swing; i.e., small pendulum oscillations are *isochronous*.

The general solution of (3) has the form

$$\phi = a \sin \omega t + b \cos \omega t.$$

If we specify that $\phi = 0$ at $t = 0$ and $\phi = \alpha$ at $t = \frac{T}{4}$, we must put $b = 0$ and $a = \alpha$, so that

$$(5) \quad \phi = \alpha \sin \omega t.$$

α is therefore the amplitude of ϕ , i.e., the maximum displacement of the particle measured in units of angle (radians).

For finite deflections the isochronism is destroyed because of the non-linearity of Eq. (1) which applies in that case. In order to integrate (1) we multiply it on the left and right by $\frac{d\phi}{dt}$; this amounts to passing from the equation of motion to the equation of energy. An integration yields

$$(6) \quad \left(\frac{d\phi}{dt}\right)^2 = 2\omega^2 \cos \phi + C.$$

C is determined by the condition that $\frac{d\phi}{dt} = 0$ for $\phi = \alpha$, i.e.,

$$C = -2\omega^2 \cos \alpha.$$

Alternately we can proceed directly from the equation of energy. With the meaning of H indicated in Fig. 24 we obtain

$$(6a) \quad \frac{m}{2} l^2 \left(\frac{d\phi}{dt}\right)^2 + mgh = mgH$$

where $\begin{cases} h = l(1 - \cos \phi) \\ H = l(1 - \cos \alpha), \end{cases}$

which is evidently identical to (6).

Consider now the equality

$$\cos \phi - \cos \alpha = 2 \left(\sin^2 \frac{\alpha}{2} - \sin^2 \frac{\phi}{2} \right);$$

we substitute it in (6) to obtain

$$(7) \quad \frac{d\left(\frac{\phi}{2}\right)}{\left(\sin^2 \frac{\alpha}{2} - \sin^2 \frac{\phi}{2}\right)^{\frac{1}{2}}} = \omega dt$$

or

$$(8) \quad \int_0^{\frac{\phi}{2}} \frac{d\left(\frac{\phi}{2}\right)}{\left(\sin^2 \frac{\alpha}{2} - \sin^2 \frac{\phi}{2}\right)^{\frac{1}{2}}} = \omega t.$$

We have thus arrived at an *elliptic integral of the first kind*. In order to explain this name we shall have to speak in passing of the "rectification of the ellipse," i.e., the measurement of the length of an arc of an ellipse. Let us use the parametric form of the equation of an ellipse,

$$x = a \sin v$$

$$y = b \cos v$$

from which we calculate

$$ds^2 = dx^2 + dy^2 = (a^2 \cos^2 v + b^2 \sin^2 v) dv^2,$$

$$ds = [a^2 - (a^2 - b^2) \sin^2 v]^{\frac{1}{2}} dv.$$

We now put

$$k^2 = + \frac{a^2 - b^2}{a^2} \quad (< 1 \text{ for } a > b),$$

and obtain for the length of the arc of the ellipse between the endpoint $v=0$ of the minor axis and an arbitrary point v of the ellipse

$$(9) \quad s = a \int_0^v (1 - k^2 \sin^2 v)^{\frac{1}{2}} dv.$$

This is an "elliptic integral of the second kind."

The elliptic integral of the first kind is the simpler of the two from the viewpoint of function theory. In the "Legendre standard form" it is

$$\int_0^v \frac{dv}{(1 - k^2 \sin^2 v)^{\frac{1}{2}}}.$$

We shall put our integral (8) in this form by means of the transformation

$$\sin \frac{\phi}{2} = \sin \frac{\alpha}{2} \cdot \sin v.$$

$$(10) \quad \left(\sin^2 \frac{\alpha}{2} - \sin^2 \frac{\phi}{2} \right)^{\frac{1}{2}} = \sin \frac{\alpha}{2} \cos v,$$

$$\frac{d\frac{\phi}{2}}{\left(\sin^2 \frac{\alpha}{2} - \sin^2 \frac{\phi}{2} \right)^{\frac{1}{2}}} = \frac{dv}{\cos \frac{\phi}{2}} = \frac{dv}{(1 - k^2 \sin^2 v)^{\frac{1}{2}}},$$

where the "modulus" k stands for

$$(11) \quad k = \sin \frac{1}{2} \alpha.$$

If we wish to calculate the period T , we must put in Eq. (8)

$$t = \frac{T}{4} \quad \text{and} \quad \phi = \alpha,$$

so that, according to (10), $v = \frac{\pi}{2}$. This yields the so-called "complete integral of the first kind," which is designated by the letter K ,

$$(12) \quad K = \int_0^{\frac{\pi}{2}} \frac{dv}{(1 - k^2 \sin^2 v)^{\frac{1}{2}}}.$$

ω being defined by (2), we then obtain from (8) the period

$$(13) \quad T = 4K \left(\frac{l}{g} \right)^{\frac{1}{2}}.$$

From (12) we can read off directly that

$K = \frac{\pi}{2}$ as $k \rightarrow 0$, i.e., according to (11), for sufficiently small amplitudes α ;
 $K = \infty$ as $k \rightarrow 1$, i.e., according to (11), for $\alpha = \pi$, 180° swing to upright position.

In the first case we obtain our former expression (4), as would be expected. In the latter case the deviation from this expression reaches an extreme.

In general a binomial expansion and term-by-term integration of (12) leads to

$$K = \frac{\pi}{2} \left(1 + \frac{k^2}{4} + \frac{9k^4}{64} + \dots \right).$$

The corresponding expression for T is

$$(14) \quad T = 2\pi \left(\frac{l}{g} \right)^{\frac{1}{2}} \left(1 + \frac{1}{4} \sin^2 \frac{\alpha}{2} + \frac{9}{64} \sin^4 \frac{\alpha}{2} + \dots \right),$$

which gives the deviation from isochronism for finite deflections in quantitative fashion.

Astronomical clocks have simply-constructed pendulums with $\alpha \leq 1\frac{1}{2}^\circ$. For them the first correction term in the parenthesis of (14) amounts to approximately 1 part in 20,000.

§ 16. The Compound Pendulum

This problem is essentially that of rotation of a rigid body about a fixed axis, treated already in § 11, subsec. 1, from which it differs only in that the external forces are now specified to be gravitational. Let s be the distance of the center of gravity G from the fixed axis O [we use the term "center of gravity" deliberately here, though, from (3.12), it coincides with the center of mass]; moreover, let ϕ be the angle which the line OG makes with the vertical. The total moment L of the gravitational forces acting on the individual elements of mass dm is evidently

$$(1) \quad L = -mgs \sin \phi,$$

where m is the total mass; from (11.4) the equation of motion is then

$$(2) \quad I\ddot{\phi} = -mgs \sin \phi.$$

A comparison with the equation of motion (15.1) of the simple pendulum shows that the length l of the equivalent simple pendulum, i.e., the simple pendulum having the same period of oscillation as our compound one, is

$$(3) \quad l = \frac{I}{ms}.$$

Let us replace I by the so-called *radius of gyration* a , defined by

$$(4) \quad I = ma^2.$$

The radius of gyration is therefore that distance from the point of suspension O of the pendulum at which we must concentrate the total mass m in order to obtain the moment of inertia I of the actual mass distribution. Note: in (11.8) we introduced a "reduced mass" for the distance r at which the initially unknown mass M_{red} was to be placed; here, *per contra*, the mass m is given and we are looking for the distance a at which this mass is to be located.

Comparison of (3) and (4) shows that a is the geometric mean of s and l ,

$$(5) \quad a^2 = ls.$$

Let us now lay off the equivalent pendulum length l from O along the center line OG of the pendulum. The point P thus obtained is called the *center of oscillation* (Huygens). Fig. 25 shows the relative positions of O , G and P and allows us to form a picture of the relation between s , a and l .

FIG. 25. Point of suspension O , center of gravity G , and center of oscillation P of a compound pendulum. The radius of gyration a is the geometric mean of the equivalent pendulum length l and distance from center of gravity s .

We now claim that the roles of O and P are interchangeable. So far O has been our point of suspension, P the center of oscillation. We shall now take P as the point of suspension and show that O becomes the center of oscillation. This is the idea underlying the *reversible pendulum*.

The scheme below tabulates the symbols so far used and completes the list for purposes of what is to follow.

Point of Suspension	Center of Oscillation	Equivalent Pend. Length	Moment of Inertia	Radius of Gyration	Distance of Mass Center
O	P	l	I	a	s
P	O'	l_P	I_P	a_P	$l-s$

Our assertion is that

$$l_P = l, \text{ i.e., } O' = O.$$

Proof: let us calculate l_P from equations (3) and (4) rewritten in terms of the corresponding new symbols. We have

$$(6) \quad l_P = \frac{I_P}{m(l-s)} = \frac{a_P^2}{l-s}.$$

Now according to Eq. (10) of the supplement to this section

$$(6a) \quad a_P^2 = l(l-s)$$

so that indeed the last member of (6) equals l .

The pendulum is used in the determination of the gravitational acceleration g at different points on or below the surface of the earth. Since in practice no simple pendulum is available and since in a compound pendulum the moment of inertia I cannot be calculated accurately (not only because of the complicated shape of the bob, but also because of possible internal inhomogeneities), one is forced to resort to the experimental method of the reversible pendulum for the determination of the equivalent pendulum length. We have to imagine that the pendulum of Fig. 25 is provided with two knife-edges for its points of support, one at O and one at P , the latter with its edge facing up, and both with their triangular cross-sections in the plane of the drawing. The knife-edge at P can be moved up and down by means of a micrometer screw. Given a sufficiently long period of observation the number of oscillations can be counted with very great accuracy, so that the equality or inequality of the periodic times for oscillations about O and P can be determined exceedingly precisely, and, if necessary, corrected by means of the micrometer screw.

The principle of the reversible pendulum is a first illustration of a type of very general reciprocity relation which recurs in all branches of physics.

Another example of such a relation is the interchangeability of source point and field point ("Aufpunkt") in acoustics and electrodynamics.

SUPPLEMENT: A RULE CONCERNING MOMENTS OF INERTIA

We have in mind the rule of parallel axes, which states that the moment of inertia of a body of mass m about an axis through an arbitrary point O is equal to the sum of its moment of inertia about the parallel axis through the center of mass G and ms^2 , where s is the distance between G and the axis through O .

If y is the direction of the axis in question and x the direction from O to G , the distance r from the axis through O of some element of mass dm must be

$$r^2 = x^2 + z^2.$$

Here x is measured from O . If, instead, x is measured from G , and if, as in Fig. 25, $OG=s$, we have

$$r^2 = (x+s)^2 + z^2 = x^2 + z^2 + 2xs + s^2.$$

If we sum over all dm , it follows that

$$(7) \quad I = I_G + 2s \int x dm + ms^2.$$

The middle term vanishes [cf., for instance, Eq. (13.3b)] provided the plane $x=0$ passes through the center of mass. If this is the case,

$$(8) \quad I = I_G + ms^2,$$

as asserted above.

Accordingly we have from Fig. 25 that

$$(8a) \quad I_P = I_G + m(l-s)^2.$$

But from (8) and (8a)

$$I_P - I = ml^2 - 2m ls$$

which, in view of (4), can be written

$$(9) \quad a_P^2 - a^2 = l^2 - 2ls$$

or, by virtue of (5),

$$(10) \quad a_P^2 = l^2 - ls = l(l-s).$$

This is the relation that was used in (6a).

§ 17. The Cycloidal Pendulum

This pendulum was invented by Christian Huygens¹, the most ingenious watchmaker of all time. Its purpose is to eliminate the lack of isochronism of the ordinary simple pendulum. This is achieved by making the mass point move on a cycloidal instead of a circular arc. Later on we shall see how this motion can be realized in practice.

The parametric representation of a common cycloid is

$$(1) \quad \begin{aligned} x &= a(\phi - \sin \phi), \\ y &= a(1 - \cos \phi). \end{aligned}$$

The parameter ϕ is the angle through which a wheel of radius a rolling on the horizontal x -axis has turned from its initial position. The common cycloid is generated by a point on the periphery of the wheel (Fig. 26).

FIG. 26. Generation of common cycloid by point on the periphery of a rolling wheel. Definition of angle of rotation ϕ .

For our pendulum we need a cycloid that has its cusps at the top rather than on the bottom (cf. Fig. 27 on p. 96); this is generated by having our wheel roll on the underside of the x -axis. The x of such a curve is that given in (1) while its y is obtained by subtracting the y given in (1) from $2a$,

$$(2) \quad \begin{aligned} x &= a(\phi - \sin \phi), \\ y &= a(1 + \cos \phi). \end{aligned}$$

The component of gravity mg along the tangent of the trajectory (in our case the cycloid) is

$$F_s = -mg \cos(y, s) = -mg \frac{dy}{ds}.$$

The general relation (11.14) therefore yields

$$(3) \quad m\dot{v} = -mg \frac{dy}{ds},$$

where, just as in the case of the circular pendulum, the mass m cancels on

¹ *Horologium Oscillatorium*, Paris (1673). Collected Works, Vol. 18, The Hague (1934).

the left and right. Differentiation of (2) gives

$$\begin{aligned} dx &= a(1 - \cos \phi) d\phi, & dy &= -a \sin \phi d\phi. \\ ds^2 &= a^2(2 - 2 \cos \phi) d\phi^2, & ds &= 2a \sin \frac{\phi}{2} d\phi. \end{aligned}$$

Thus in our case

$$(4) \quad v = \frac{ds}{dt} = 2a \sin \frac{\phi}{2} \frac{d\phi}{dt} = -4a \frac{d}{dt} \cos \frac{\phi}{2}$$

and

$$(5) \quad \frac{dy}{ds} = -\frac{1}{2} \frac{\sin \phi}{\sin \phi/2} = -\cos \frac{\phi}{2}.$$

If we replace (4) and (5) in (3), we obtain

$$(6) \quad \frac{d^2}{dt^2} \cos \frac{\phi}{2} = -\frac{g}{4a} \cos \frac{\phi}{2}.$$

This equation differs from Eq. (15.3) of the simple pendulum only in that the dependent variable is now called $\cos \frac{\phi}{2}$ rather than ϕ . This is of course of no consequence for the integration of (6). The earlier Eq. (15.4) therefore holds unchanged, viz.

$$(7) \quad T = 2\pi \left(\frac{l}{g} \right)^{\frac{1}{2}} \text{ with } l = 4a,$$

the latter because in (6) $4a$ took the place of our former l .

Eq. (15.3) described only the small displacements of a simple pendulum and was obtained from the exact relation (15.1) by an approximation; our present equation (6) and Eq. (7) resulting from an integration thereof are, on the other hand, exact for oscillations of arbitrary amplitude. The cycloidal pendulum is then rigorously isochronous; its periodic time is completely independent of the amplitude of oscillation.²

As regards the method used, we notice that in (6) the motion of our particle was represented not by its Cartesian coordinates or by some parameter bearing an immediate relation to the cycloidal curve, but by one half the angle of rotation ϕ of the wheel generating the cycloid. We see that

² The cycloid can also be called *tautochrone* (oscillations on a cycloid are "isochronous to each other"); it is also called *brachistochrone* (because it answers the question, "on what curve must a mass acted on by constant gravitational force slide in order to traverse the distance between two given endpoints in the least possible time?"). It turns out that the mass takes less time on a cycloid than on a straight line or any other curve joining the same points). The brachistochrone problem is all the more notable because it was for it that the first principles of the Calculus of Variations were developed.

this parameter, although only indirectly connected with the cycloid, provides the simplest method of approach to the problem. Its introduction gives us a foretaste of the general Lagrange method of Chapter VI, which enables us to introduce arbitrary parameters as dependent variables in the equations of motion.

Just as remarkable as Huygens' discovery of the isochronism of the cycloidal pendulum is the way in which he actually achieved the frictionless motion of the bob on the cycloid. He availed himself of the rule that the evolute of a cycloid is another cycloid equal to the generating one. If, therefore, we tie a string of length $l=4a$ to the point O of Fig. 27 in which the two upper cycloid arcs form a cusp, and if this string be pulled taut so that it rests against the right part of the cycloid (or the left part if deflected to the left), the endpoint P of the string describes the lower cycloidal arc. The guiding of the bob along the lower cycloid effected in this manner is almost as frictionless as the guiding of the simple pendulum along a circular arc.

Actually Huygens' idea has been abandoned in the practice of pendulum clock construction; according to investigations of Bessel among others it is sufficient to install a spring — usually a short elastic lamina — at the upper end of the pendulum. If the length of the lamina and the mass of the bob are suitably chosen, a sufficient degree of isochronism is achieved.

FIG. 27. Huygens' isochronous cycloidal pendulum.

§ 18. The Spherical Pendulum

We require the pendulum to be suspended in such a fashion that the mass point m is able to move freely on the surface of a sphere of radius l (the length of the pendulum). It is then subject to the condition of constraint

$$(1) \quad F = \frac{1}{2}(x^2 + y^2 + z^2 - l^2) = 0,$$

where the factor $\frac{1}{2}$ has been added for convenience's sake.

Here r , the number of conditions of constraint, equals 1, and $X_1 = X_2 = 0$, $X_3 = -mg$, so that the Lagrange equations of the first kind (12.9) take the form

$$(2) \quad \begin{aligned} m\ddot{x} &= \lambda x, \\ m\ddot{y} &= \lambda y, \\ m\ddot{z} &= -mg + \lambda z. \end{aligned}$$

In view of Eqs. (13.13) and (13.13a), elimination of λ from the first two equations (2) yields the constancy of angular momentum about the z -axis, or, what amounts to the same thing, the conservation of the areal velocity

$$(3) \quad x \frac{dy}{dt} - y \frac{dx}{dt} = 2 \frac{dS}{dt} = C \quad (S = \text{area swept out}).$$

If, on the other hand, we multiply the Lagrange equations (2) by \dot{x} , \dot{y} , \dot{z} , we obtain the equation of energy, for condition (1) is independent of t (cf. p. 68). Addition yields

$$(4) \quad m(\dot{x}\ddot{x} + \dot{y}\ddot{y} + \dot{z}\ddot{z}) = -mg\dot{z} + \lambda(x\dot{x} + y\dot{y} + z\dot{z}).$$

But from (1)

$$\frac{dF}{dt} = x\dot{x} + y\dot{y} + z\dot{z} = 0.$$

On the other hand we evidently have

$$\dot{x}\ddot{x} + \dot{y}\ddot{y} + \dot{z}\ddot{z} = \frac{1}{2} \frac{d}{dt} (\dot{x}^2 + \dot{y}^2 + \dot{z}^2) = \frac{1}{2} \frac{dv^2}{dt}.$$

Integration of (4) with respect to t then gives

$$(5) \quad \frac{m}{2} v^2 = -mgz + \text{const.},$$

which we shall write in the form

$$(5a) \quad T + V = E \quad \text{with} \quad V = mgz.$$

Let us finally multiply the Lagrange equations by x , y , z , respectively. With the aid of (1) this allows us to calculate λ ,

$$\lambda^2 - mgz = m(x\ddot{x} + y\ddot{y} + z\ddot{z})$$

or

$$(6) \quad \lambda = mg \frac{z}{l} + m \left(\frac{x}{l} \ddot{x} + \frac{y}{l} \ddot{y} + \frac{z}{l} \ddot{z} \right).$$

Now the normal to the surface of the sphere at the point x, y, z has direction cosines $\frac{x}{l}, \frac{y}{l}, \frac{z}{l}$, so that apart from sign the second term on the right is the inertial force F_n^* normal to the spherical surface; similarly the first term on the right is, apart from sign, the component F_n of gravity in the same direction. According to d'Alembert the sum of these two must be equilibrated by the reaction R_n of the surface of the sphere, or, physically speaking, by the tension in the pendulum suspension. The meaning of Eq. (6) can hence be summed concisely by the equation

$$(7) \quad \lambda = -(F_n + F_n^*) = R_n.$$

We notice that within a factor l , λ is the constraint which is exerted on the motion by virtue of condition (1), this constraint acting in a direction normal to the motion. Corresponding statements hold in more general cases where several conditions of constraint and therefore several Lagrange multipliers are present.

In order to carry out a second integration of (5) we shall pass to spherical coordinates given by

$$\begin{aligned}x &= l \cos \phi \sin \theta \\y &= l \sin \phi \sin \theta \\z &= l \cos \theta.\end{aligned}$$

We form

$$\begin{aligned}\dot{x} &= l \dot{\theta} \cos \phi \cos \theta - l \dot{\phi} \sin \phi \sin \theta, \\ \dot{y} &= l \dot{\theta} \sin \phi \cos \theta + l \dot{\phi} \cos \phi \sin \theta, \\ \dot{z} &= -l \dot{\theta} \sin \theta.\end{aligned}$$

The equation of conservation of angular momentum (3) becomes

$$(8) \quad 2 \frac{dS}{dt} = x\dot{y} - y\dot{x} = l^2 \sin^2 \theta \cdot \dot{\phi} = C$$

and the equation of energy (5a),

$$(9) \quad \frac{ml^2}{2} (\dot{\theta}^2 + \sin^2 \theta \dot{\phi}^2) + mgl \cos \theta = E.$$

A further change of variables

$$u = \cos \theta, \quad \dot{\theta} = -\frac{1}{(1-u^2)^{1/2}} \frac{du}{dt}$$

transforms (8) into

$$(10) \quad \dot{\phi} = \frac{C}{l^2(1-u^2)}$$

and (9) into

$$(11) \quad \left(\frac{du}{dt}\right)^2 = U(u) = \frac{2}{ml^2} (E - mgl u) (1 - u^2) - \frac{C^2}{l^4}.$$

This relation between t and u allows us to find t as a function of u ,

$$(12) \quad t = \int \frac{du}{U^{1/2}}.$$

Eq. (10) can now likewise be written in integrated form, for from (10) and (11)

$$\frac{d\phi}{du} = \dot{\phi} \cdot \frac{dt}{du} = \frac{C}{l^2(1-u^2)} \frac{1}{U^{1/2}},$$

FIG. 28. Spherical pendulum treated as mass point m moving under gravity on the surface of a sphere of radius l .

so that one obtains

$$(13) \quad \phi = \frac{C}{I^2} \int \frac{du}{1-u^2} \cdot \frac{1}{U^{\frac{1}{2}}}.$$

U is a function of third degree in $u = \cos \theta$. $U^{\frac{1}{2}}$ is real only for $U > 0$. If then the constants of the equation correspond to a real physical problem, there must be two values $u = u_2 < u = u_1$ in the interval

$$-1 < u < +1$$

between which U is positive (cf. Fig. 29).

$u_1 = \cos \theta_1$ and $u_2 = \cos \theta_2$ are the two latitudes between which the mass point oscillates back and forth. If the integration of (12) or (13) reaches one of these limits of u , not only the direction of integration but also $U^{\frac{1}{2}}$ must change sign, in order that the integrals remain real and positive. Between two successive turning points one quarter of the full period of oscillation elapses, i.e.,

$$(14) \quad \frac{T}{4} = \int_{u_2}^{u_1} \frac{du}{U^{\frac{1}{2}}}.$$

FIG. 29. Curve of third degree $U(u)$ and its intersections $u = u_1$ and $u = u_2$ with the abscissa. $u_2 < u_1 < 0$ means that the trajectory is located in the lower hemisphere.

FIG. 30. "Bird's-eye" view of the path of the spherical pendulum. Angle of precession $\Delta\phi$. A passage from θ_1 over θ_2 back to θ_1 corresponds to a half-period, $\Delta\phi$ therefore to a full cycle.

Note that now the oscillation is no longer periodic in space as in the case of the pendulum moving in a plane, but is modified by a slow *precession*. The angle of precession $\Delta\phi$ by which the mass advances (or recedes) in a full period T is calculated from (13) to be

$$(15) \quad 2\pi + \Delta\phi = \frac{4C}{I^2} \int_{u_2}^{u_1} \frac{du}{(1-u^2)U^{\frac{1}{2}}}.$$

This precession is illustrated in Fig. 30, which is taken from A. G. Webster, "Dynamics of Particles," Leipzig, Teubner (1912), p. 51.

The integral (12) is an elliptic integral of the first kind, just like the integral (15.8) for the simple pendulum. This is the generic name applied to all integrals whose integrand contains the square root of a polynomial of the third or fourth degree in the variable of integration in the denominator. That Eq. (15.8) falls in this class can be seen by introducing the transformation $u = \sin \frac{\phi}{2}$, so that u becomes our variable of integration; if, moreover, we put $a = \sin \frac{\alpha}{2}$, (15.8) goes over into

$$\int \frac{du}{[(a^2 - u^2)(1 - u^2)]^{\frac{1}{2}}}$$

In particular, expression (14) for T is, just like (15.12), a complete integral of the first kind. On the other hand, integral (13), which has the two factors $(1 \pm u)$ in addition to $U^{\frac{1}{2}}$ in the denominator, is an "elliptic integral of the third kind," and (15) is a "complete elliptic integral of the third kind."

Problem III.1 shows that for infinitesimal oscillations the equation expressing the motion of the spherical pendulum becomes elementary and the angle of precession $\Delta\phi \rightarrow 0$.

§ 19. Various Types of Oscillations

Free and Forced, Damped and Undamped Oscillations

Free, undamped oscillations were treated in § 3, subsec. 4; we called them harmonic oscillations. At this point we shall consider, first of all,

Undamped, Forced Oscillations

We shall take as their differential equation

$$(1) \quad m\ddot{x} + kx = c \sin \omega t,$$

where $\omega = \frac{2\pi}{T}$ is the circular frequency of the driving force.

We have here made the differential equation linear in the dependent variable x , which is permissible, at any rate, for small oscillations (cf. simple pendulum). The same remark applies to the remaining examples in this and the following section.

The restoring force is $-kx$ as in (3.19); c of Eq. (1) is the amplitude of the driving force causing our particle to oscillate.

By virtue of the addition of the right member, (1) is an inhomogeneous linear differential equation. The left side, when set equal to zero, gives the associated homogeneous differential equation, as previously mentioned in connection with Eq. (3.23).

A particular solution of the inhomogeneous differential equation is given by

$$x = C \sin \omega t,$$

where C must satisfy the equation

$$C(k - m\omega^2) = c.$$

If, with (3.20) as model, we put

$$(2) \quad \omega_0 = \left(\frac{k}{m}\right)^{\frac{1}{2}},$$

we obtain

$$(3) \quad C = \frac{c/m}{\omega_0^2 - \omega^2}.$$

The general solution of (1) is formed from this particular solution and the general solution of the associated homogeneous equation:

$$(4) \quad x = C \sin \omega t + A \cos \omega_0 t + B \sin \omega_0 t.$$

The amplitude C of the first term grows with increasing ω to become infinite for $\omega = \omega_0$; thereupon it jumps to negative infinity, and decreases slowly in absolute value toward 0 as $\omega \rightarrow \infty$.

Actually, when C becomes negative the amplitude does not change sign, for amplitudes are positive by definition. We therefore continue to define the amplitude by $|C|$ and put the change of sign that takes place into the sine factor, where it appears as a phase change of $\delta = \pm\pi$.

The foregoing is illustrated in Figs. 31a, b, where $|C|$ and δ have been plotted as functions of ω .

In Fig. 31b we cannot *a priori* decide whether the phase leads or lags for $\omega > \omega_0$, i.e., whether we are to take $\delta = +\pi$ or $\delta = -\pi$. We shall, however, anticipate and consider undamped vibrations as a limiting case of damped vibrations (see below); this leads us to decide in favor of $-\pi$, so that the first term of (4) can be written in detail

$$(4a) \quad x = \frac{c/m}{\omega^2 - \omega_0^2} \sin(\omega t - \pi) \quad (\omega > \omega_0).$$

FIG. 31. Amplitude and phase of undamped forced oscillations.

The fact that the amplitude becomes infinite for $\omega = \omega_0$ illustrates the phenomenon of *resonance* between free and forced oscillations, a phenomenon that plays an important role in all of physics. The denominator of (3) and (4a) whose vanishing causes this infinite amplitude is called a "resonance denominator." It is intuitively clear that the closer the proper frequency of the oscillating system is to that of the driving force, the better the system will follow this force.

Incidentally we must keep in mind that we are guilty of gross extrapolation when we deduce infinite amplitudes at resonance, for in almost all cases our linear differential equation holds only for infinitesimal oscillations.

So far we have directed all our attention to the first term of the right member of Eq. (4). The other two terms are determined by the initial conditions. Let us take

$$x=0, \dot{x}=0 \text{ at } t=0,$$

so that, from (4),

$$A=0, \omega C + \omega_0 B = 0, \text{ hence } B = -\frac{\omega}{\omega_0} C.$$

It follows that

$$(5) \quad x = C \left(\sin \omega t - \frac{\omega}{\omega_0} \sin \omega_0 t \right).$$

Let us make the content of this equation clearer by considering the special case of near resonance of the two frequencies ω and ω_0 .

We put

$$\omega = \omega_0 + \Delta\omega$$

and expand

$$\sin \omega t - \frac{\omega}{\omega_0} \sin \omega_0 t = \sin \omega_0 t + t \Delta\omega \cos \omega_0 t - \sin \omega_0 t - \frac{\Delta\omega}{\omega_0} \sin \omega_0 t.$$

Eq. (5) then yields

$$x = C \Delta\omega \left(t \cos \omega_0 t - \frac{1}{\omega_0} \sin \omega_0 t \right).$$

and, by virtue of (3), in the limit $\Delta\omega=0$,

$$(6) \quad x = \frac{0}{2m\omega_0^3} (\sin \omega_0 t - \omega_0 t \cos \omega_0 t).$$

This type of oscillation, illustrated in Fig. 32, is no longer periodic as was that of free oscillations; indeed t appears in (6) as a secular term (i.e., no longer solely in the argument of a trigonometric function). For

$t \rightarrow \infty$ the amplitude approaches the value $C = \infty$ as indicated in Fig. 31 for the case $\omega = \omega_0$.

FIG. 32. Resonance of free and forced oscillations. Secular increase of amplitude.

Free, Damped Oscillations

These have the differential equation

$$(7) \quad m\ddot{x} + kx = -w\dot{x}.$$

The frictional term on the right has been put proportional to the velocity, an assumption which finds its justification in the hydrodynamics of slow, laminar (=non-turbulent) flow (e.g., air friction).

Eq. (7) is a homogeneous linear differential equation. As before we put

$$(7a) \quad \frac{k}{m} = \omega_0^2, \quad \omega_0 = \text{undamped proper frequency.}$$

Let us also make the convenient change of symbols

$$(7b) \quad \frac{w}{m} = 2\rho, \quad \rho > 0.$$

Eq. (7) then takes the form

$$(8) \quad \ddot{x} + 2\rho\dot{x} + \omega_0^2 x = 0.$$

The method described under Eq. (3.23) now proves its full worth. As there, we substitute

$$(8a) \quad x = Ce^{\lambda t}$$

in (8) and thus obtain the *characteristic equation* in λ ,

$$\lambda^2 + 2\rho\lambda + \omega_0^2 = 0$$

with the two roots

$$\lambda = -\rho \pm (-\omega_0^2 + \rho^2)^{\frac{1}{2}} = \begin{cases} \lambda_1 \\ \lambda_2 \end{cases}.$$

Expression (8a) must therefore be generalized to

$$(8b) \quad x = C_1 e^{\lambda_1 t} + C_2 e^{\lambda_2 t}.$$

We now distinguish two cases:

$$1. \quad \rho < \omega_0, \quad 2. \quad \rho > \omega_0.$$

The first case is that usually prevailing in practice. The motion is a periodic oscillation with decaying amplitude. The second case is that of strong or "aperiodic" damping. In both cases we shall specialize the motion by imposing the condition, $x=0$ at $t=0$, which, according to (8b), leads to $C_2 = -C_1$.

$$1. \quad \rho < \omega_0. \quad \lambda = -\rho \pm i(\omega_0^2 - \rho^2)^{\frac{1}{2}},$$

$$x = 2C_1' e^{-\rho t} \sin (\omega_0^2 - \rho^2)^{\frac{1}{2}} t.$$

For small ρ the periodic time

$$T = \frac{2\pi}{(\omega_0^2 - \rho^2)^{\frac{1}{2}}}$$

differs little from that of the undamped oscillation. $e^{-\rho t}$ is the damping factor, ρT the *logarithmic decrement*.

$$2. \quad \rho > \omega_0. \quad \lambda_1 \text{ and } \lambda_2 \text{ are real and we obtain}$$

$$x = 2C_1 e^{-\rho t} \sinh(\rho^2 - \omega_0^2)^{\frac{1}{2}} t$$

where \sinh is the hyperbolic sine.

We shall finally deal with a type of oscillation including all those so far considered, namely that of

Damped, Forced Oscillations

We may write their differential equation in the form

$$m\ddot{x} + w\dot{x} + kx = c \sin \omega t$$

or, with the abbreviations defined in (7a, b),

$$(9) \quad \ddot{x} + 2\rho\dot{x} + \omega_0^2 x = \frac{c}{2m\omega} (e^{i\omega t} - e^{-i\omega t}).$$

To the general integral (8b) of the homogeneous equation we must now add a particular solution which we shall write in the form

$$x = |O| \sin (\omega t + \delta) = \frac{|O|}{2i} (e^{i(\omega t + \delta)} - e^{-i(\omega t + \delta)}).$$

Let us introduce this in (9). A comparison of the factors of $e^{\pm i\omega t}$ left and right yields

$$|C| (-\omega^2 + 2i\rho\omega + \omega_0^2) e^{i\delta} = \frac{c}{m},$$

$$|C| (-\omega^2 - 2i\rho\omega + \omega_0^2) e^{-i\delta} = \frac{c}{m}.$$

Multiplication and division of these two relations yields

$$|C|^2 = \left(\frac{c}{m}\right)^2 \frac{1}{(\omega_0^2 - \omega^2)^2 + 4\rho^2\omega^2}$$

$$e^{2i\delta} = \frac{\omega_0^2 - \omega^2 - 2i\rho\omega}{\omega_0^2 - \omega^2 + 2i\rho\omega},$$

respectively. Accordingly

$$(10) \quad |C| = \frac{c}{m} \frac{1}{[(\omega_0^2 - \omega^2)^2 + 4\rho^2\omega^2]^{\frac{1}{2}}},$$

$$(11) \quad \tan \delta = \frac{1 e^{2i\delta} - 1}{i e^{2i\delta} + 1} = - \frac{2\rho\omega}{\omega_0^2 - \omega^2}.$$

Compare the plot of these two functions of ω in Fig. 33 with Figs. 31a, b.

Fig. 33 shows that our formerly infinite resonance maximum has been depressed to a finite value as a result of the damping (note, by the way, that the maximum value no longer occurs at the exact point $\omega = \omega_0$, but rather at a somewhat smaller ω ; cf. problem III.2).

Fig. 33 also demonstrates that with increasing ω , δ goes from the value 0 at $\omega = 0$ to negative values; for $\omega = \omega_0$ it exactly equals $-\frac{1}{2}\pi$, and it approaches $-\pi$ as $\omega \rightarrow \infty$. Thus we have justified the arbitrary choice between $\pm\pi$, made earlier (in Fig. 31), when we were dealing with the undamped case. As a matter of fact we see now that the phase of the oscillation always *lags* behind that of the driving force. For further examples of forced vibrations see problems III.3 and III.4.

FIG. 33. Amplitude and phase of damped forced oscillations.

§ 20. Sympathetic Oscillations

The types of oscillation so far considered have concerned one mass point. We shall now deal with types of oscillation involving two masses capable of oscillation, these two masses being weakly coupled to each other. Sympathetic oscillations have for many years been important in electric measurements. There one speaks of a primary and a secondary circuit, the latter usually being "inductively" coupled to the former. The primary circuit is made to oscillate ("is excited"), whereupon the secondary circuit does likewise, and especially strongly so if resonance prevails. Indeed the "doubly tuned coupling stage" widely used in radio consists of a primary circuit and a secondary one tuned to the former. Here we shall of course restrict ourselves to coupled *mechanical* oscillations, which have often been used as models for electrical ones.

A particularly instructive example of sympathetic oscillations is furnished by the so-called "coupled pendulums." In the case of resonance these are two equally long and equally heavy pendulums. We may picture them most simply as oscillating in the same plane; their coupling may be effected by means of a helical spring as indicated in Fig. 35. If the spring offers but slight resistance to the relative motion of the two pendulums we speak of weak coupling; in the case of greater spring tension we speak of strong coupling. We assume that the coupling of our pendulums is *weak*. If the pendulums are not exactly equal in length or in weight, we shall say that they are "out of tune," or "detuned."

We shall first describe the phenomena which are observed in the case of resonance.

FIG. 34. Coupled pendulums in the case of resonance.

Let the first pendulum be excited, the second one being initially at rest. In Fig. 34 we have drawn a picture of the resulting oscillations.

The oscillations of each pendulum are *modulated*. The energy alternates between one pendulum and the other. When one pendulum oscillates with maximum amplitude, the other one is at rest.

If, instead (cf. Fig. 35) both pendulums are set in motion simultaneously and with equal strength, either in the same direction (Fig. 35, left), or in opposite directions (Fig. 35, right), no energy is exchanged. These two oscillatory modes are called the *normal modes of oscillation* of our coupled system of two degrees of freedom. We have the general rule that *an oscillatory system of n degrees of freedom has n normal modes of oscillation*.

FIG. 35. The two normal modes of oscillation of coupled pendulums in resonance.

If, on the other hand, the pendulums are detuned, an energy exchange still takes place to be sure, but this exchange is of such a nature that the initially excited pendulum has a minimum amplitude different from zero. Only the pendulum initially at rest again reaches the state of rest in the course of the motion. Thus the "sympathy" of the two pendulums is upset by imperfect tuning.

We shall now sketch the theory for *complete resonance*, making the simplest possible assumptions: we neglect all damping, and approximate the circular trajectories of the bobs by the tangents at their lowest points, which is permissible for sufficiently small displacements. Let x_1 be the amplitude of oscillation of pendulum I, x_2 that of pendulum II; call k the "coupling coefficient," i.e., the spring tension caused by an elongation of unit length, divided by the mass of one of the pendulums. The simultaneous differential equations of the problem are

$$(1) \quad \begin{aligned} \ddot{x}_1 + \omega_0^2 x_1 &= -k(x_1 - x_2) \\ \ddot{x}_2 + \omega_0^2 x_2 &= -k(x_2 - x_1). \end{aligned}$$

If we introduce in (1)

$$(2) \quad z_1 = x_1 - x_2, \quad z_2 = x_1 + x_2,$$

subtraction and addition yield the two equations for the normal modes,

$$(3) \quad \begin{aligned} \ddot{z}_1 + \omega_0^2 z_1 &= -2kz_1 \quad \text{or} \quad \ddot{z}_1 + (\omega_0^2 + 2k)z_1 = 0, \\ \ddot{z}_2 + \omega_0^2 z_2 &= 0 \end{aligned}$$

respectively, with the corresponding frequencies

$$(4) \quad \begin{aligned} \text{for } z_1: \quad \omega &= (\omega_0^2 + 2k)^{\frac{1}{2}} \approx \omega_0 + \frac{k}{\omega_0}; \\ \text{for } z_2: \quad \omega' &= \omega_0. \end{aligned}$$

The general solutions of Eqs. (3) are

$$(5) \quad \begin{aligned} z_1 &= a_1 \cos \omega t + b_1 \sin \omega t; \\ z_2 &= a_2 \cos \omega' t + b_2 \sin \omega' t. \end{aligned}$$

At the moment of excitation $t=0$ let

$$(6) \quad x_2 = \dot{x}_2 = 0, \quad \dot{x}_1 = 0, \quad x_1 = C,$$

giving

$$(7) \quad \dot{z}_1 = \dot{z}_2 = 0, \quad z_1 = z_2 = C.$$

It follows that

$$(8) \quad b_1 = b_2 = 0, \quad a_1 = a_2 = C,$$

so that

$$z_1 = C \cos \omega t, \quad z_2 = C \cos \omega' t.$$

Finally

$$(9) \quad \begin{aligned} x_1 &= \frac{z_1 + z_2}{2} = C \cos \frac{\omega' - \omega}{2} t \cdot \cos \frac{\omega' + \omega}{2} t \\ x_2 &= \frac{z_2 - z_1}{2} = -C \sin \frac{\omega' - \omega}{2} t \cdot \sin \frac{\omega' + \omega}{2} t. \end{aligned}$$

According to (4) $\frac{\omega - \omega'}{2} \cong \frac{k}{2\omega_0} \ll 1$ in the case of weak coupling. The first factors of the right members of (9) therefore vary slowly with time; it is this circumstance which determines the *beats* in the oscillation illustrated in Fig. 34.

The theory is not quite so simple if the two pendulums are out of tune, i.e., if $l_1 \neq l_2$ or/and $m_1 \neq m_2$. Letting c be the tension of the spring due to unit elongation, we now put

$$\omega_1^2 = \frac{g}{l_1}, \quad \omega_2^2 = \frac{g}{l_2}, \quad k_1 = \frac{c}{m_1}, \quad k_2 = \frac{c}{m_2}$$

and instead of (1) we obtain the initial equations

$$(10) \quad \begin{aligned} \ddot{x}_1 + \omega_1^2 x_1 &= -k_1 (x_1 - x_2) \\ \ddot{x}_2 + \omega_2^2 x_2 &= -k_2 (x_2 - x_1). \end{aligned}$$

Here again there are two normal modes, which can be obtained by an extension of the method set forth in (3.24). [In Eq. (1) we were able to use a more convenient method especially suited to that case; this method is not applicable in general.] We substitute

$$(11) \quad x_1 = A e^{i\lambda t}, \quad x_2 = B e^{i\lambda t}$$

and obtain from (10) the two characteristic equations

$$(12) \quad \begin{aligned} A(\omega_1^2 - \lambda^2 + k_1) &= k_1 B \\ B(\omega_2^2 - \lambda^2 + k_2) &= k_2 A. \end{aligned}$$

The so-called *secular equation*³ obtained from (12) is quadratic in λ^2 , since

$$(13) \quad \frac{B}{A} = \frac{\omega_1^2 - \lambda^2 + k_1}{k_1} = \frac{k_2}{\omega_2^2 - \lambda^2 + k_2}$$

so that

$$(14) \quad \{\lambda^2 - (\omega_1^2 + k_1)\} \{\lambda^2 - (\omega_2^2 + k_2)\} = k_1 k_2.$$

For small k_1, k_2 (14) has the two approximate roots

$$(15) \quad \lambda^2 = \begin{cases} \omega_1^2 + k_1 + \frac{k_1 k_2}{\omega_1^2 - \omega_2^2} \\ \omega_2^2 + k_2 + \frac{k_1 k_2}{\omega_2^2 - \omega_1^2}. \end{cases}$$

We designate these two roots of the secular equation by ω^2 and ω'^2 ; furthermore we generalize the tentative solution (11) in the same manner as was done in (3.24b), using the principle of superposition of solutions of linear differential equations. Written in real form the general solution is then

$$(16) \quad \begin{aligned} x_1 &= a \cos \omega t + b \sin \omega t + a' \cos \omega' t + b' \sin \omega' t \\ x_2 &= \gamma a \cos \omega t + \gamma b \sin \omega t + \gamma' a' \cos \omega' t + \gamma' b' \sin \omega' t. \end{aligned}$$

Here γ and γ' are the specific values of B/A which arise from (13) for $\lambda^2 = \omega^2$ and $\lambda^2 = \omega'^2$ respectively.

Let us once again take as the condition of excitation at $t=0$

$$x_2=0, \dot{x}_2=0, \dot{x}_1=0, x_1=C.$$

This yields

$$(17) \quad \begin{aligned} \gamma a + \gamma' a' &= 0, \quad \gamma \omega b + \gamma' \omega' b' = 0, \\ \omega b + \omega' b' &= 0, \quad a + a' = C, \end{aligned}$$

from which

$$b = b' = 0$$

and

$$a = \frac{\gamma}{\gamma - \gamma'} C, \quad a' = \frac{\gamma}{\gamma - \gamma'} C.$$

³ The word originated in the perturbation theory of celestial mechanics.

If we substitute these values in (16), we have

$$(18) \quad \begin{aligned} x_1 &= \frac{C}{\gamma' - \gamma} (\gamma' \cos \omega t - \gamma \cos \omega' t) \\ x_2 &= \frac{C}{\gamma' - \gamma} \gamma \gamma' (\cos \omega t - \cos \omega' t). \end{aligned}$$

In the equation for x_2 we can perform the trigonometric transformation used in (9) to obtain

$$(19) \quad x_2 = \frac{2\gamma\gamma'}{\gamma' - \gamma} C \sin \frac{\omega' - \omega}{2} t \cdot \sin \frac{\omega' + \omega}{2} t$$

We see that the second pendulum still comes to rest at the times

$$\frac{\omega' - \omega}{2} t = n\pi;$$

FIG. 36. Oscillograph of two slightly detuned coupled pendulums.

not so the first pendulum, which [cf. the first Eq. (18) and Fig. 36] retains a finite amplitude when that of x_2 is at a maximum. Imperfect tuning results in an incomplete transfer of energy.

If we desire to apply the foregoing theory to electrical phenomena, we must extend it to include damping of the pendulums; damping has its electrical analogue in the Ohmic resistance (our acceleration term corresponds to the self-induction, our restoring force to capacitive effects); moreover the analysis of electrical oscillations in coupled circuits demands that we introduce "acceleration and velocity coupling" in addition to the "position coupling" [k multiplied by $\pm(x_2 - x_1)$] which was the only type of coupling taken into account in our mechanical problem.

In problem III.5 we shall investigate the motion of an experimentally convenient arrangement, in which the pendulums are suspended bifilarly from a flexible wire and oscillate not in the plane of their positions of rest, but perpendicularly to it.

An interesting arrangement, in which both coupled pendulums are, so to speak, realized in the same body, is that of an oscillating helical spring.⁴

⁴ For details the reader is referred to the *Wüllner-Festschrift*, Teubner (1905): *Lissajous Figures and Resonance Effects of Oscillating Helical Springs; Their Use in the Determination of the Poisson Ratio*.

Such a spring (cf. Fig. 37) is capable not only of an oscillation (y) along its axis but also of a rotary oscillation (x) about this axis. For finite displacements the coupling between these two motions is produced by the spring itself. For if the spring is pulled vertically downward, a lateral force is experienced; the spring seeks to withdraw along the wire-direction in order to uncoil itself. If, on the other hand, the spring is coiled up, it will seek to shorten itself along the y -axis. In other words, if one excites an oscillation in the y -direction, an x -oscillation is induced, and conversely. (Note: as far as the elastic stress on the material is concerned, the y -oscillation is one of torsion, the x -oscillation one of deflection. For details about this consult Vol. II this series.)

By means of the adjustable mass Z , one can bring the vertical and horizontal oscillations into accurate or approximate resonance. If then one of the two vibrations is excited, an exchange of amplitudes of the type of Fig. 34 or Fig. 36 takes place.

FIG. 37. Torsional and deflection oscillations of a helical spring.

§ 21. The Double Pendulum

As at the beginning of the previous section, we shall first describe the empirical phenomena involved.

From a heavy pendulum (a chandelier, for instance) we suspend a light pendulum of about the same period of oscillation. Let us impart a sharp impulse to the heavy bob; the light bob will be set in vigorous motion, which suddenly subsides and stays at zero for a short time. At this instant one perceives that the heavy bob, which had previously remained practically at rest, now starts oscillating with noticeable amplitude. This oscillation soon ceases, however, whereupon in its turn the light pendulum again begins to move with considerable vigor, and so forth.

As mentioned, we demand that the masses of the two bobs, M and m , be very unequal, but that the equivalent lengths L , l be approximately the same. We let

$$\frac{m}{M} = \mu \ll 1.$$

We shall treat the displacements, X of the heavy pendulum, x of the light one, as small quantities, so that once again we can approximate arcs of circles by their tangents. Consequently we must also keep the angles ϕ and ψ (cf. Fig. 38, where ψ belongs to the relative

FIG. 38. Schematic arrangement of a double pendulum.

displacement $x - X$ small. We can therefore put

$$(1) \quad \begin{aligned} \sin \phi = \phi = \frac{x}{L}, \quad \sin \psi = \psi = \frac{x-X}{l} \quad \text{and} \quad \sin(\psi - \phi) = \psi - \phi = \frac{x-X}{l} - \frac{x}{L}. \\ \cos \phi = \cos \psi = \cos(\phi - \psi) = 1. \end{aligned}$$

The upper pendulum is acted upon not only by the force of gravity, but also by the lower pendulum; the string tension^{*} $S \approx mg \cos \psi$ contributes a component tangential to the motion of M of amount $-mg \cos \psi \sin(\phi - \psi)$. Thus we arrive at the equations of motion

$$(2) \quad \begin{aligned} M\ddot{X} &= -M\frac{g}{L}X + mg\left(\frac{x-X}{l} - \frac{x}{L}\right) \\ m\ddot{x} &= -m\frac{g}{l}(x-X) \end{aligned}$$

or, in more convenient form,

$$(3) \quad \begin{aligned} \ddot{X} + \left(\frac{g}{L} + \mu\frac{g}{l} + \mu\frac{g}{L}\right)X &= \mu\frac{g}{l}x, \\ \ddot{x} + \frac{g}{l}x &= \frac{g}{l}X. \end{aligned}$$

From now on we shall put $L = l$ and introduce the abbreviation

$$(4) \quad \omega_0^2 = \frac{g}{l}.$$

Our Eqs. (3) then become

$$(5) \quad \begin{aligned} \ddot{X} + \omega_0^2(1 + 2\mu)X &= \mu\omega_0^2 x, \\ \ddot{x} + \omega_0^2 x &= \omega_0^2 X. \end{aligned}$$

These equations of motion state that the upper pendulum is μ times more weakly coupled to the lower one than vice versa.

To integrate (5) we use a substitution similar to (20.11),

$$(6) \quad x = Ae^{i\lambda t}; \quad X = Be^{i\lambda t}.$$

From (5) we have as a result

$$(7) \quad \begin{aligned} A(\omega_0^2 - \lambda^2) &= B\omega_0^2 \\ B[\omega_0^2(1 + 2\mu) - \lambda^2] &= A\mu\omega_0^2. \end{aligned}$$

^{*} In the present elementary treatment we have to introduce this tension S as a descriptive auxiliary quantity; later, when we analyse the same problem by means of the general Lagrange method, this procedure will become superfluous. In order to determine S we reason as follows: the tension in the suspension of the light bob is in equilibrium with gravity and inertial force (centrifugal force); the latter is a small quantity of second order and can therefore be neglected. We then have $S = mg \cos \psi$ as stated above.

If we put the two values of B/A obtained from these two equations equal, we arrive at the quadratic equation in λ^2 ,

$$(8) \quad (\lambda^2 - \omega_0^2)^2 + 2\mu\omega_0^2(\omega_0^2 - \lambda^2) = \mu\omega_0^4.$$

Let its two roots be called $\lambda^2 = \omega^2$ and $\lambda^2 = \omega'^2$. Omission of higher powers of μ easily yields their approximate values

$$(9) \quad \left. \begin{matrix} \omega \\ \omega' \end{matrix} \right\} = \omega_0 \left(1 \pm \frac{1}{2}\mu^{\frac{1}{2}} \right).$$

Written in real form, the general solution of (5) is then

$$(10) \quad \begin{aligned} x &= a \cos \omega t + b \sin \omega t + a' \cos \omega' t + b' \sin \omega' t, \\ X &= \gamma a \cos \omega t + \gamma b \sin \omega t + \gamma' a' \cos \omega' t + \gamma' b' \sin \omega' t. \end{aligned}$$

As in § 20, γ and γ' are here the values of B/A which result from (7) for $\lambda^2 = \omega^2$ and $\lambda^2 = \omega'^2$ respectively, viz.,

$$(11) \quad \gamma = -\mu^{\frac{1}{2}}, \quad \gamma' = +\mu^{\frac{1}{2}} \quad \text{and hence} \quad \gamma' - \gamma = 2\mu^{\frac{1}{2}}.$$

Let the excitation of the system at $t=0$ be given by

$$(12) \quad x=0, \quad \dot{x}=0, \quad X=0, \quad \dot{X}=0.$$

It follows that

$$\left. \begin{aligned} a + a' &= 0 \\ \gamma a + \gamma' a' &= 0 \end{aligned} \right\} a = a' = 0.$$

$$\left. \begin{aligned} \omega b + \omega' b' &= 0 \\ \gamma \omega b + \gamma' \omega' b' &= 0 \end{aligned} \right\} b = \frac{0}{\omega(\gamma - \gamma')}; \quad b' = \frac{0}{\omega'(\gamma' - \gamma)}.$$

Thus we obtain the final solutions

$$(13) \quad \begin{aligned} x &= \frac{0}{\gamma - \gamma'} \left(\frac{\sin \omega t}{\omega} - \frac{\sin \omega' t}{\omega'} \right) \\ X &= \frac{0}{\gamma - \gamma'} \left(\frac{\gamma}{\omega} \sin \omega t - \frac{\gamma'}{\omega'} \sin \omega' t \right). \end{aligned}$$

Let us pass from these to the velocities \dot{x} and \dot{X} , taking (11) into account. We end up with

$$(14) \quad \begin{aligned} \dot{x} &= \frac{0}{2\mu^{\frac{1}{2}}} (\cos \omega' t - \cos \omega t), \\ \dot{X} &= \frac{0}{2} (\cos \omega' t + \cos \omega t). \end{aligned}$$

Given the same phase, the velocity of the heavy upper bob is hence $\mu^{\frac{1}{2}}$ times smaller than that of the light lower one; notice also that (14)

satisfies our initial conditions (12). The same can be said about the displacements themselves. Like the velocities, these are subject to beats because of the closeness of the values of ω and ω' . This modulation can be shown explicitly by writing the equations (13) and (14) in a form resembling Eq. (20.9).

We conclude the chapter with a problem which also pertains to the class of coupled oscillations and leads to oscillations very similar to the ones treated above. We shall, however, avail ourselves of a simpler mathematical method resembling that of the forced⁶ undamped oscillations of § 19, so that we have to cope with the integration of only one differential equation rather than with that of a system of two simultaneous ones.

Let us suspend our pocket watch from a smooth nail, in such a way that the watch hangs completely free and friction is reduced to a minimum. By means of gentle contact with our fingers or a piece of cloth we bring the watch into a state of complete rest. When released, the timepiece at once begins to move, performing increasing oscillations about the vertical rest position. These oscillations reach a maximum, then gradually decrease once more to zero, after which the process repeats itself.

In these oscillations of the watch we are evidently confronted with a motion reacting against the rhythm of the balance wheel, i.e., a manifestation of the principle of conservation of angular momentum. The fluctuation of the oscillation amplitude, on the other hand, is caused by interference between the free pendulum oscillations of the watch in the gravitational field and the forced oscillations excited by the balance wheel.

We shall follow § 13, subsec. 2 in our notation. Accordingly we let M be the angular momentum of the total motion of the system. We decompose it into that of the pendulum motion (p) and that of the balance wheel oscillations (δ),

$$(15) \quad M = M_p + M_\delta.$$

M_p is calculated about the point of suspension O (nail), M_δ about the center B of the balance wheel. The latter is permitted because a *pure* angular momentum (i.e., one caused by a motion in which the center of mass of the system remains fixed) can, just like a force couple (cf. p. 128), be shifted

⁶ We can say quite generally that the excitation of forced oscillations in a system by means of an external force is equivalent to coupling with a second system on which the first one does not react. In the case about to be described it is certainly true that the reaction of the pendulum oscillations on the balance wheel is vanishingly small.

at will in its plane⁷; indeed, due to the symmetry of the balance wheel about B , the inertial action of the balance consists of a pure moment of momentum. Let ω be the circular frequency of the balance wheel; it is determined by the stiffness of the balance spring. Let ω_0 be the undisturbed, i.e., proper circular frequency of the pendulum oscillations. According to (11.6) and (16.4) we put

$$(16) \quad M_p = I\dot{\phi}, \quad I = m_p a^2;$$

m_p is the total mass of the watch, a its radius of gyration measured from O . We postulate a sinusoidal balance wheel oscillation which we shall therefore describe by $\phi_b = \alpha \sin \omega t$, B being the vertex of angle ϕ_b . The angular momentum of the balance wheel is then

$$(17) \quad M_b = m_b \omega b^2 \alpha \cos \omega t,$$

where m_b is the mass of the balance wheel, b its radius of gyration measured from B .

As in the case of the compound pendulum [Eq. (16.1)] the moment of the external force is

$$(18) \quad L = -m_p g s \phi,$$

where we have, as usual, made the approximation for small ϕ . Here s is the distance of the center of gravity of the watch from O , and ϕ the angle formed at O by the vertical and a line through the center of gravity. We now apply (13.9), use therein the values given by (15), (16), (17), and (18), and obtain the equation of motion

$$(19) \quad \ddot{\phi} + \frac{g s}{a^2} \phi = \frac{m_b}{m_p} \left(\frac{b}{a}\right)^2 \alpha \omega^2 \sin \omega t$$

for our system.

This equation represents the type of oscillation which was treated in §19 as undamped forced oscillation. Again we put

$$\frac{g s}{a^2} = \omega_0^2$$

⁷ This is a direct consequence of the fact that the angular momentum of a system about a given axis can be decomposed into the sum of the angular momentum of the system about a parallel axis through its mass center and the angular momentum of the mass center (containing the total mass of the system) about the given axis. In our case the latter term vanishes since the angular momentum of the mass center of the balance wheel due to the oscillation of the watch as a whole was included in M_{pend} .

where ω_0 is, we recall, the proper frequency of the pendulum motion; let us moreover abbreviate

$$c = \frac{m_b}{m_p} \left(\frac{b}{a} \right)^2 \alpha \omega^2 \ll 1.$$

Equation (19) becomes

$$(20) \quad \ddot{\phi} + \omega_0^2 \phi = c \sin \omega t.$$

The solution satisfying the initial conditions $\phi=0$, $\dot{\phi}=0$ at $t=0$ is

$$(21) \quad \phi = \frac{c}{\omega_0^2 - \omega^2} \left(\sin \omega t - \frac{\omega}{\omega_0} \sin \omega_0 t \right).$$

The constant c is so small (factor m_b/m_p) that the oscillation is of visible magnitude only when the relation $\omega_0 = \omega$ is approximated, i.e., when approximate resonance exists between the external pendulum oscillations and the internal oscillations of the balance wheel. Surprisingly it turns out that this resonance is more or less well realized in pocket watches of not too small a size (ladies' watches are unsuitable for our purposes).

Eq. (21) further shows that amplitude modulation goes hand in hand with the approach to resonance $\omega_0 \rightarrow \omega$. The period T of the beats is determined by the requirement

$$(22) \quad \omega T = \omega_0 T \pm 2\pi,$$

and has therefore the value

$$(22a) \quad T = \frac{2\pi}{|\omega - \omega_0|}.$$

It can be determined very accurately by counting the number of pendulum oscillations between two nodes of the beats, and furnishes therefore a convenient and precise measure of the degree of resonance. We can refer back to Fig. 32 which, as pointed out, represents the same differential equation as (20); we must, however, bear in mind that in the diagram we postulated complete resonance, i.e., $T = \infty$.

If one leaves the watch to itself for some time, one observes that the beats have ceased. The reason for this is evidently friction (at the point of suspension and in the air), which we have so far neglected. This friction damps the contribution of the free pendulum oscillations to the motion of the watch, leaving only the forced oscillations due to the motion of the balance wheel, the latter contribution (cf. Fig. 33, for instance) being somewhat reduced in amplitude due to friction. We can reason as follows: initially the forced oscillation is present in its full amount, and the free pendulum oscillation is excited to such a degree that at $t=0$ it just cancels the forced one—in agreement with the initial conditions $\phi = \dot{\phi} = 0$.

Indeed the initially motionless state of the watch can be interpreted as being caused by an impulse exactly cancelling the balance wheel oscillation. The effect of this impulse is gradually used up by friction, so that only the forced oscillation due to the balance wheel remains.

The example of the watch appeared in the literature for the first time in the "Elektrotechnische Zeitschrift" of the year 1904, in connection with the phenomenon of "hunting" of synchronous machinery, then timely and surprising. Two synchronous alternators feeding the same power line and connected in parallel show undesirable fluctuations in their motions and their currents when resonance occurs. They provide a greatly magnified picture of the beats of our watch and of the coupling and resonance phenomena occurring in the coupled oscillations that we have just analyzed.

CHAPTER IV

THE RIGID BODY

§ 22. *Kinematics of Rigid Bodies*

At the beginning of § 7 we saw that a rigid body is endowed with six degrees of freedom; these we shall subdivide into three of translation and three of rotation.

Let us consider the body in two different positions, the "initial position" and the "final position." We pick out an arbitrary point of the body as "point of reference" O , and describe a sphere of reference (say of unit radius) about it. On this sphere we mark two points A and B . Once we have guided the three points OAB from their initial positions to their final ones, all other points of the rigid body have similarly reached their destinations.

First we take the point O from its initial position O_1 to its final position O_2 . Let this be achieved by means of a parallel displacement or *translation* in which each point of the body is subjected to the same rectilinear displacement $O_1 \rightarrow O_2$. We have thus described the three degrees of freedom of translation.

The sphere K_1 described about O_1 is now in coincidence with the corresponding sphere K_2 described about O_2 . In general this is not true of the position of the points A, B , which we designate by A_1, B_1 on K_1 and A_2, B_2 on K_2 . We shall show that there is one definite *rotation* about the point $O_1 = O_2$ which will take points A_1, B_1 over into A_2, B_2 . Axis and angle of this rotation define the three degrees of freedom of rotation to be added to those of translation.

In order to construct the axis of rotation, i.e., the point Ω at which the axis cuts the unit sphere, we connect A_1 to A_2 and B_1 to B_2 by means of arcs of great circles. At the centers A' and B' of these arcs we erect their perpendicular bisectors whose intersection is the point Ω in question. The angle of rotation, which we shall also call Ω , is

$$(1) \quad \Omega = \sphericalangle A_1 \Omega A_2 = \sphericalangle B_1 \Omega B_2.$$

The equality of these two angles results from the congruence of the shaded spherical triangles $A_1 \Omega B_1$ and $A_2 \Omega B_2$ of Fig. 39, whose three corresponding sides are equal to each other. It follows that the two angles designated by γ in Fig. 39 are equal. If we subtract one or the other of these angles

from the total angle $A_1\Omega B_2$ we obtain the right or middle member of Eq. (1). This equation evidently states that the same rotation Ω not only takes point A_1 over into A_2 , but also point B_1 into B_2 .

So far the magnitude and direction of the translation are still arbitrary¹ within wide limits, for we have free choice over the reference point O . The magnitude and axis of the rotation, on the other hand, are *independent* of the choice of the reference point. For let us substitute for O a new reference point O' . The difference between the translations associated with O' and O for a given total displacement of the rigid body is again a translation. This latter translation, however, does not affect the positions of the points A, B on the spheres K_1 and K_2 . It follows that the construction of Fig. 39 carries over unchanged to the present case and yields not only the same angle of rotation Ω as previously, but also an axis of rotation passing through the point of reference O' and parallel to our former axis.

Of much greater importance than finite displacements of the rigid body are its infinitesimal displacements which succeed each other continuously to result in a finite motion. We shall therefore assume that now the magnitude O_1O_2 of the translation and the angle Ω of rotation are arbitrarily small. Let us divide them by the correspondingly small interval of time Δt . We then obtain the velocity \mathbf{u} of translation and the angular velocity ω of rotation,

$$(2) \quad \mathbf{u} = \frac{\overrightarrow{O_1O_2}}{\Delta t}, \quad \omega = \frac{\Omega}{\Delta t}.$$

As before, the angular velocity is independent of the choice of reference point O , whereas \mathbf{u} depends on this choice. The heavy type indicates that

¹ In the supplement to § 23 we shall see that we can, in particular, make the direction of the translation parallel to the axis of rotation. We then speak of a "screw displacement."

FIG. 39. Construction of the point Ω determining the axis of rotation for a rigid body revolving about a fixed point O . This diagram also suggests how the resultant of two finite rotations can be found.

ω is to be regarded as a vector which expresses not only the magnitude, but also the axial direction of rotation of the angular velocity.

We can easily show that ω does indeed possess vector character. In Fig. 15 and Eq. (13.4), while discussing virtual rotations, we derived the relation

$$(3) \quad \delta s = \delta \phi \times r.$$

If we now pass from the virtual rotation $\delta \phi$ to the angular velocity $\omega = \frac{d\phi}{dt}$ and from the virtual displacement δs caused by the rotation to the velocity $w = \frac{ds}{dt}$, we obtain from (3) that

$$(4) \quad w = \omega \times r.$$

As in Fig. 15, r is here the radius vector from the point of reference O located on the axis of rotation to the point P whose velocity w is to be determined.

Consider now the total effect of two successive infinitesimal rotations $\omega_1 dt$ and $\omega_2 dt$ on the motion of the point P of the rigid body, reference point O being common to both axes ω_1 and ω_2 . We have

$$(4a) \quad w_1 = \omega_1 \times r, \quad w_2 = \omega_2 \times r, \quad w_1 + w_2 = (\omega_1 + \omega_2) \times r.$$

In the last of these equations the left member is the velocity w , resulting from w_1 and w_2 . A comparison with (4) shows that

$$(5) \quad \omega_r = \omega_1 + \omega_2$$

is likewise the resultant angular velocity, equivalent to the two rotations $\omega_1 dt$ and $\omega_2 dt$ in its effect on the rigid body. We conclude that *angular velocities add like vectors*. As in the case of vectors their order in addition is immaterial, i.e., *their addition is commutative*, for

$$(6) \quad \omega_1 + \omega_2 = \omega_2 + \omega_1.$$

Neither of these two laws is valid for finite rotations. Their composition does not follow the simple rules of vector algebra, but those of the algebra of *quaternions* invented by Hamilton. Moreover the effect of two finite rotations depends on their order; two such rotations do not commute.

At this point it is convenient to discuss the difference between polar and axial vectors.

Examples of *polar vectors* are velocity, acceleration, force, radius vector, etc. They can be represented by directed segments provided with an arrow head. In a rotation of the system of coordinates their rectangular components transform like the coordinates themselves, i.e., according to

the scheme of orthogonal transformations with determinant $+1$. In an inversion of the coordinate system through the origin, in which x, y, z are replaced by $-x, -y, -z$ respectively so that the transformation has determinant -1 , the components of polar vectors change sign.

Angular velocity, angular acceleration, torque and angular momentum are examples of *axial vectors*. In accordance with their nature they are represented by an axis on which sense and magnitude of rotation are indicated (e.g., by a curved arrow and a number). If, instead, we represent them by means of an arrow of corresponding magnitude laid off on the axis, we must make some arbitrary agreement about the direction of this arrow, such as the rule of the right-handed screw. In a pure rotation of the coordinate system the rectangular components of axial vectors transform like the components of their associated arrows, i.e., orthogonally; in an inversion of the coordinates through the origin, however, these rectangular components do not change sign. In such a transformation the rule of the right-handed screw must be replaced by that of the left-handed screw, in agreement with the fact that an inversion through the origin takes a right-handed coordinate system over into a left-handed one.

The vector product of two polar vectors is an axial vector (e.g., the moment of a force). The vector product of an axial and a polar vector is a polar vector [e.g., the velocity \mathbf{w} in Eq. (4)]. The reader may easily convince himself of this by checking the behavior of these products under inversion of coordinates.²

After this digression we return to the kinematics of the rigid body. The motion of each one of its points is composed of the velocity \mathbf{u} of Eq. (2) connected with translation and the velocity \mathbf{w} in Eq. (4) connected with rotation. The velocity \mathbf{v} of an arbitrary point of the rigid body is hence given by

$$(7) \quad \mathbf{v} = \mathbf{u} + \boldsymbol{\omega} \times \mathbf{r}.$$

The choice of the reference point O is completely up to us; for it we have

$$(7a) \quad \mathbf{v} = \mathbf{u}.$$

For many purposes it is advantageous to put O at the mass center G . This becomes evident if, for instance, we wish to calculate the kinetic

² From now on we shall simply talk about the torque \mathbf{L} , the angular velocity $\boldsymbol{\omega}$, where the reader should bear in mind that we mean by this the axial vectors representing the torque and the angular velocity respectively. When, on the other hand, we speak of the plane of the torque and the plane of the angular velocity, we mean, of course, the planes perpendicular to the axial vectors \mathbf{L} and $\boldsymbol{\omega}$ respectively.

energy of the body,

$$(8) \quad T = \int \frac{dm}{2} v^2.$$

To this end we form, with the help of (7),

$$(8a) \quad v^2 = u^2 + (\omega \times \mathbf{r})^2 + 2\mathbf{u} \cdot (\omega \times \mathbf{r})$$

and accordingly break up T into three parts,

$$(9) \quad T = T_{\text{transl}} + T_{\text{rot}} + T_m,$$

where T_m is a "mixed" energy which is determined by the translation and the rotation combined.

Since \mathbf{u} has the same value for all points dm , we evidently have

$$(10) \quad T_{\text{transl}} = \frac{u^2}{2} \int dm = \frac{m}{2} u^2.$$

In order to calculate T_m we perform the transformation

$$(11) \quad T_m = \int \mathbf{u} \cdot \omega \times \mathbf{r} \, dm = \mathbf{u} \cdot \omega \times \int \mathbf{r} \, dm = m \mathbf{u} \cdot \omega \times \mathbf{R},$$

where \mathbf{R} is the directed segment from O to the mass center G ,

$$(11a) \quad \mathbf{R} = \frac{1}{m} \int \mathbf{r} \, dm$$

as in Eq. (13.3b). If now we let O coincide with G , we have $\mathbf{R} = 0$ and, from (11),

$$(11b) \quad T_m = 0.$$

The kinetic energy T then becomes simply the sum of T_{transl} and T_{rot} . Notice, in passing, that if the body rotates about a fixed point and if one chooses this fixed point as reference point O , not only T_m , but also T_{transl} vanishes (in both cases because $\mathbf{u} = 0$), so that

$$(11c) \quad T = T_{\text{rot}}.$$

We shall now focus our attention on the rotational contribution to the kinetic energy. If we square the components of $\omega \times \mathbf{r}$, we obtain from the middle term of the right member of (8a)

$$(12) \quad \begin{aligned} 2T_{\text{rot}} = & \omega_x^2 \int (y^2 + z^2) \, dm + \omega_y^2 \int (z^2 + x^2) \, dm + \omega_z^2 \int (x^2 + y^2) \, dm \\ & - 2\omega_x \omega_y \int yz \, dm - 2\omega_x \omega_z \int zx \, dm - 2\omega_y \omega_z \int xy \, dm. \end{aligned}$$

With the notation

$$(12a) \quad \begin{aligned} I_{xx} &= \int (y^2 + z^2) dm \dots \\ I_{xy} &= \int xy dm \dots \end{aligned}$$

this yields

$$(12b) \quad 2T_{\text{rot}} = I_{xx}\omega_x^2 + I_{yy}\omega_y^2 + I_{zz}\omega_z^2 - 2I_{yz}\omega_y\omega_z - 2I_{zx}\omega_z\omega_x - 2I_{xy}\omega_x\omega_y.$$

According to the definition introduced in (11.3), I_{xx} is the moment of inertia of the mass distribution about the x -axis; a corresponding statement holds for I_{yy} and I_{zz} . We shall call I_{xy} , I_{yz} , I_{zx} the *products of inertia* (the name "centrifugal moments" is sometimes used synonymously). We can also abbreviate I_{xx} , . . . without ambiguity to I_x , . . .

In accordance with (11.5) we put the left member of (12) equal to $I\omega^2$ and with the abbreviations

$$(13) \quad \frac{\omega_x}{\omega} = \alpha, \quad \frac{\omega_y}{\omega} = \beta, \quad \frac{\omega_z}{\omega} = \gamma$$

obtain

$$(13a) \quad I = I_{xx}\alpha^2 + I_{yy}\beta^2 + I_{zz}\gamma^2 - 2I_{yz}\beta\gamma - 2I_{zx}\gamma\alpha - 2I_{xy}\alpha\beta.$$

α , β , γ are the direction cosines of the vector ω whose axis is arbitrarily located in the rigid body. It follows from (13a) that the moment of inertia about any axis is completely determined once the six magnitudes I_{ik} are given.

A sextet of magnitudes of the type of our I_{ik} is called a *tensor*, or, more precisely, a *symmetrical tensor*. The name originated in the theory of elasticity where stress and strain tensors play a central role. In general a tensor is very aptly written as a square scheme, which in our case would be

$$(13b) \quad I_{ik} = \begin{pmatrix} I_{xx} & -I_{xy} & -I_{xz} \\ -I_{yx} & I_{yy} & -I_{yz} \\ -I_{zx} & -I_{zy} & I_{zz} \end{pmatrix}$$

where $I_{xy} = I_{yx}$, . . .

From an elementary viewpoint the mathematics of tensors is less concrete and easily intelligible than that of vectors. Whereas a vector is represented by a line segment, we must resort to a surface of second degree for the geometrical representation of a tensor. In our case this "tensor surface" is obtained as follows: we put

$$(14) \quad \alpha = \frac{\xi}{\rho}, \quad \beta = \frac{\eta}{\rho}, \quad \gamma = \frac{\zeta}{\rho},$$

where ξ , η , ζ are interpreted as Cartesian coordinates, hence $\rho = (\xi^2 + \eta^2 + \zeta^2)^{\frac{1}{2}}$

as radius vector from the point O . We now set ρ equal to $I^{-\frac{1}{2}}$, so that along every axis through O we lay off, not I , but rather the reciprocal of $I^{\frac{1}{2}}$ (else we should not obtain a surface of *second degree*). In this manner we obtain from (13a)

$$(15) \quad 1 = I_{xx}\xi^2 + I_{yy}\eta^2 + I_{zz}\zeta^2 - 2I_{yz}\eta\zeta - 2I_{xz}\xi\zeta - 2I_{xy}\xi\eta.$$

Apart from possible degeneracies this is the equation of an ellipsoid, since for a finite mass distribution I is, in general, greater than zero. The surface represented by (15) is called the *momental ellipsoid*.

If one transforms the coordinates so that they coincide with the principal axes of the ellipsoid, one obtains an equation of the form

$$(15a) \quad 1 = I_1\xi_1^2 + I_2\xi_2^2 + I_3\xi_3^2,$$

where I_1, I_2, I_3 are the three *principal moments of inertia*. The products of inertia vanish for the principal axes, which can be regarded as a definition of the latter. The tensor scheme (13b) reduces to diagonal form. When the tensor is described in a system of coordinates different from that of the principal axes one must mentally add the three direction parameters of the principal axes; thus we are again lead to the six magnitudes characterizing a symmetrical tensor.

FIG. 40a—c. (a) Momental ellipsoid of the toy top. (b) Momental ellipsoid of the flywheel top. (c) An example of a spherical top.

Every plane of symmetry of the mass distribution is of course also a plane of symmetry of the momental ellipsoid. A mass distribution with rotational symmetry has a momental ellipsoid of revolution, i.e., in addition to the principal axis along the "axis of figure" it possesses infinitely many other "equatorial" principal axes. As examples we may mention two types of tops; one is of the conical type used as toy, the other has the shape of a flywheel and is usually employed for demonstration purposes (Figs. 40a and b). In the first type the moment of inertia about the axis of the body is a minimum, so that the corresponding principal axis is longer than the equatorial ones (by virtue of the relation $\rho = I^{-\frac{1}{2}}$); we have a *prolate spheroid*. In the second case the moment of inertia about the axis of figure is a maximum, hence the corresponding principal axis is, for the

same reason, smaller than the equatorial ones; the result is an *oblate spheroid*.

Incidentally a momental ellipsoid becomes one of revolution not only for mass distributions with rotational symmetry, but also whenever more than two planes of symmetry pass through an axis, as for example in the case of a square or hexagonal prism.

Similarly the ellipsoid degenerates into a sphere not only in the case of a spherically symmetrical distribution, but also in cases such as that of a cubical distribution, for instance, because here there exist more planes of symmetry than are compatible with the ellipsoidal shape of the tensor surface. In such a case we speak of a "spherical top." In a spherical top (cf. Fig. 40c) any axis is a principal axis.

§ 23. Statics of Rigid Bodies

This subject forms the theoretical basis for the whole field of structural mechanics dealing with such topics as the construction of bridges, trusses, arches, etc., and for this reason it is treated with the greatest detail in the texts of mechanical engineering, both analytically and graphically. Here we shall restrict ourselves to the general features of the subject.

(1) The Conditions of Equilibrium

These, like all questions of equilibrium, are governed by the principle of virtual work. Since this principle can be regarded as the special case of d'Alembert's principle in which the inertial forces vanish, our present analysis can be directly modeled after that of the principles of linear and angular momentum of § 13. Indeed the virtual displacements (translation and rotation) used there are evidently compatible with the internal connections of the rigid body and correspond to the two component parts of the general motion of a rigid body considered in the preceding section.

By deleting the inertial forces in Eqs. (13.3) and (13.9), we obtain the general conditions of equilibrium of a rigid body,

$$(1) \quad \sum \mathbf{F}_k = 0, \quad \sum \mathbf{L}_k = 0.$$

The \mathbf{F}_k are external forces acting at arbitrary points P_k of the rigid body. The first Eq. (1) asks us to lay off the force vectors end to end in arbitrary order and with no regard to their points of application, and to examine the resulting *force polygon*. According to Eq. (1) *for equilibrium the polygon of forces must be closed*.

The \mathbf{L}_k are the moments of the \mathbf{F}_k about a reference point O whose choice is arbitrary but which must be the same for all the \mathbf{F}_k . The second Eq. (1) asks us to replace these \mathbf{L}_k by their (axial) vector representations

(cf. p. 37) and to examine the polygon of torques arising when all these vectors are added vectorially. According to the second Eq. (1) *the torque polygon must also be closed for equilibrium.*

In analogy to Eqs. (13.12) and (13.13) we can pass from the two vector equations (1) to the following six component equations:

$$(2) \quad \begin{aligned} \sum X_k &= \sum Y_k = \sum Z_k = 0 \\ \sum (y_k Z_k - z_k Y_k) &= \sum (z_k X_k - x_k Z_k) = \sum (x_k Y_k - y_k X_k) = 0. \end{aligned}$$

These represent the projections of the vector equations (1) on the coordinate axes; the x_k, y_k, z_k are the coordinates of the points of application, measured from O as origin.

(2) Equipollence; the Reduction of Force Systems

If the external forces (or torques) are not in equilibrium, we can ask whether there exists a single force (or single torque) of such properties that under its action alone the rigid body moves in the same way as it would under the action of the given system of forces (or torques).

Posing this question is, among other things, useful (even though in general not sufficient) for the determination of the forces which are exerted on a rigid body by its supports if the rigid body is acted on by a system of forces which themselves are not sufficient to bring about a state of equilibrium.

We obtain the answer by drawing the closing segment in the now "open" polygon F_1, F_2, \dots, F_n , once in the direction in which the polygon is traced (F_{n+1}) and once (cf. Fig. 41) in the opposite direction (F_r , resultant force). Nothing is changed thereby. We have now a closed force polygon F_1, \dots, F_{n+1} , and a single force F_r , which, taken together, are *equipollent* to the "open" polygon of forces F_1, \dots, F_n . The forces F_1, \dots, F_{n+1} are, however, in equilibrium and can therefore be left out, so that the single force F_r is equipollent to the given system of forces F_1, \dots, F_n . Mathematically,

$$(3) \quad F_r = \sum_{k=1}^n F_k.$$

The same process of reasoning can be carried out with an "open" torque polygon. One thereby obtains a resultant force moment L_r which

FIG. 41. Construction of the resultant force for an "open" polygon of forces.

is equipollent to the given system of moments L_1, L_2, \dots, L_n , i.e.,

$$(4) \quad L_r = \sum_{k=1}^n L_k$$

Let us mention in passing that there is nothing to stop us from making the single force F_r act at the same point O which serves as reference point in the calculation of moments L_k . This choice is indicated in Fig. 41.

(3) Change of Reference Point

Eq. (3) immediately shows that F_r is independent of the choice of reference point O . If F_r' is the resultant single force associated with a different reference point O' , we therefore have

$$(5) \quad F_r' = F_r.$$

From Eq. (4), on the other hand, we have with corresponding meaning of L_r'

$$(6) \quad L_r' = \sum_{k=1}^n L_k' \text{ with } L_k' = r_k' \times F_k,$$

where r_k' is the radius vector from O' to the point of application P_k of F_k . Let a be the vector distance from O' to O . Then

$$(6a) \quad r_k' = a + r_k, \quad L_k' = a \times F_k + r_k \times F_k = a \times F_k + L_k.$$

Therefore

$$(6b) \quad L_r' = \sum_{k=1}^n a \times F_k + \sum_{k=1}^n L_k = a \times \sum_{k=1}^n F_k + L_r.$$

But in view of (3)

$$a \times \sum_{k=1}^n F_k = a \times F_r.$$

Thus we have

$$(7) \quad L_r' = L_r + a \times F_r.$$

(4) Comparison of Kinematics and Statics

As remarked in connection with Eq. (22.2), in kinematics ω is independent of the choice of reference point, whereas u depends on that choice. We write

$$(8) \quad \omega' = \omega$$

and, from (22.7), with $\mathbf{v}=\mathbf{u}'$ and $\mathbf{r}=\mathbf{a}$,

$$(9) \quad \mathbf{u}' = \mathbf{u} + \boldsymbol{\omega} \times \mathbf{a}.$$

This equation has the same structure as the preceding Eq. (7) provided we disregard the sequence of the factors in the corresponding vector products. If we also take into consideration Eqs. (5) and (8), we arrive at a remarkable reciprocity between statics and kinematics which can be expressed by the scheme below:

This crosswise reciprocity holds as well between the concepts of force couple and rotational couple which we shall now take up.

The *force couple* (or "couple," for short) is a basic element in elementary statics. As is well known, a couple consists of two parallel and opposite forces of equal magnitude, $\pm \mathbf{F}$, whose lines of action are a finite distance, say l , apart. If we carry out the reduction of such a couple in the sense of subsec. 2, we obtain

$$(10) \quad \mathbf{F}_r = 0, \quad \mathbf{L}_r = \vec{L}, \quad |\vec{L}| = |\mathbf{F}| l,$$

where one should think of the vector \vec{L} as directed normal to the plane of the two forces. Whereas, however, the former \mathbf{L}_r was, so to speak, attached to the reference point O , our present \vec{L} is the same for all reference points and completely free to move in space; i.e., two given couples can be added vectorially to yield a third couple; two couples of equal and opposite moments located in parallel planes cancel, etc.

Let us follow up the crosswise reciprocity indicated by our scheme by defining a rotational couple. By a *rotational couple* we understand two equal and opposite rotational velocities $\pm \boldsymbol{\omega}$, whose axes are parallel to each other and a distance l apart. According to the rule of addition (22.5), the reduction of a rotational couple yields a resultant rotational velocity $\boldsymbol{\omega}_r = 0$. Our rotational couple generates then a pure translation perpendicular to the plane of the two axes of rotation. The magnitude of the velocity of translation is easily found to be $|\vec{u}| = \omega l$. The

analogy to Eqs. (10) in the sense of our reciprocity scheme is therefore complete. Whereas our former \mathbf{u} depended on the choice of the reference point O , the $\vec{\mathbf{u}}$ equivalent to a rotational couple is independent of O , and can be translated parallel to itself in space in any manner whatever. From this it follows that two arbitrarily located rotational couples add vectorially just like their velocities of translation $\vec{\mathbf{u}}$; two rotational couples of equal and opposite moment $\pm \omega l$ located in parallel planes cancel, etc.

SUPPLEMENT: WRENCHES AND SCREW DISPLACEMENTS

From (7) we see that \mathbf{L}_r depends on the reference point. We are therefore tempted to choose this point in such a way that \mathbf{L}_r and \mathbf{F}_r become parallel. We then obtain an especially simple picture of our system of forces called a *wrench*, i.e., a single force and a moment acting about this force or, equivalently, a couple located in a plane perpendicular to the force. If our initial reference point is O , the position of O' required for a wrench is obtained as follows: in Eq. (7) we decompose \mathbf{L}_r into \mathbf{L}_p parallel to \mathbf{F}_r and \mathbf{L}_n perpendicular to it and determine \mathbf{a} from the equation

$$(11) \quad \mathbf{L}_n = -\mathbf{a} \times \mathbf{F}_r.$$

From (5) and (7) we then have for the reference point O' ,

$$\mathbf{F}_r' = \mathbf{F}_r, \quad \mathbf{L}_r' = \mathbf{L}_p \parallel \mathbf{F}_r$$

as demanded by the definition of a wrench. Eq. (11) states that for this purpose the reference point O must be displaced a certain distance

$$\mathbf{a} = -\frac{|\mathbf{L}_n|}{|\mathbf{F}_r|}$$

normal to \mathbf{F}_r and \mathbf{L}_n .

A line of reasoning exactly reciprocal in the sense of the preceding discussion leads to the *screw displacement*. With Eq. (9) as starting point we decompose \mathbf{u} into \mathbf{u}_p parallel to ω and \mathbf{u}_n perpendicular to it. The displacement \mathbf{a} of the reference point required for a screw is determined by the equation

$$(12) \quad \mathbf{u}_n = -\omega \times \mathbf{a}.$$

From (8) and (9) we then obtain for the reference point O' ,

$$(13) \quad \omega' = \omega, \quad \mathbf{u}' = \mathbf{u}_p \parallel \omega,$$

which in fact represents a screw displacement. Eq. (12) states that the reference point O must here be displaced by a certain distance normal to ω and \mathbf{u}_n .

Attractive as the concept of the wrench and the screw displacement may be, it is of no great practical value in the treatment of specific problems involving rotation. For this reason mention of them has been relegated to a supplement.

§ 24. *Linear and Angular Momentum of a Rigid Body. Their Connection with Linear and Angular Velocity*

Let us imagine that a momentum of translation (linear momentum, impulsive force) and a momentum of rotation (moment of momentum, impulsive torque) have been imparted to a rigid body. Let the first one of these be designated by the letter \mathbf{p} , the latter by \mathbf{M} .

\mathbf{p} is calculated as a sum over all linear momenta $d\mathbf{p} = \mathbf{v} dm$, i.e.,

$$(1) \quad \mathbf{p} = \int d\mathbf{p} = \int \mathbf{v} dm.$$

With the help of Eq. (22.7) we get

$$\mathbf{p} = \mathbf{u} \int dm + \boldsymbol{\omega} \times \int \mathbf{r} dm$$

or, with introduction of the radius vector \mathbf{R} from O to the center of mass, cf. (22.11a),

$$(2) \quad \mathbf{p} = m\mathbf{u} + m\boldsymbol{\omega} \times \mathbf{R}.$$

In particular, if we choose $O = G$, we have $\mathbf{R} = 0$ and

$$(3) \quad \mathbf{p} = m\mathbf{u}.$$

The angular momentum \mathbf{M} of the rigid body, on the other hand, is composed of the moments of all the elements of linear momentum taken about the common reference point O . We therefore have

$$(4) \quad \mathbf{M} = \int \mathbf{r} \times d\mathbf{p} = \int dm (\mathbf{r} \times \mathbf{v}),$$

from which, because of (22.7) and (22.11a),

$$(5) \quad \mathbf{M} = \int dm (\mathbf{r} \times \mathbf{u}) + \int dm \mathbf{r} \times (\boldsymbol{\omega} \times \mathbf{r}) = m\mathbf{R} \times \mathbf{u} + \int dm \mathbf{r} \times (\boldsymbol{\omega} \times \mathbf{r}).$$

The first term on the right vanishes for $O = G$ as well as for $\mathbf{u} = 0$, so that in both these cases

$$(6) \quad \mathbf{M} = \int dm \mathbf{r} \times (\boldsymbol{\omega} \times \mathbf{r}).$$

In order to evaluate this integral we remind the reader of the vector rule for the triple cross-product, valid for any three vectors \mathbf{A} , \mathbf{B} , \mathbf{C} ,

$$(7) \quad \mathbf{A} \times (\mathbf{B} \times \mathbf{C}) = \mathbf{B}(\mathbf{A} \cdot \mathbf{C}) - \mathbf{C}(\mathbf{A} \cdot \mathbf{B}).$$

It follows that

$$\mathbf{r} \times (\boldsymbol{\omega} \times \mathbf{r}) = \boldsymbol{\omega} r^2 - \mathbf{r}(\boldsymbol{\omega} \cdot \mathbf{r})$$

and therefore, taking the x -component as example,

$$\begin{aligned} (8) \quad M_x &= \int [\mathbf{r} \times (\boldsymbol{\omega} \times \mathbf{r})]_x dm \\ &= \omega_x \int (x^2 + y^2 + z^2) dm - \omega_y \int x y dm - \omega_z \int x z dm. \end{aligned}$$

By introducing the moments and products of inertia from (22.12a), we can then write (6) in the form

$$\begin{aligned} (9) \quad M_x &= I_{xx}\omega_x - I_{xy}\omega_y - I_{xz}\omega_z \\ M_y &= -I_{yx}\omega_x + I_{yy}\omega_y - I_{yz}\omega_z \\ M_z &= -I_{zx}\omega_x - I_{zy}\omega_y + I_{zz}\omega_z. \end{aligned}$$

We have thus arrived at a linear relation between the dynamic vector \mathbf{M} and the kinematic vector $\boldsymbol{\omega}$; this relation is achieved by means of the tensor I of Eq. (22.13b). We therefore say that \mathbf{M} is a "linear vector function" of $\boldsymbol{\omega}$. Such linear vector functions play an important role in all aspects of the tensor calculus, especially in the theory of elasticity (cf. Vol. II, this series).

Eqs. (9) can be put into instructive form if we make use of expression (22.12b) for the kinetic energy of rotation. For then we simply have

$$(10) \quad M_i = \frac{\partial T_{\text{rot}}}{\partial \omega_i}, \quad i = x, y, z.$$

Notice, moreover, that this expression is valid not only for the case $O=G$ or $\mathbf{u}=0$ presupposed in (9), but also for $\mathbf{u} \neq 0$ and arbitrary position of O . For in the more general case one need only complete expression (22.12b) for T_{rot} by adding expression (22.11) for T_m , so that the term

$$\frac{\partial T_m}{\partial \omega_i} = m(\mathbf{R} \times \mathbf{u})_i$$

will be added on the right of Eq. (10). But this is the same term which appears on the right side of Eq. (5) for \mathbf{M} whenever O and G do not coincide. Since, finally, the total kinetic energy T differs from $T_{\text{rot}} + T_m$ only by the term T_{transl} independent of $\boldsymbol{\omega}$ [cf. (22.9) and (22.10)], we can generalize (10) in the form

$$(10a) \quad M_i = \frac{\partial T}{\partial \omega_i}, \quad i = x, y, z$$

valid for arbitrary position of O .

What has been said of the angular momentum \mathbf{M} is also valid for the

linear momentum \mathbf{p} . Here we consider at once the general case $O \neq G$ and from Eqs. (22.9), (22.10) and (22.11) form

$$\frac{\partial T}{\partial u_i} = m u_i + m(\boldsymbol{\omega} \times \mathbf{R})_i$$

which is in agreement with Eq. (2) for \mathbf{p} . The equation complementary to (10a) is therefore

$$(11) \quad p_i = \frac{\partial T}{\partial u_i}, \quad i = x, y, z.$$

Eqs. (10a) and (11) are special cases of a much more general relationship connecting momentum and velocity coordinates of an arbitrary mechanical system. The proof of this must be postponed to Chapter VI, § 36. Here we shall only concern ourselves with the geometrical meaning of Eq. (10), which leads us to the celebrated geometrical construction of Poinsot. The *Poinsot method* tells us how to find the position of the axis of angular momentum \mathbf{M} with reference to a given axis of rotation. The same can be said of this method as of the foregoing equations, namely, that it is not restricted to the case of the rigid body, but is applicable whenever one deals with a symmetric tensor; one represents this tensor by means of a tensor surface of second degree, and asks for the linear vector function given by means of this tensor.

The Poinsot construction runs as follows: from the center O of the momental ellipsoid we lay off the angular velocity vector $\boldsymbol{\omega}$ and construct the tangent plane to the ellipsoid at the point where $\boldsymbol{\omega}$ intersects it. The perpendicular from O to this tangent plane gives the direction of \mathbf{M} . As proof we need merely recall that for an arbitrary surface $f(\xi, \eta, \zeta) = \text{const.}$, the direction cosines of the normal to the tangent plane are proportional to

$$(12) \quad \frac{\partial f}{\partial \xi}, \frac{\partial f}{\partial \eta}, \frac{\partial f}{\partial \zeta}.$$

In our case $f(\xi, \eta, \zeta) = \text{const.}$ is the equation (22.15) of the momental ellipsoid and its derivatives with respect to ξ, η, ζ are indeed proportional to the components of \mathbf{M} of Eq. (9).

We may also interpret the Poinsot construction as the direct geometrical expression of our Eq. (10), for the momental ellipsoid is essentially identical to the surface $T_{\text{rot}} = \text{const.}$

Our Figs. 42a, b represent the case of the symmetrical momental ellipsoid, where $\boldsymbol{\omega}$, \mathbf{M} and the axis of symmetry ("axis of figure") \mathbf{f} are coplanar; so that the tangent plane can be represented as the tangent to the cross-section of the ellipse in this plane. In the prolate ellipsoid of

revolution (i.e., spheroid), Fig. 42b, \mathbf{M} and \mathbf{f} , the axis, lie on opposite sides of $\boldsymbol{\omega}$; in the oblate spheroid of Fig. 42a, \mathbf{M} lies between \mathbf{f} and $\boldsymbol{\omega}$. The case of the ellipsoid with three unequal axes presents a more difficult graphical problem.

In conclusion we emphasize that the relations discussed in this section are basically nothing but expressions of the Newtonian definition, "the quantity of motion is the measure of the same, arising from the velocity and the quantity of matter conjointly," extended to the rigid body. The reason why our present relations are so much more involved than the one between momentum and velocity of a single particle is that in particle mechanics the "quantity of matter," i.e., the mass, is a *scalar*, whereas in the case of the rigid body the moment of inertia that takes its place is a *tensor*.

FIG. 42. Poincaré construction giving the relative position of angular velocity $\boldsymbol{\omega}$ and angular momentum \mathbf{M} for the two cases where the momental ellipsoid degenerates into a) an oblate spheroid, b) a prolate spheroid.

§ 25. Dynamics of a Rigid Body. Survey of its Forms of Motion

Let us first consider the rigid body moving freely in space. As reference point we choose its center of mass, and reduce all the forces acting on the body to forces acting on this point, in agreement with the prescription of § 23. We need then only deal with a single resultant force \mathbf{F} and a resultant torque \mathbf{L} . The equations of motion are the equations of momentum and of moment of momentum of § 13; they read

$$(1) \quad \dot{\mathbf{p}} = \mathbf{F},$$

$$(2) \quad \dot{\mathbf{M}} = \mathbf{L}.$$

Since the rigid body possesses but six degrees of freedom, these two vector equations suffice for the complete description of its state of motion.

Eqs. (1) and (2) can be treated separately whenever \mathbf{F} is independent of the angular velocity and \mathbf{L} independent of the translational velocity. In ballistics, for instance, this is not the case. If it is the case, (1) becomes a problem of pure particle mechanics, (2) a problem of rotation about a fixed point or, as we shall say for brevity, a "problem of the spinning top."

At this point we shall be interested principally in the latter. With the choice of reference point made above, we can disregard the force of

gravity since it has no moment about the mass center. If, furthermore, we neglect air resistance, friction and the like, we are confronted with the problem of the *spinning top under no forces*. Thus the gyroscope in a Cardan suspension (cf. Fig. 47) is a top under no forces provided we can neglect the mass of the gimbals in comparison with that of the flywheel, which is approximately valid in the usual constructions. Otherwise we would be confronted with a considerably more involved mathematical problem.

We shall also deal with rotation about a fixed point other than the mass center. As remarked on p. 122, it is then advisable to take this fixed point as reference point O and introduce the gravitational moment L acting about it. In that case we speak of a *heavy top*. Subsecs. 4 and 5 are devoted to its discussion.

We shall postpone the complete analytical treatment of the top under no forces until the following section, where we shall become acquainted with the tool provided by *Euler's equations*. The complete treatment of the heavy top — to the extent to which it can be carried through at all — must be postponed even further, namely to § 35. There we shall have at our command the yet more powerful method of the *generalized Lagrange equations*.

For the top under no forces Eq. (2) yields $\dot{M}=0$. This can be integrated at once to yield

$$(3) \quad M = \text{const.}$$

The angular momentum of a top under no forces is constant in magnitude and spatial direction. This statement completely parallels Galileo's law of inertia, but in general does not lead to an expression for velocity and position in space which is as simple as in the other case.

(1) The Spherical Top Under No Forces

Only in the case of a spherical momental ellipsoid do we have $M = I\omega$, from which $M = \text{const.}$ leads to $\omega = \text{constant}$. The axis of rotation is in permanent coincidence with the fixed axis of angular momentum. Each point of the body, no matter what the external shape of the same (cf. Fig. 40c, for instance), describes a circle about this axis with constant velocity.

(2) The Symmetrical Top Under No Forces

Here a simple rotational motion occurs only if the direction of M coincides with one of the principal axes, that is, either with the axis of the body or an equatorial axis. The *general* form of motion of the symmetrical top under no forces is the so-called *regular precession*.

We explain this form of motion with the aid of Fig. 43. We have drawn the axis of the angular momentum, which is fixed in space, vertically upward; let M be the point at which it intersects a unit sphere described about the center of the momental ellipsoid. Call R and F the points of intersection of this sphere and the axes of rotation and of symmetry at an arbitrary instant. Since by the Poinsot method these three axes lie in a meridian plane through F , the three points M , R and F are located on a great circle passing through the fixed point M ; in the case of a momental oblate spheroid, which we shall postulate for definiteness, M is situated between F and R . At any instant the motion consists of a rotation about OR . In this process F advances normally to the arc of the great circle just mentioned. The angular distance between F and M is not changed thereby; thus we can draw the instantaneous path of F as a short arc of a circle of latitude about M (arrow at the left in Fig. 43). Now R too must change its position — it must move to the great circle defined by M and the new position of F . In this motion the angular distance between M and R is conserved, since it is determined by the Poinsot construction. Thus R , too, advances on the arc of a circle of latitude about M (arrow at right of Fig. 43). The relative position of points F , M , and R is now the same as initially, so that our process of reasoning can be repeated. It follows that *axes of symmetry and rotation each describe a circular cone about the spatially fixed angular momentum, each cone being traced with constant angular velocity;*

FIG. 43. Regular precession of the symmetrical top under no forces.

the latter because the angular velocity is completely determined by the magnitude of M and its position with respect to the momental ellipsoid. Thus the character of the regular precession has been fully described.

The same applies of course to a momental prolate spheroid, with the only difference (cf. Fig. 42b) that R would now be located between F and M .

(3) The Unsymmetrical Top Under No Forces

The form of motion of the symmetrical top just derived could have been described with more brevity, but less clarity of detail, as follows:

through the terminus of the angular momentum vector M we pass the "invariable plane" ϵ (cf. p. 73) normal to M . About the origin of M we construct the ellipsoid of twice the kinetic energy ("Poinset ellipsoid") which is similar to the momental ellipsoid. The Poinset ellipsoid is tangent to ϵ^3 , and the point of tangency is the terminus of the angular velocity vector ω . The instantaneous motion of the top consists of a rotation of this ellipsoid about ω . In this process the ellipsoid rolls without slipping on the plane ϵ^4 . If the Poinset ellipsoid is one of revolution, the curve of the point of tangency becomes a circle about M ; the cones described by ω ("space cone") and the axis of figure therefore become circular cones. Thus we have again the regular precession of the top.

The same construction now leads at once to the Poinset picture of the force-free motion of a general ("unsymmetrical") top of three distinct principal moments of inertia. Again we let the Poinset ellipsoid roll on the invariable plane ϵ (cf. footnote 3 below). Now the curve of contact is no longer a circle, but a transcendental curve which in general does not close on itself. Similarly the cones which describe the motion of the axis of rotation and of the body "axis" in space are now transcendental cones. The analysis of the unsymmetrical top, even when under no forces, leads to elliptic integrals [cf. § 26, (3)], while that of the symmetrical top under no forces requires only elementary functions. Of course even for the unsymmetrical top a pure rotation about one of the three principal axes is a steady rotation whose representation is elementary.

(4) The Heavy Symmetrical Top

Here we shall not treat the spherical top separately, since its motion is hardly simpler than that of the symmetrical top.

For the heavy symmetrical top the fixed point O (point of support in the socket) no longer coincides with the center of mass G (located on the axis of symmetry); call s the distance OG . The magnitude of the gravitational torque is then

$$(4) \quad |L| = mgs \sin \theta,$$

where θ is the angle between the vertical and the axis of figure. L is normal to the vertical and to the axis of symmetry or, in other words, it lies along the line of intersection of the horizontal plane with the equatorial plane of the momental ellipsoid. This line of intersection is called the *line of nodes*,

³ This follows from the Poinset construction of p. 132 and from Eq. (26.17a) soon to be encountered.

⁴ Rolling without sliding is equivalent in meaning to the equality of the rate of change of the angular velocity vector ω as observed from space and from the body. In this connection refer to Eq. (26.8a), where this equality is proved.

a term borrowed from astronomy. For a more precise definition of signs refer to p. 141.

Our general Eq. (2) can no longer be integrated immediately as in the case of a top under no forces; rather, the angular momentum is subject to continuous change given by the law

$$(5) \quad d\mathbf{M} = \mathbf{L} dt.$$

Thus the infinitesimal vector $\mathbf{L} dt$ adds to the vector \mathbf{M} at any given instant t to give the angular momentum at $t+dt$. The terminus of \mathbf{M} advances in the direction of the instantaneous line of nodes, i.e., normal to the vertical and the axis of symmetry. From this it follows that the projections of \mathbf{M} on the vertical as well as on this axis must be constant. Let us call the two constants

$$(6) \quad M' = M_{\text{vert}} \text{ and } M'' = M_{\text{sg}}.$$

The two quantities M' and M'' , which can be prescribed arbitrarily, are two constants of integration of the equations of motion.

A third constant is that of total energy E . Corresponding to Eq. (6.18) we have the gravitational potential energy

$$(6a) \quad V = mgs \cos \theta$$

so that

$$(7) \quad T + mgs \cos \theta = E.$$

In order to pass to an analytical description of the motion we must express T and the projections of \mathbf{M} mentioned in (6) in terms of suitable position parameters of the top (the Eulerian angles); this will be carried out in § 35. The calculation of the motion is there shown to lead to elliptic integrals.

The *regular precession* is now no longer the general form of motion as in the case of the top under no forces, but only results for specially chosen values of M' , M'' and E . The precessional motion usually observed with a heavy top excited in the customary way appears to be — but is not — regular; it can be called *pseudo-regular precession*. Finally a *pure rotation* about the vertically oriented axis of figure is also a possible (stable or unstable) form of motion, no matter what the magnitude of ω .

So far we have considered only the equation of angular momentum (2). We must throw a quick glance at the equation of linear momentum (1). Its right member consists of the force \mathbf{F} acting at the fixed point O , which is composed of the force of gravity $m\mathbf{g}$ acting vertically downward, and the

reaction of the support, F_{sup} . The change in momentum in the left member is

$$\dot{\mathbf{p}} = m \frac{d}{dt} (\boldsymbol{\omega} \times \mathbf{R}) = m \dot{\mathbf{V}}$$

from Eq. (24.2) with $\mathbf{u}=0$, where \mathbf{V} is the velocity of the center of mass. Eq. (1) then makes the simple statement that

$$F_{\text{sup}} = m(\dot{V} - g).$$

In other words, the law of linear momentum demands that at any given instant the support furnish a force equal to the mass of the top \times the acceleration of the mass center diminished by the gravitational acceleration.

(5) The Heavy Unsymmetrical Top

In spite of the efforts of many great mathematicians, all attempts to integrate the differential equations of this problem in the most general form have failed so far. Among the integrals of angular momentum (6) the first remains in effect, to be sure, because even here the gravitational torque acts about a horizontal axis so that the terminus of the vector \mathbf{M} remains in a horizontal plane fixed in space. The second integral (6) is, however, invalidated, because it is based on the symmetry of the momental ellipsoid. Of course the energy integral (7) is valid also for a general momental ellipsoid.

The soluble special cases of the problem postulate either a particular mass distribution or a particular form of motion.

The best-known case is that of Kowalewski. The momental ellipsoid is here assumed to be symmetrical; the center of mass no longer lies on the axis of the body, but in the equatorial plane defined as the plane perpendicular to the axis and passing through the fixed point; in addition it is required that the moment of inertia about the axis of the body be one half the equatorial one. In that case the form of motion need not be restricted.

The case of Staudé concerns the question as to which axes can serve as axes of steady rotation when directed vertically. It turns out that these axes lie in the body on a cone of second degree which, in addition to the three principal axes, contains also the axis through the center of mass. To each axis belongs a (to within a sign) definite angular velocity. Neither mass distribution nor position of the center of mass need be specialized in this problem.

The case of Hesse, finally, is concerned with the analogue to the simple motion of a pendulum (spherical pendulum or, in particular, ordinary pendulum). For such motion the mass center must lie on a certain axis in the momental ellipsoid, and the initial excitation must be of proper form,

just as in the case of the symmetrical top, whose mass center describes a pure pendulum motion only if the initial angular momentum has no component along the axis of symmetry.

§ 26. Euler's Equations.

Quantitative Treatment of the Top Under No Forces

(1) Euler's Equations of Motion

We distinguish between a reference system x, y, z fixed in space and a second one, X, Y, Z fixed in the body. In the (x, y, z) -system the angular momentum for motion under no forces has an invariable position: $\mathbf{M} = \text{constant}$ [Eq. (25.3)]; seen from the body, the position of \mathbf{M} varies continuously. We want to study the law of this variation.

Let us therefore focus our attention on a point P fixed in the body, and a point Q fixed in space, the two points being momentarily in coincidence. Let \mathbf{v} be the velocity of P in space, \mathbf{V} that of Q in the body. According to the kinematic Eq. (22.4), $\mathbf{v} = \boldsymbol{\omega} \times \mathbf{r}$. As seen from the body, Q moves with equal but opposite velocity to that of P as seen from space, so that

$$\mathbf{V} = -\boldsymbol{\omega} \times \mathbf{r} = \mathbf{r} \times \boldsymbol{\omega}.$$

In tabular form we have

	Seen from Space	Seen from Body
P	$\mathbf{v} = \boldsymbol{\omega} \times \mathbf{r}$	$\mathbf{V} = 0$
Q	$\mathbf{v} = 0$	$\mathbf{V} = \mathbf{r} \times \boldsymbol{\omega}$

For point Q we choose the spatially fixed terminus of the vector \mathbf{M} and hence write

$$\mathbf{r} = \mathbf{M}, \quad \mathbf{V} = \frac{d\mathbf{M}}{dt}.$$

Thus $\frac{d\mathbf{M}}{dt}$ means "change in the body" (we called the change in space $\dot{\mathbf{M}}$; it is equal to zero here).

From the second line of our table we then read off

$$(1) \quad \frac{d\mathbf{M}}{dt} = \mathbf{M} \times \boldsymbol{\omega}.$$

This completes the derivation of *Euler's equations for a rotating body under no forces*.

We shall rewrite them in terms of their components in the (X, Y, Z) -system. We shall call $\omega_1, \omega_2, \omega_3$ the components of ω , and M_1, M_2, M_3 those of M . Eq. (1) yields

$$\begin{aligned} \frac{dM_1}{dt} &= M_2 \omega_3 - M_3 \omega_2, \\ (2) \quad \frac{dM_2}{dt} &= M_3 \omega_1 - M_1 \omega_3, \\ \frac{dM_3}{dt} &= M_1 \omega_2 - M_2 \omega_1. \end{aligned}$$

The system of the X, Y, Z is so far completely arbitrary. If, now, we take the directions X, Y, Z along the principal moments of inertia of Eq. (22.15a) and call these I_1, I_2, I_3 , we obtain, by virtue of the general relation (24.9),

$$(3) \quad M_1 = I_1 \omega_1, \quad M_2 = I_2 \omega_2, \quad M_3 = I_3 \omega_3;$$

and (2) takes the simple form

$$\begin{aligned} I_1 \frac{d\omega_1}{dt} &= (I_2 - I_3) \omega_2 \omega_3, \\ (4) \quad I_2 \frac{d\omega_2}{dt} &= (I_3 - I_1) \omega_3 \omega_1, \\ I_3 \frac{d\omega_3}{dt} &= (I_1 - I_2) \omega_1 \omega_2. \end{aligned}$$

It is these remarkably symmetrical and elegant equations one usually thinks of when one speaks of Euler's equations.

Let us now extend them to include the case that an external torque L is in effect. In that case the terminus of M is no longer fixed in space, but, according to (25.2), has the velocity $v = L$.

As seen from the body, our point Q now moves with a velocity composed of $v = L$ and $V = r \times \omega$. It follows that Eq. (1) must be changed to

$$(5) \quad \frac{dM}{dt} = M \times \omega + L$$

and the components of L with respect to X, Y, Z must be added to the right members of (2) and (4). This yields *Euler's equations of motion for a rigid body with a fixed point*.

We shall write these equations explicitly only for the case of the heavy symmetrical top, where L acts about the line of nodes and, from (25.4), has the magnitude

$$|L| = mgs \sin \theta.$$

In order to dispel all ambiguities contained in the meaning of the words vertical, axis of symmetry, line of nodes, we agree that

the positive side of the spatially fixed z -axis points up and defines the vertical;

the positive side of the Z -axis passes through the mass center and defines the axis of symmetry; it makes an angle θ with the vertical;

the line of nodes is the semi-infinite line normal to the positive z - and Z -axes and in the direction of advance of a right-handed screw as θ increases.

We further specify that the distance s is to be a positive quantity. Call ϕ the angle which the line of nodes makes with the positive X -axis. The components of L with respect to X, Y, Z are then given by

$$(5a) \quad mgs \sin \theta \cos \phi, \quad -mgs \sin \theta \sin \phi, \quad 0$$

respectively, and with $I_1 = I_2$ equations (4) go over into

$$(6) \quad \begin{aligned} I_1 \frac{d\omega_1}{dt} &= (I_1 - I_3) \omega_2 \omega_3 + mgs \sin \theta \cos \phi \\ I_1 \frac{d\omega_2}{dt} &= (I_3 - I_1) \omega_3 \omega_1 - mgs \sin \theta \sin \phi \\ I_3 \frac{d\omega_3}{dt} &= 0. \end{aligned}$$

The last equation shows that for the heavy symmetrical top (and therefore *a fortiori* for one under no forces) we have

$$(7) \quad I_3 \omega_3 = M_3 = \text{const.},$$

which we already knew. We see at the same time that Euler's equations are not suited for a further integration for the heavy top, since as yet we are ignorant of the relation between the ω_1, ω_2 and the θ, ϕ .

As far as the $\omega_1, \omega_2, \omega_3$ are concerned, we wish to emphasize very strongly that they are not velocities in the ordinary sense, i.e., not derivatives with respect to time of spatial measurements of some sort. Indeed, in view of the expression defined on p. 50, we can aptly designate them as "non-holonomic velocity components."

We shall finally write (5) in a somewhat different form. Since \mathbf{v} is the velocity as seen from space, we can generalize our expression by substituting $\mathbf{v} = \dot{\mathbf{M}}$ for $\mathbf{v} = \mathbf{L}$. We thus obtain

$$(8) \quad \dot{\mathbf{M}} = \frac{d\mathbf{M}}{dt} + \boldsymbol{\omega} \times \mathbf{M},$$

an equation which, by the analysis of p. 139, is valid for all (axial or polar)

vectors. If, specifically, we apply it to the angular velocity vector ω , it simply yields

$$(8a) \quad \dot{\omega} = \frac{d\omega}{dt}.$$

For the angular velocity vector ω and only for this vector the spatial change is equal to the change as judged from the body. It is this rule to which we referred in the footnote on p. 136.

(2) Regular Precession of the Symmetrical Top Under No Forces and Euler's Theory of Polar Fluctuations

We need not say any more about the spherical top. Its general motion is a pure rotation about an axis fixed in the body. This follows at once from Eqs. (4) if we put $I_1 = I_2 = I_3$. As we know from § 25, subsec. 1, this axis is at the same time fixed in space and coincides with the angular momentum direction.

Let us now turn to the symmetrical top, $I_1 = I_2 \neq I_3$. The third Eq. (4) yields

$$\omega_3 = \text{const.}$$

as we already know from Eq. (7). The first two equations are

$$(9) \quad \begin{aligned} I_1 \frac{d\omega_1}{dt} &= (I_1 - I_3) \omega_2 \omega_3 \\ I_1 \frac{d\omega_2}{dt} &= (I_3 - I_1) \omega_1 \omega_3 \end{aligned}$$

It is convenient to consolidate them into one by introducing a complex variable. Multiply the second equation by i and add to the first to obtain

$$(10) \quad I_1 \frac{ds}{dt} = i(I_3 - I_1) s \omega_3, \quad s = \omega_1 + i\omega_2.$$

Let us abbreviate this by putting

$$(11) \quad \alpha = \frac{I_3 - I_1}{I_1} \omega_3,$$

so that an integration of (10) gives

$$(12) \quad s = s_0 e^{i\alpha t}, \quad s_0 = \text{constant of integration.}$$

s is the projection of the angular velocity vector ω on the equatorial plane of the top, if we use this plane as the complex plane of s . Eq. (12) states that this projection describes a circle of radius s_0 with the constant angular velocity α . At the same time the total angular velocity vector

ω describes a circular cone about the axis of figure. The vertex angle β of the cone is given by

$$(12a) \quad \tan \beta = \frac{(\omega_1^2 + \omega_2^2)^{\frac{1}{2}}}{\omega_3} = \frac{|\omega_2|}{\omega_3}.$$

This is the picture of the regular precession which is seen by an observer located on the top. (To an observer fixed in space the axis of the top rotates of course about the instantaneous axis of rotation which, as we saw earlier describes in its turn a circular cone about the spatially fixed angular momentum vector M .) Since it is our intention to apply the foregoing to the earth, the viewpoint of the observer located on the top rather than that of the one fixed in space will be useful, as it corresponds to the viewpoint of a human being located on the earth.

The earth is a top whose momental ellipsoid is an oblate spheroid. We call the *geometric North Pole* the point at which the axis of symmetry pierces the surface of the earth; it is, in general, distinct from the *celestial North Pole* which is the point at which the angular velocity vector cuts through the earth's surface. According to the Euler theory reproduced above, the celestial North Pole describes a circle about the geometric North Pole, a phenomenon called *Eulerian motion*. Inasmuch as it is the path of the rotational pole, this circle is also referred to as the *polhode*.

A suitable measure of the flattening of the earth is the so-called ellipticity

$$(13) \quad \frac{I_2 - I_1}{I_1} \sim \frac{1}{300}.$$

The angular velocity of the earth is determined by the length of the day; we have

$$(14) \quad \omega_3 \sim \omega = \frac{2\pi}{\text{day}}$$

from which, according to (11),

$$(15) \quad \alpha = \frac{I_2 - I_1}{I_1} \omega_3 = \frac{2\pi}{300} \text{ day}^{-1}.$$

Thus Euler's period for the precession amounts to

$$(16) \quad \frac{2\pi}{\alpha} = 300 \text{ days} = 10 \text{ months}.$$

We are accustomed to think of the axis of rotation of the earth as fixed in the globe and passing through the geometrical poles. This is not rigorously true. Every movement of mass on the earth along a longitude

must change the position of the axis of rotation⁵, and every movement of mass along a circle of latitude must change the angular velocity, that is, the length of the day; both changes are a result of the law of conservation of angular momentum. Let us imagine that this movement has ceased and that the celestial pole is deviated from the geometric one. In that case the axis of rotation would, by virtue of the Eulerian motion, commence a circular motion about the geometric pole.

Let us now compare our theoretical results with the observations of polar fluctuations, which have been gathered by international cooperation. In Fig. 44 we have sketched the polhode obtained between the years 1895 and 1900.

FIG. 44. Polar fluctuations between the years 1895 and 1900. Confirmation of Chandler's period.

The average deviation of the celestial pole, i.e., the mean radius of Euler's circle, amounts to about $\frac{1}{2}''$ of arc or 4 meters on the earth's surface,

according to observations between these years. But instead of a period of 10 months we have, according to Fig. 44, $3\frac{1}{2}$ complete revolutions for the four years 1896–1900, which corresponds to a period of 14 months.

The fourteen-month period is called Chandler's period after its discoverer. Its explanation lies in the elastic deformations that the earth suffers as a result of the changed centrifugal effect caused by polar fluctuations. The modulus of elasticity of the earth compares in magnitude to that of steel.

The observed polhode, as drawn in Fig. 44, can now be explained as a superposition of 1) fluctuations occurring with Chandler's period, 2) annual fluctuations evidently of meteorological origin, and 3) deviations at irregular intervals which may point to isolated and unrelated mass transports. No trace remains of Euler's ten-month period which was derived by assuming the earth to be an ideal rigid body.

⁵ The terrestrial mass transport most important for this effect seems to be the yearly migration of the air pressure maximum from the continent of Asia to the Pacific Ocean and back.

In agreement with usage in gyroscopic theory we have here described the motion of the earth's axis first investigated by Euler as a "precession under no forces." We have thus usurped a word having an entirely different meaning in astronomical usage. There, "precession" denotes a slow rotation of the earth's axis about the normal to the ecliptic which causes an advance of the equinoctial points of $50''$ per year. This *precession of the equinoxes* has a period of $\frac{360^\circ}{50''} = 26,000$ years. Instead of "precession of the equinoxes" we could also speak of an "advance of the line of nodes" (line of inter-section of the plane of the ecliptic with the equatorial plane of the earth); as mentioned earlier, our designation, "line of nodes," was borrowed from astronomy.

The precession of the equinoxes is not a free one, but rather a motion forced on the global top by the joint effect of the attractions of sun and moon.

We shall clarify this effect by means of Fig. 45, where we have, at least qualitatively, anticipated the theory of the heavy symmetrical top.

FIG. 45. Precession of the earth's axis, called "precession of the equinoxes."

The diagram shows the plane of the ecliptic on which a circle is drawn. One should think of the circumference of this circle as being uniformly "smeared" with the masses of sun \odot and moon \circ (actually we should draw two circles, one for the sun and one for the moon⁶; we have fused these two circles into one). The uniform mass distribution represents a time average over the instantaneous positions relative to the earth of sun and moon during their revolutions (in the sense of a Gaussian perturbation method). We justify the taking of this time average by the experimental fact that the periods of sun and moon are very small compared with the precession period mentioned above, so that this precession can in no way

⁶ As a matter of fact the moon is so close to the earth that its effect is about twice as great as that of the sun.

depend on the instantaneous positions of sun and moon. At the center of the $\odot + \rangle$ circle we see a cross-section of the earth with its two protuberances at the equator. Only these latter have a part in the phenomenon in question; for the attraction of the $\odot + \rangle$ ring tends to pull the two protuberances into the plane of the ecliptic, an effect which is intuitively almost obvious. We therefore have a torque about the line of nodes N in the sense of the arrow drawn about N . Now this torque is of the same type as the gravitational torque acting on a top whose mass center lies below the fixed point of support. The result is therefore similar to that in the case of the top. Rather than yield to the torque the axis of figure "escapes" in a perpendicular direction and describes a cone of precession about the vertical, here the normal to the ecliptic.

To be sure, the *regular* precession is only a special form of motion of the heavy top (cf. p. 137); under the present circumstances one would therefore expect the more general *pseudo-regular* precession consisting of a regular precession on which small "nutations" are superposed. Now these small nutations are nothing but the conical oscillations of the axis of figure occurring under no forces, hence, in our case, the polar fluctuations that take place with the period of Euler (or that of Chandler, obtained from the former by global deformation). The pseudo-regular precession to be expected is thus obtained from the precession of the equinoxes by addition of the Eulerian nutations occurring in the absence of forces.

Here we must once more apologize for the ambiguous use of a term. In astronomy one understands by nutation not a *free* fluctuation of the earth's axis, but one *forced* on it by the motion of the moon. Contrary to our preceding assumption in Fig. 45, the orbital plane of the moon does not coincide with that of the ecliptic, but is tilted at an angle of 5° with respect to it. Under joint action of sun and earth its normal too describes a cone of precession about the normal to the ecliptic. This precession is tantamount to a *recession of the lunar nodes* (intersection of moon's orbit with ecliptic) which, however, occurs at a much livelier rate than the advance of the line of nodes of the earth, viz., in $18\frac{1}{2}$ years. It is understandable that the earth's axis is in its turn implicated in this precession; the recession of the lunar nodes results in the *astronomical nutation of the earth's axis*, which takes place with the same period.

(3) Motion of an Unsymmetrical Top Under No Forces. Examination of its Permanent Rotations as to Stability

We turn to the integration of Eqs. (4) in the case $I_1 \neq I_2 \neq I_3$. Multiplication of these equations by ω_1 , ω_2 , ω_3 and addition yields

$$I_1 \omega_1 \frac{d\omega_1}{dt} + I_2 \omega_2 \frac{d\omega_2}{dt} + I_3 \omega_3 \frac{d\omega_3}{dt} = 0$$

or, integrated,

$$(17) \quad \frac{1}{2}(I_1 \omega_1^2 + I_2 \omega_2^2 + I_3 \omega_3^2) = \text{const.} = E.$$

E is the energy constant, and the left member is the kinetic energy, in agreement with Eq. (22.12b) specialized to principal axes. Instead of (17) one can evidently also write

$$(17a) \quad E_{\text{kin}} = \frac{1}{2} \mathbf{M} \cdot \boldsymbol{\omega}.$$

We can instead multiply Eqs. (4) by $I_1 \omega_1$, $I_2 \omega_2$, $I_3 \omega_3$; addition once more yields zero on the right. The result of the integration can be written

$$(18) \quad (I_1 \omega_1)^2 + (I_2 \omega_2)^2 + (I_3 \omega_3)^2 = \text{const.} = |\mathbf{M}|^2.$$

On the left we have the sum of the squares of the angular momentum components. This sum, as we know, remains invariant in the absence of forces, even if the components themselves vary in the course of the motion.

In (17) and (18) we have two linear homogeneous equations for ω_1^2 , ω_2^2 , ω_3^2 , from which we can, for instance, solve for ω_2^2 and ω_3^2 in terms of ω_1^2 :

$$(19) \quad \begin{aligned} \omega_2^2 &= \beta_1 - \beta_2 \omega_1^2, & \beta_1 &= \frac{2EI_2 - |\mathbf{M}|^2}{I_2(I_2 - I_1)}, & \beta_2 &= \frac{I_1(I_3 - I_1)}{I_2(I_2 - I_1)}, \\ \omega_3^2 &= \gamma_1 - \gamma_2 \omega_1^2, & \gamma_1 &= \frac{2EI_3 - |\mathbf{M}|^2}{I_3(I_3 - I_1)}, & \gamma_2 &= \frac{I_1(I_3 - I_1)}{I_3(I_3 - I_1)}. \end{aligned}$$

If we replace these values of ω_2 and ω_3 in the first Eq. (4), we have

$$(20) \quad \frac{d\omega_1}{[(\beta_1 - \beta_2 \omega_1^2)(\gamma_1 - \gamma_2 \omega_1^2)]^{\frac{1}{2}}} = \frac{I_2 - I_3}{I_1} dt.$$

t is therefore an elliptic integral of the first kind in ω_1 (cf. p. 100); function theory allows us to state conversely that ω_1 is an elliptic function of the time. The same holds of course for ω_2 and ω_3 .

We furthermore deduce from Eqs. (17) and (18) that the polhode cone or *body cone* is no longer a circular cone as in the case of the symmetrical top, but a cone of fourth degree.

We shall finally consider the rotations of the unsymmetrical top about one of its three principal axes which, as we know [cf. § 25, toward end of (3)], are steady rotations. Let us, for definiteness, put

$$A > B > C.$$

We shall show that the rotations about the axes of the *greatest* and *smallest* principal moment of inertia are stable, those about the axis of the *intermediate*

principal moment are unstable. We choose Eqs. (17) and (18) as starting point. It will be convenient in connection with the diagrams below to rewrite these in terms of the angular momentum components M_1, M_2, M_3 ,

$$(21a) \quad \frac{M_1^2}{I_1} + \frac{M_2^2}{I_2} + \frac{M_3^2}{I_3} = \text{const.},$$

$$(21b) \quad M_1^2 + M_2^2 + M_3^2 = \text{const.} = |M|^2.$$

Eq. (21b) describes a sphere of radius $|M|$, (21a) an ellipsoid with three distinct axes (a "non-degenerate" ellipsoid).

Case 1. Rotation about the longest axis of the ellipsoid (21a). In a pure rotation the sphere is tangent to the ellipsoid from the *outside* at point A , Fig. 46a. A small jolt will in general alter both the sphere and the ellipsoid. The point of tangency A will change to a small curve of intersection which remains, however, in the neighborhood of A . A narrow body cone is the result; the original rotation proves to be stable.

FIG. 46a. Stable rotation of unsymmetrical top about the longest axis of the momental ellipsoid.

The same is true in case 3, rotation about the shortest axis of the ellipsoid (21a). The sphere now lies inside the ellipsoid and is hence tangent to it from the *inside*. A small jolt will again cause the point of tangency to transform into a neighboring curve; again the original rotation is stable.

Case 2. Rotation about the intermediate axis. The sphere *intersects* the ellipsoid in a curve of the fourth degree; its singular point B (foremost point of Fig. 46b) represents the original rotation. If the top is given a small impulse, the curve of intersection splits into two branches. The axis of rotation wanders off along one of these branches and moves further and further from its initial position in the body. The rotation is unstable.

It is instructive to prove this analytically; one proceeds from the differential equations (4). One can show (problem IV.2) that the lateral components generated by a small perturbation of the original rotation satisfy two simultaneous differential equations of first order. These have solutions of trigonometric character in cases 1 and 3, exponential character in case 2 (method of infinitesimal oscillations as stability criterion).

FIG. 46b. Unstable rotation of unsymmetrical top about the intermediate axis of the momental ellipsoid.

Let us perform the following experiment with a (full) matchbox: we hold the box between thumb and forefinger at opposite ends of its shortest edge and flip it into the air, thus imparting to it considerable angular momentum about this shortest edge. We notice that if the box originally shows its label, it will continue to do so throughout the motion. The same phenomenon occurs, though less clearly, if we hold the box at opposite ends of its longest edge, and flip it as before. If, instead, we hold it at opposite ends of the intermediate edge, with the striking surface showing, and repeat the procedure, we shall not see this surface throughout the motion, but rather a distinct change of colors.

Another striking example of instability of a state of motion is the following: occasionally one finds smooth-worn, flat pebbles in nature which, if spun about their vertical axis on a flat support, show stability of motion only for one sense of rotation; if made to spin in the opposite sense, they will start to wobble more and more violently, and finally end up by spinning in the stable direction opposite to their original angular momentum. The same can often be observed with small pocketknives (penknives) set to stand edgewise with blade folded in, when one gives them a gentle impulse.

We can perform a geometrically well-defined, instructive experiment in this connection. Let us take the wooden model of a non-degenerate flat ellipsoid of principal axes a , b , c (a and b much larger than c) and equip it with a heavy metal strip which, in its original position, hugs the upper surface of the ellipsoid in its (ac) -section. The strip can be rotated about the short c -axis, but is clamped down during each experiment. In the position ac the strip does not disturb the symmetry of the mass distribution. Both senses of spin about c are therefore equally stable. Let us now turn the strip by a small angle from this position. The two principal axes of inertia a and b are then each displaced by a small angle γ ; the symmetry of the lower surface facing the plane support is determined by the two principal radii of curvature in the planes ac and bc ; thus the symmetry of this surface remains unchanged. The direction of spin in the sense of the acute angle γ is now geometrically "distinguishable" from that in the opposite sense. Indeed the former is stable, the latter unstable since it is accompanied by rolling motions which increase with time.

A more elegant, though less easily achievable, form of the experiment is the following (G. T. Walker demonstrated it to us at Trinity College, Cambridge, in 1899): the non-degenerate ellipsoid is made of brass sheet; a certain circular region about the point of support has been stamped out and can be moved with respect to the remaining ellipsoidal shell. By a small angular displacement of this circular plug the curvature relations of the lower surface near the point of support are altered with respect to the

inertial distribution of the shell, which remains sensibly unchanged. This alteration is so slight that it passes unnoticed when the ellipsoid is examined. Nevertheless one sense of spin is again preferred to the other.

These experiments with the non-degenerate ellipsoid, while enlightening in themselves, also furnish an adequate substitute for the analytical theory of the phenomenon. Such a theory would have to investigate the rolling oscillations which might accompany the spin in one direction or the other when a small perturbation is superposed on this spin; it would show that the characteristic equation for the frequency of these oscillations has only real roots in the one case, some complex roots in the other. In the first case one would decide that the spin was stable, in the second, that it was unstable, i.e., subject to secular increase of the perturbation. Equations for this treatment are set up in the treatise of Routh (Advanced Part, Art. 241 and ff.) cited in § 42.

§ 27. *Demonstration Experiments Illustrating the Theory of the Spinning Top; Practical Applications*

We begin by describing the well-known device known as *Cardan's suspension*, which affords an unusually effective means of demonstrating the properties of tops and gyroscopes.

FIG. 47. Gyroscope in Cardan's suspension. Axis of rotation of outer ring = vertical, axis of rotation of inner ring = horizontal perpendicular to paper, axis of rotation of gyroscope = horizontal in plane of paper.

The suspension consists of an outer and an inner ring. The outer ring has a vertical axle borne by the outer frame or cage; the inner ring has an horizontal axle with bearings in the outer ring. The flywheel-shaped top revolves with its axis perpendicular to the axis of rotation of the inner ring. Fig. 47 shows the flywheel axle pointing normal to that of the outer ring, which causes the inner ring to lie in a horizontal plane. We shall designate this arrangement of the apparatus as its normal position.

On the axle of the flywheel provision is made for a means by which angular momentum can be imparted to the wheel while in its normal position, with the gimbals at rest. This angular momentum must be so great that all phenomena are essentially dominated by it and the effect of the mass of the gimbals becomes negligible.

In the following experiments a considerable angular momentum and the initial normal position are presupposed.

1. We exert a slight pressure downward on the *inner ring*. This ring does not give way; instead it is the *outer ring* that turns. Thus the axis of the flywheel moves backward or forward in an horizontal plane, depending on the position of the point at which the pressure is exerted. Instead of pressing on the inner ring we can load it unilaterally by means of a small weight. As long as the angular momentum remains sufficiently great, the top then describes a *regular precession* with horizontal axis.

2. We press on the *outer ring*. It remains motionless, whereas the *inner ring* turns upward or downward from its horizontal position depending on the sense in which pressure is exerted on the outer one. We can even deliver a vigorous blow to the outer ring without its yielding noticeably. All one perceives in that case is a rapid conical oscillation of the axis of the top about an axis close to that of the normal position.

3. If the pressure on the outer ring continues so that, with continual rotation of the inner ring, the axis of the top approaches the vertical, we notice that the resistance of the outer ring weakens more and more. One can then without effort set the outer ring spinning rapidly, but only in that sense which corresponds to the direction of the pressure originally exerted on the ring. If one attempts to rotate the outer ring in the opposite sense, the flywheel "rebels"; its axis suddenly tends in the opposite direction, thus causing the inner ring to flip through an angle of 180° . Now we can turn the outer ring without effort in this opposite direction, but another flipping of the top occurs if we return to the original sense of rotation.

4. This is the *tendency of the spins to align parallel to each other* which was emphasized by Foucault. The axis of the top is stable in the vertical position as long as its spin is *homologous* (=in the same sense) to that of the outer ring. If the spins are anti-parallel, this position is, on the contrary, unstable to a high degree and the axis comes to rest only when the opposite direction has been attained; in this latter direction homologous parallelism of the two spin axes prevails again. If we exert pressure on alternate sides of the outer ring in the proper rhythm, we can cause the top to revolve continually about the axis of the inner ring.

5. If we tie the inner ring to the outer one, so that the movability of the inner ring is destroyed, the resistance of the top to motion is destroyed as well. Seemingly without a will of its own, the top then obeys all pressures exerted on the outer ring, just as if it did not have any spin. Thus, typical gyroscopic effects occur only in the case of the top with three degrees of freedom, and are completely absent in that of two degrees. One can, however, reconstitute the missing degree of freedom by clamping the top to the rotating surface of the turning stool described on p. 74; this must be done in such a way that the axis of the outer ring, which has so far been

kept vertical, is tilted with respect to the axis of the stool (which remains vertical) at not too small an angle. Then the axis of the top with two degrees of freedom tends to align itself with the axis of the rotating support, just as a compass needle turns towards the North Pole, i.e., in the sense of the homologous parallelism described above. Thus the single ring containing the top will come to lie in a vertical plane, with one or the other of the axle pins of the top uppermost, depending on the sense in which the stool is rotated.

The explanation of all these phenomena is contained in the fundamental principle (25.5),

$$(1) \qquad dM = L dt.$$

1. If we press on the inner ring, L is horizontal and coincides with the axis of rotation of the inner ring. The angular momentum M is directed toward the left or right of Fig. 47 and is hence deflected laterally by L . If then we are allowed to assume that the axis of the top, originally in coincidence with the angular momentum, tends to remain in coincidence by following it, we have explained the lateral deflection of the axis of figure, that is, the rotation of the outer ring. That the assumption made here is actually valid for sufficiently rapid spin of the top will be justified in § 35 (cf. the discussion about the pseudo-regular precession in that section).

2. If we exert pressure on the outer ring, L is directed vertically. The angular momentum, originally directed horizontally to the right or left, is deflected upward or downward. Under the same assumption as in 1, we therefore obtain a rotation of the inner ring. If we impart a very strong blow to the outer ring, our assumption regarding the coincidence of angular momentum and axis of the top is only approximately satisfied; we then obtain the small conical oscillations mentioned earlier, which betray a small dislocation of the two axes.

3 and 4. By the same token we see that if the axis of angular momentum is almost vertical and if we rotate the outer ring in a sense homologous to that of the spin of the top, the axis of angular momentum becomes more nearly vertical. Gimbals and flywheel then rotate as a whole about the vertical. The resistance of the outer ring vanishes. If we rotate the outer ring in the non-homologous or anti-parallel sense, a small deviation of the axis of angular momentum from the vertical suffices to make the former recede further and further from the vertical; the almost-vertical position of the top proves to be unstable with respect to such a non-homologous rotation.

5. If we tie inner and outer ring together, the axis of angular momentum can no longer move in a vertical plane when a vertical torque L is imposed thereon by a rotation of the outer wheel. The torque is therefore transmitted to the whole system. This is possible because the horizontal change in direction that the vector M suffers can be compensated by the bearings of the outer ring, since inner and outer ring are now rigidly connected. Not so on the turning stool, where the angular momentum can follow the imposed L at least to some extent, which explains why the axis of the top tends to point in the direction of the axis of the stool.

We shall now discuss some practical applications. Let it be remarked in advance that details on many points of the discussion can be found in the older literature from which much of the following is borrowed.

(1) The Gyrostabilizer and Related Topics

Around the year 1870 Henry Bessemer, whose name is renowned in metallurgy, built a drawing room cabin destined for navigation on the English Channel. The cabin was suspended so that it could move about a fore-aft axis of the ship and was to be stabilized against the ship's roll by means of a flywheel. The axis of the flywheel was, however, rigidly fixed in the cabin, and therefore lacked the required third degree of freedom (cf. above under 5). As a result the construction was a failure soon to be abandoned.

It was O. Schlick, mentioned in connection with the mass balancing of piston engines (cf. p. 76), who successfully worked out the present problem. His method was applied to several steamers, including the "Silvana" of the Hamburg-America Line, and the Italian "Conte di Savoia" (considerable literature on the latter exists in American publications). In the "Silvana" the flywheel had a weight of 5,100 kg., a diameter of 1.6 m., and made 1,800 r.p.m. (a peripheral velocity of 150 m. per sec.). It was fixed in a cage which could, like a pendulum, swing about an axis in the port-starboard direction, so that the axis of symmetry of the flywheel oscillated in the vertical fore-aft plane of the ship. This cage corresponds to the inner ring of our demonstration top, the ship's hull itself to the outer one. The vertical of Fig. 47 is replaced by the long axis of the ship; instead of the former rotations about the vertical there is now the rolling of the vessel. The required three degrees of freedom then consist in the rolling of the ship, the oscillations of the cage, and the spin of the flywheel. When the vessel rolls, the axis of the flywheel, vertical in its normal position, alternately swings fore and aft in its cage, so that the energy contained in the rolling is converted to energy of motion and position of the cage. The rolling of the ship and the swinging of the cage are now coupled to each

other; if, in particular, their corresponding proper oscillations are in resonance, conditions resembling those of coupled pendulums obtain. To be sure, no damping of the ship's oscillation has so far been achieved. But it is now possible to absorb the oscillation energy of the cage and thus the energy of roll of the vessel by a braking device acting at the axle of the cage, just as the velocity of a car is reduced by a brakeshoe tangent to the wheel. Of course the braking action at the cage must not be so strong as to prevent the deflection of the flywheel axis altogether; for then we should again be confronted with the ineffective top of two degrees of freedom. Graphs of the rolling motion, similar to seismograms in an earthquake, show that there exists an optimum or "best compromise" value of braking action; in the "Silvana" the amplitude of roll was reduced to $\frac{1}{10}$ to $\frac{1}{20}$ of its original value almost as soon as the flywheel was put in action; the amplitude of oscillation of the frame hovered around 30° to 40° under these circumstances.

Nevertheless the gyrostabilizer has not been applied extensively. This is partly due to the danger inherent in the construction — a rapidly rotating, massive flywheel is an unpleasant passenger —, partly to the invention of an even more successful competitor, the Frahm stabilization tank, a device based on an entirely different principle.

A problem connected with the foregoing is that of stabilizing by gyroscopic action a turntable on board a ship. We do not know to what extent this problem has been solved for practical use; for obvious reasons work on it has been going on in all countries.

(2) The Gyrocompass

This is the finest and most nearly perfect gyroscopic device. Its conception goes back to Foucault. After Foucault had demonstrated the rotation of the earth by means of his pendulum experiments (cf. Ch. V, § 31), he made plans to achieve the same end by means of spinning tops. Of his several attempts we mention only the gyrocompass which was to replace the magnetic compass. The Foucault gyrocompass consists of a spinning top of two degrees of freedom constrained to the horizontal plane, which points, not to the magnetic North Pole, but to the actual celestial North Pole, the axis of rotation of the earth. Actually we dealt with this arrangement already in the fifth of our demonstration experiments, where we put the top with fixed inner ring on the turning stool. The rotating earth now takes the place of the turning platform of the stool. The only difference between the two cases lies in the fact that we were able to impart an arbitrarily large angular velocity to the rotating platform, resulting in a very strong orientation effect on the top, whereas the angular velocity of

the earth is very small, so that the alignment of the Foucault gyroscope takes a considerable time. In the earlier arrangement we mentioned that the angle between the axes of rotation of the outer ring and the stool should not be too small. In the present case this angle is the complement of the geographic latitude, the "co-latitude" at the point of observation. At the two poles of the earth, where this angle is zero, the orientation power of the gyrocompass vanishes. In general it is proportional to the angular velocity of the earth, the angular momentum of the top and the sine of the co-latitude.

Foucault's experiments lead only to rough indications of the effect. Its full realization was achieved by Hermann Anschütz-Kaempfe, by means of successive improvements in construction. His original goal was to reach the North Pole by means of a submarine passing under the drift ice. Since the readings of a magnetic compass become very unreliable near the North Pole, failing altogether inside a submarine, he had the idea of making the top serve as his direction-finder. It is true that in the pursuit of this idea through several decades he did not reach the North Pole; but his experimentation lead to an ideal instrument which has become indispensable in navigation.

The Anschütz gyroscope, unlike that of Foucault, is not constrained to a horizontal plane, but is merely pulled back into this plane by its weight, like a pendulum. Originally it was arranged so as to swim in a bath of mercury. Later constructions made use of two or three tops whose effects strengthened and corrected each other. The angular momentum of the spinning tops is kept constant by electric drive. In the latest Anschütz construction the whole system is enclosed in a sphere which floats with almost no friction in a second sphere of only slightly larger radius. Since the gyroscope is taken along on trips during which it may not be touched for several months, provision must be made for a particularly ingenious automatic lubrication method.

Measures to eliminate the harmful effects of the ship's own motion are of special importance. When the ship travels in a curve or changes its speed, the gyrocompass, with its ability to oscillate about the horizontal plane, is sensitive to the corresponding inertial forces. These exert pressures on the axis of spin, causing it to deflect from its undisturbed position, with the result that erroneous readings are obtained. One can show that the motion of the vessel becomes harmless if the free oscillation of the compass needle about the meridian has the period

$$T = 2\pi \left(\frac{I}{g} \right)^{\frac{1}{2}} = (8\pi)^{\frac{1}{2}} 10^3 \text{ sec} = 84.4 \text{ min.}$$

which is the same as that of a pendulum of length equal to the earth's radius

$$l = \frac{2}{\pi} \cdot 10^7 \text{ m.}$$

(Law of Schuler, completed by Glitscher⁷).

A further beautiful application of the gyroscope concerns the automatic steering mechanism of large steamers. If a ship is to retain its course in spite of the motion of waves and ocean currents, the uninterrupted attention of the helmsman and the corresponding corrective action of the steering mechanism are required. This corrective action is, however, always too late by a certain amount of time, therefore causing losses in mileage and time. The gyrocompass is, on the contrary, a sense organ which "feels" much more accurately and swiftly than man, and takes instantaneous countermeasures. As a result of these countermeasures the line of travel becomes almost rigorously rectilinear (actually loxodromic, i.e., a rhumb line), which results in a considerable saving in energy. For this reason every passenger ship of good size is now equipped with such an automatic steering mechanism.

(3) Gyroscopic Effects in Railroad Wheels and Bicycles

A set of rolling wheels of a railroad car is a spinning top whose angular momentum can become considerable for fast trains. When the wheels go around a curve, the angular momentum must, at any instant, be deflected to a position determined by the normal to the curve. For this, according to Eq. (1), a torque is required whose axis lies along the direction of travel. Since such a torque (often called "gyroscopic couple") is not present, the "gyroscopic effect" will result in a countertorque which presses the set of wheels against the outer rail and pulls it off the inner one. This countertorque adds to the moment of the centrifugal force about the direction of travel. The latter effect is compensated, as we know, by adequate banking of the roadbed. Both moments have the form

$$mv\omega$$

where v is the velocity of travel, and ω the angular velocity of the train in the curve; m is, in the present case, the mass of the set of wheels reduced to the wheel periphery, whereas in the centrifugal effect m is the total mass of the car carried by the wheels. Our gyroscopic couple and its equal and opposite countertorque are therefore extremely small compared with the moment of the centrifugal force; one could compensate for it by lifting the outer rail a very slight additional amount.

⁷ Cf. *Wissensch. Veröffentl. aus den Siemenswerken*, 19, 57 (1940).

More serious effects may result from any vertical irregularities in the rails, such as, for instance, a "hump" on one of the rails (to this category also belong the increasing and decreasing elevation of one of the rails at the beginning and end of a banked curve). Such a hump causes a deviation of the angular momentum in a vertical direction, and hence a countertorque which seeks to twist the set of wheels out of the rail-bed by pressing, say, the front wheel of the set against the rail, and pushing the last wheel of the set away from the rail. The play allowed by the rails will thus cause the flanges of the wheels to bite now into one rail, now into the other. This has indeed been observed on test runs with fast electric trains. In order to control the condition and exact position of the rails at all times, the German Reichsbahn uses test cars equipped with gyroscopic instruments, the latter manufactured by the Anschütz company.

A bicycle is a doubly non-holonomic system; for, like the wheel in problem II.1, it has five degrees of freedom in finite motion, but only three such degrees in infinitesimal motion (rotation of the rear wheel in its instantaneous plane, to which the rotation of the front wheel is coupled by the condition of pure rolling; rotation about the handle bar axis; and common rotation of front and rear wheel about the line connecting their points of contact with the ground), as long as we do not consider the degrees of freedom of the cyclist himself. It is well-known that given sufficient velocity the stability of this system relies on the fact that either by means of rotations of the handle bar, or by means of unconsciously released motions of the body, the cyclist calls forth suitable centrifugal effects. That the gyroscopic effects of the wheels are very small compared with these can be seen from the construction of the wheel; if one wanted to strengthen the gyroscopic effects, one should provide the wheels with heavy rims and tires instead of making them as light as possible. It can nevertheless be shown^a that these weak effects contribute their share to the stability of the system. This is the case because, just as in the automatic steering mechanism of ships, they react more quickly against a sinking of the center of gravity than do the centrifugal effects. In the small oscillations which one has to consider in testing the stability of the motion, the gyroscopic action lags the oscillations of the center of gravity by a quarter period, whereas the centrifugal action lags them by a half period.

^a Cf. F. Klein and A. Sommerfeld, *Theorie des Kreisels*, Vol. IV, p. 880 and ff. In order to carry out the stability considerations we must of course exclude all participating action on the part of the cyclist. Not only must he be assumed to ride without hands, but also with motionless body; he should act only by means of his weight. This work also offers detailed material on other applications and on the mathematical foundations of the theory of the spinning top.

SUPPLEMENT: THE MECHANICS OF BILLIARDS

The beautiful game of billiards opens up a rich field for applications of the dynamics of rigid bodies. One of the illustrious names in the history of mechanics, that of Coriolis*, is connected with it.

The following explanations have as their main object the clarification of some problems which we shall pose on the subject. In these problems not only the dynamics of the rolling and sliding ball, but also the theory of friction on the billiard cloth will come into its own.

(a) *High and Low Shots*

The experienced player almost always gives the ball a "side" or "English." For the time being we shall, however, consider only shots without English, in which the cue therefore hits the ball in its vertical median plane, and in a horizontal direction. We distinguish high and low shots.

We speak of a *high shot* if the point of impact between cue and ball lies above $\frac{7}{8}a$ (a =radius of the cue ball), as measured from the plane of the table; of a *low shot* if the ball is hit at a height less than $\frac{7}{8}a$ (cf. problem IV.3 in connection with this and the following). Only if the ball is hit at exactly this height does pure rolling take place from the very start. By virtue of the moment of inertia of a sphere given on p. 65, the rotation transmitted to the ball is then of such magnitude that the peripheral velocity corresponding to it is just equal and opposite at the point of support to the forward motion of the ball, so that the condition (II.10) of pure rolling is fulfilled.

For high shots the peripheral velocity at the point of contact generated by the rotation is opposite to that of the center of mass of the ball and exceeds the latter. The friction at the cloth opposes the excess velocity (peripheral velocity—forward velocity), thus augmenting the original velocity of the mass center: for high shots, friction acts on the ball in the direction of the shot. The final velocity under pure rolling, which sets in once the friction has consumed the excess velocity, is greater than the initial one. Balls that are hit high run for a long time and in general betray the experienced player.

For low shots the peripheral velocity at the point of contact is opposite to that of the center of mass, but outweighed by it; for even lower shots it is directed forward. In both cases friction acts in a direction opposite to that of the original impact. The final velocity under pure rolling is smaller than the initial one.

* G. Coriolis, *Théorie mathématique des effets du jeu de billard*. Paris, 1835.

As for the *impulse* Z (dimensions dyne-sec), it is of course to be interpreted as the time integral of a very great force F in the direction of the cue over the very short time of duration τ ,

$$Z = \int_0^{\tau} F dt.$$

The *impulsive torque* about the center of the ball is accordingly given by

$$Zl = \int_0^{\tau} Fl dt$$

where l is the distance of the center from the axis of the cue. The impulsive torque vector is directed perpendicularly to the plane passing through center and cue axis. For the shots without English so far considered, it is directed horizontally and is normal to the median plane mentioned above.

(b) *Follow Shots and Draw Shots*

If the ball, after being struck high, meets one of the other two balls in central impact, it transfers all its forward motion to the latter because of the equality of the two masses involved [cf. Eq. (3.27a)]; but it retains its rotational motion if we neglect the friction between the two balls during the short time of contact. The instant after the impact the center of the striking ball is therefore momentarily at rest, while its lowest point glides over the billiard cloth. The friction thus arising is constant in time and acts on the ball in the sense of the original forward motion, while its moment about the center simultaneously slows down the existing rotation. Thus the ball is accelerated from the state of rest, while its rotation decreases accordingly. The acceleration ceases as soon as the peripheral velocity at the cloth has become equal to the forward velocity of the center, whereupon pure rolling sets in. Once this stage is reached, the ball rolls on with constant final velocity (we shall neglect the very slow effect of the rolling friction). This is the theory of the *follow shot*.

The ball which is hit low similarly transfers its center of mass velocity to the struck ball and is momentarily at rest. We shall assume that the ball was hit very low, at any rate below the center, so that the peripheral velocity at the point of contact remaining after collision is directed forward. The friction now acts backward. The ball begins to move with constant backward acceleration, while at the same time its rotational velocity decreases, until pure rolling sets in. This is the theory of the *draw shot*.

Since sliding friction is independent of the velocity, the variation with time of the center of mass velocity v as well as of the peripheral velocity $u = a\omega$ is a linear one. The exercises so far considered can therefore be treated more conveniently by graphical than by mathematical methods.

To do the former we may construct a diagram in which we plot the instantaneous values of v and u as ordinates against the time (problem IV.3).

(c) *Trajectories with "English" Under Horizontal Impact*

If the ball is not hit in the vertical median plane, but to either side of it, we speak of "*right English*" and "*left English*." As long as the cue is advanced horizontally against the ball, the trajectory remains a straight line in the direction of the initial impact.

The plane of the impulsive torque is now inclined to the vertical median plane, in high shots either to the right for right English, or to the left for left English, this inclination being such that the normal to the plane of the impulsive torque (this normal is parallel to the axial vector torque) is contained in the vertical plane through the center of the ball normal to the median plane. We can decompose the torque into a vertical component and a horizontal one at right angles to the direction of the impact. The first component causes a spin about the vertical diameter of the ball and generates a small "boring friction" at the cloth which has, however, no effect on the path of the ball. The lateral component on the other hand acts in the same way that it did in the shots considered under 1 and 2, so that the phenomena there observed apply without change to shots with English. In particular the trajectory remains rectilinear.

The spin about the vertical diameter makes itself felt in the collision of the ball with a cushion or with a second ball. In the first case friction at the cushion occurs which deviates the ball to the left for right English and to the right for left English as seen by the player. The angle of reflection, which, for shots without English, is equal to the angle of incidence, is thereby altered; as a matter of fact the actual reflected path is generated from the equiangular reflected path by a rotation of the latter in the sense of the vertical spin imparted to the ball. This phenomenon is familiar to every billiards player. Together with the frictional force at the cushion there appears a frictional torque about the vertical which weakens the spin about the vertical diameter. The original English therefore gradually disappears after several impacts, a fact which is likewise known to every player. In a collision of ball against ball the effect of the English is similar, acting in the same sense as in a ball-cushion impact.

(d) *Parabolic Path Due to Shot with Vertical Component*

The plane of the impulsive torque is now not only inclined as under (c) but also tilted forward as seen by the player. The vector torque has therefore not only components along the vertical and lateral directions, but also a component in the direction of motion. Thus the point of contact has a component of sliding velocity perpendicular to the initial motion.

The friction, which is opposed to the resultant velocity of the point of contact, therefore makes an angle different from zero with the initial motion. If we convince ourselves (cf. problem IV.4) that this angle formed with the original motion remains constant during the motion, and if we remember that the magnitude of the friction likewise remains constant, we conclude that the path of the ball is a parabola in the horizontal plane, since it is under the influence of a single force of constant magnitude and direction (principle of J. A. Euler, son of the great Leonhard).

Shots of this type are very surprising to a player who does not have full knowledge of the laws of friction and the vectorial decomposition of angular momentum. They are especially useful when the two balls to be hit are at the two opposite ends of the short side of the table. In that case the vertical component of the impulse must be very strong, i.e., the cue must be guided at a small angle to the vertical.

CHAPTER V

RELATIVE MOTION

The interest in the subject matter of this chapter derives mainly from the fact that we make all our observations on the rotating earth, which is not an allowable frame of reference, either in the sense of classical mechanics or in the sense of the special theory of relativity. In general relativity, on the other hand, all systems of reference are permitted (cf. p. 15), so that a separate theory of relative motion becomes meaningless.

In this chapter we shall adopt the viewpoint that in every theoretically admitted reference system the mechanics of Newton holds rigorously. We shall then ask for the deviations from Newtonian mechanics that result from the motion of the reference system to which, for practical reasons, we are chained.

§ 28. *Derivation of the Coriolis Force in a Special Case*

Let a mass point move along a meridian of the terrestrial globe, of radius a , with the constant angular velocity μ , while at the same time the earth rotates about its axis with constant angular velocity ω . As usual, we call θ the colatitude, ϕ the (celestial !) longitude. Apart from arbitrary initial values the motion of our mass point is then given by

$$(1) \quad \theta = \mu t, \quad \phi = \omega t.$$

From the Cartesian coordinates of the point,

$$(2) \quad \begin{aligned} x &= a \sin \theta \cos \phi \\ y &= a \sin \theta \sin \phi \\ z &= a \cos \theta, \end{aligned}$$

we obtain by differentiation with respect to t ,

$$(3) \quad \begin{aligned} \dot{x} &= a\mu \cos \theta \cos \phi - a\omega \sin \theta \sin \phi \\ \dot{y} &= a\mu \cos \theta \sin \phi + a\omega \sin \theta \cos \phi \\ \dot{z} &= -a\mu \sin \theta. \end{aligned}$$

$$(4) \quad \begin{aligned} \ddot{x} &= -a\mu^2 \sin \theta \cos \phi - a\omega^2 \sin \theta \cos \phi - 2a\mu\omega \cos \theta \sin \phi \\ \ddot{y} &= -a\mu^2 \sin \theta \sin \phi - a\omega^2 \sin \theta \sin \phi + 2a\mu\omega \cos \theta \cos \phi \\ \ddot{z} &= -a\mu^2 \cos \theta. \end{aligned}$$

In the triplet of equations (4) the first terms on the right represent the usual centripetal acceleration which is associated with the motion along the meridian if the latter is at rest in space. The second terms give the centripetal acceleration resulting from the motion of a fixed point of the meridian in a circle of latitude (due to the earth's rotation about its axis). The third terms, however, constitute something new, for they represent the kinematic interplay of both motions. If we multiply (4) by $-m$, we obtain the inertial force F^* of our mass point in the compound rotation. In vector form it is

$$(5) \quad F^* = C_1 + C_2 + F_c.$$

The symbols C_1 and C_2 refer, as in (10.3), to "ordinary centrifugal forces." C_1 is directed radially outward from the earth's center and has the magnitude

$$|C_1| = m a \mu^2 = m \frac{v_1^2}{a}, \quad v_1 = a \mu.$$

C_2 is directed outward normal to the earth's axis, and has the magnitude

$$|C_2| = m a \omega^2 \sin \theta = m \frac{v_2^2}{a \sin \theta}, \quad v_2 = a \omega \sin \theta.$$

We can call the third constituent F_c the "composite centrifugal force" (force centrifuge composée) or *Coriolis force*. Its complete vector expression [cf. Eq. (29.4a)] is given by

$$(6) \quad F_c = 2m \mathbf{v}_{\text{rel}} \times \boldsymbol{\omega}.$$

We have here written \mathbf{v}_{rel} instead of the vector \mathbf{v}_1 corresponding to the preceding v_1 ; by this we wish to indicate that quite generally it is the velocity relative to the rotating reference system that gives rise to F_c .

According to (6) the magnitude of F_c is

$$(6a) \quad |F_c| = 2m v_{\text{rel}} \omega \sin(\mathbf{v}_{\text{rel}}, \boldsymbol{\omega}),$$

so that, in our case,

$$(6b) \quad |F_c| = 2m v_{\text{rel}} \omega \cos \theta.$$

$\cos \theta$ is of course just the sine of the geographic latitude. As for direction, F_c is perpendicular to both \mathbf{v}_{rel} and $\boldsymbol{\omega}$, or, equivalently, to C_1 and C_2 . The sense of F_c is given by the direction of advance of a right-handed screw turning from \mathbf{v}_{rel} to $\boldsymbol{\omega}$. This is illustrated in Fig. 48 for a particle moving from south to north. Two positions, one in the southern and one in the northern hemisphere, are shown. In the former, corresponding to the sense of the right-handed screw $\mathbf{v}_{\text{rel}} \rightarrow \boldsymbol{\omega}$, F_c acts from east to west; in the latter, from west to east.

Instead of a single particle we can also consider a continuous sequence of such particles, hence a river flowing along the meridian. Fig. 48 then tells us that the inertial force of the water moving from south to north presses against the *right bank in the northern hemisphere, against the left bank in the southern hemisphere*. The change of sign in the pressure is evidently connected with the sine of the geographic latitude occurring in (6b). This rule is valid not only for south-north flow, but, as will be shown in the next section, for any direction of \mathbf{v}_{rel} , and therefore, in particular, also for the north-south direction of flow. This is intuitively obvious in our example. The west-east velocity of the water deriving from the earth's rotation depends on its distance from the axis of rotation, hence on the geographic latitude. If the stream moves from south to north, the water in the northern hemisphere has an excess of west-east momentum imported from more southerly latitudes; this excess manifests itself as a pressure eastward, that is, against the right bank. But similar reasoning must hold in the case of north-south motion. In that case the water imports a deficiency of west-east motion from the northern latitudes.

FIG. 48. Special derivation of Coriolis force: a mass point moves along a meridian of the rotating earth with constant velocity \mathbf{v}_{rel} corresponding to the constant angular velocity μ as seen from the earth's center.

Let us mentally add the deficient amount in the sense of Fig. 41, once with + sign, once with - sign. The part added with - sign has an east-west direction, and therefore exerts a pressure westward, i.e., again on the right bank. The same process of reasoning shows that in the southern hemisphere the river exerts excess pressure on its left bank, for south-north as well as north-south motion of the water.

Geographers have proved by numerous examples that the pressure against the right bank in the northern hemisphere manifests itself in a stronger erosion of the right embankment (Baer law of river displacements); in addition the water stands slightly but measurably higher at the right shore of the river.

Of much greater significance are the effects of the Coriolis force on ocean currents (deviation of the Gulf Stream and tidal currents of the northern hemisphere to the right).

It is, however, in the atmosphere that its effects are most pronounced. The well-known law of Buys-Ballot states that the wind does not blow in the direction of the pressure gradient, but is deviated considerably,

to the right in the northern, to the left in the southern hemisphere; it is only at the equator that it follows the pressure gradient exactly.

All these phenomena are immediate results of Newton's first law and in the last analysis derive from the fact that in mechanics the rotating earth is not an admissible reference frame.

In this section we have calculated the Coriolis force with the help of spherical polar coordinates. In problem V.1 we shall derive it in cylindrical coordinates.

§ 29. *The General Differential Equations of Relative Motion*

We replace the earth by an arbitrary rigid body B , which rotates with instantaneous angular velocity ω about a fixed point O . Let P be a particle which moves with arbitrarily varying velocity relative to B . Its velocity with respect to space is then composed of this relative velocity and the velocity in space of a point of the body instantaneously in coincidence with P . According to (22.4) the latter is given by $\omega \times \mathbf{r}$. As in (22.4) we shall designate by \mathbf{w} the velocity of P with respect to space; furthermore we shall call \mathbf{v} (instead of \mathbf{v}_{rel}) the relative velocity of P with respect to B . We then have

$$(1) \quad \mathbf{w} = \mathbf{v} + \omega \times \mathbf{r}.$$

Let us agree that temporal changes be designated by an overhead dot if observed from space, by $\frac{d}{dt}$ if observed from the body B . We can then write

$$(2a) \quad \mathbf{w} = \dot{\mathbf{r}},$$

$$(2b) \quad \mathbf{v} = \frac{d\mathbf{r}}{dt},$$

$$(2c) \quad \dot{\mathbf{r}} = \frac{d\mathbf{r}}{dt} + \omega \times \mathbf{r}.$$

The acceleration of our point P in space is given from (1) as

$$(3) \quad \dot{\mathbf{w}} = \dot{\mathbf{v}} + \omega \times \dot{\mathbf{r}} + \dot{\omega} \times \mathbf{r}.$$

In the middle term of the right member we substitute the value of $\dot{\mathbf{r}}$ from (2a) and (1) to obtain

$$(3a) \quad \omega \times \dot{\mathbf{r}} = \omega \times \mathbf{v} + \omega \times (\omega \times \mathbf{r}).$$

We shall transform the first term on the right of (3) by replacing the arbitrary vector \mathbf{r} in (2c) by \mathbf{v} . This yields

$$(3b) \quad \dot{\mathbf{v}} = \frac{d\mathbf{v}}{dt} + \boldsymbol{\omega} \times \mathbf{v}.$$

Substitution of (3a) and (3b) into (3) gives

$$(4) \quad \dot{\mathbf{w}} = \frac{d\mathbf{v}}{dt} + 2\boldsymbol{\omega} \times \mathbf{v} + \boldsymbol{\omega} \times (\boldsymbol{\omega} \times \mathbf{r}) + \dot{\boldsymbol{\omega}} \times \mathbf{r}.$$

We notice that according to (26.8a) we can write either $\dot{\boldsymbol{\omega}}$ or $\frac{d\boldsymbol{\omega}}{dt}$ in the last term of Eq. (4).

From (4) we proceed to the inertial force acting on our particle by multiplying both sides by $-m$. At the left we then have the inertial force \mathbf{F}^* in space; the first term on the right is the inertial force observed in the non-inertial reference system B , which we shall call $\mathbf{F}_{\text{rel}}^*$. The second term on the right gives the expression for the Coriolis force which we met in (28.6), viz.,

$$(4a) \quad -2m \boldsymbol{\omega} \times \mathbf{v} = +2m \mathbf{v} \times \boldsymbol{\omega} = \mathbf{F}_c.$$

Our present treatment therefore supplements that of the preceding section by furnishing a general derivation of the Coriolis force. In the next to last term of Eq. (4) one easily recognizes (after multiplication by $-m$) the ordinary centrifugal force \mathbf{C} , which appears to act on our particle by virtue of the rotation of the reference system B , and which was designated by \mathbf{C}_2 in Eq. (28.5).

From (4) we therefore have, collecting all the terms,

$$(5) \quad \mathbf{F}^* = \mathbf{F}_{\text{rel}}^* + \mathbf{C} + \mathbf{F}_c + m\mathbf{r} \times \dot{\boldsymbol{\omega}}.$$

Here we replace $\mathbf{F}_{\text{rel}}^*$ by its value from the definition

$$\mathbf{F}_{\text{rel}}^* = -m \frac{d\mathbf{v}}{dt}$$

and recall that due to the equilibrium of external and inertial forces in the system fixed in space we must have

$$\mathbf{F} + \mathbf{F}^* = 0.$$

Thus we obtain the *general differential equation of relative motion*

$$(6) \quad m \frac{d\mathbf{v}}{dt} = \mathbf{F} + \mathbf{C} + \mathbf{F}_c + m\mathbf{r} \times \dot{\boldsymbol{\omega}}.$$

We see that in the system B there appear, in addition to the actual external force, the *fictitious forces* \mathbf{C} and \mathbf{F}_c ; from the standpoint of an observer moving with B , they act in the same manner as the external

force \mathbf{F} ; actually, they result solely from the inertia of the particle m fixed in, or moving relative to, a non-Newtonian reference frame. The last term on the right of (6) is of similar origin; it stems from a possible acceleration or change in direction of the rotation. Applied to the earth it corresponds to the polar fluctuations and can certainly be neglected as vanishingly small. The differential equation (6) will be used in the three following sections and in problems V.1 and V.2.

§ 30. Free Fall on the Rotating Earth; Nature of the Gyroscopic Terms

Whenever we try to measure the effect of gravity, it is not just the gravitational attraction itself, but the resultant of the earth's attraction \mathbf{F} and the centrifugal force \mathbf{C} that is observed. The flattening of the geoid, i.e., of the mean terrestrial surface, is itself determined by this resultant, and, in fact, in such a manner that the geoid is everywhere normal to it. If we put

$$(1) \quad \mathbf{F} + \mathbf{C} = -m \mathbf{g},$$

the gravitational acceleration \mathbf{g} is a vector which has the magnitude g , but a direction along the normal to the geoid, rather than along the produced radius of the earth.

From (29.6) we obtain, in view of (1) and (28.6) and with neglect of the term in $\dot{\omega}$,

$$(2) \quad \frac{d\mathbf{v}}{dt} = -\mathbf{g} + 2\mathbf{v} \times \boldsymbol{\omega}.$$

Let us now resolve this vector equation into coordinate equations by introducing an orthogonal system ξ, η, ζ , fixed in the earth, and defined as follows (cf. Fig. 49):

- ξ = north-south direction on the earth,
 (3) η = west-east direction on the earth,
 ζ = point of observation \rightarrow zenith =
 normal to geoid.

We then have, in component form,

$$(4) \quad \begin{aligned} \mathbf{v} &= \left(\frac{d\xi}{dt}, \frac{d\eta}{dt}, \frac{d\zeta}{dt} \right); \\ \mathbf{g} &= (0, 0, g); \\ \boldsymbol{\omega} &= (-\omega \cos \phi, 0, \omega \sin \phi); \end{aligned}$$

FIG. 49. Free fall on rotating earth. System of coordinates: ξ along a meridian, η along a circle of latitude, ζ along the normal to the geoid.

ϕ being the geographic latitude as in Fig. 49. It then follows from (2) that

$$\begin{aligned}
 \frac{d^2\xi}{dt^2} &= 2\omega \sin \phi \frac{d\eta}{dt} \\
 (5) \quad \frac{d^2\eta}{dt^2} &= -2\omega \sin \phi \frac{d\xi}{dt} - 2\omega \cos \phi \frac{d\zeta}{dt} \\
 \frac{d^2\zeta}{dt^2} + g &= 2\omega \cos \phi \frac{d\eta}{dt}
 \end{aligned}$$

Before proceeding to integrate (5) we wish to examine the general character of these equations. They are distinguished by the fact that the array of coefficients of the right-hand side is antisymmetric. Let us introduce abbreviations

$$(6) \quad \alpha = 2\omega \sin \phi, \quad \beta = 0, \quad \gamma = -2\omega \cos \phi.$$

The array then is clearly antisymmetric about the diagonal, as shown below:

$$(7) \quad \begin{array}{c|ccc} & \frac{d\xi}{dt} & \frac{d\eta}{dt} & \frac{d\zeta}{dt} \\ \hline \frac{d^2\xi}{dt^2} & 0 & \alpha & \beta \\ \hline \frac{d^2\eta}{dt^2} & -\alpha & 0 & \gamma \\ \hline g + \frac{d^2\zeta}{dt^2} & -\beta & -\gamma & 0 \end{array}$$

This *antisymmetric* character indicates *conservation of energy*. If diagonal terms were present or if, speaking more generally, the array of coefficients had a *symmetric part*, we should have *dissipation of energy*.

For let us multiply Eqs. (5) row by row by $\frac{d\xi}{dt}$, $\frac{d\eta}{dt}$, $\frac{d\zeta}{dt}$, and add. All the coefficients of α , β and γ on the right vanish, and we are left with

$$\frac{1}{2} \frac{d}{dt} \left[\left(\frac{d\xi}{dt} \right)^2 + \left(\frac{d\eta}{dt} \right)^2 + \left(\frac{d\zeta}{dt} \right)^2 \right] + g \frac{d\zeta}{dt} = 0,$$

that is,

$$(8) \quad T + V = \text{const.}$$

Here T and V are the kinetic and potential energy of relative motion (where we have put the mass=1). This conservative character of our array of coefficients can be made evident even without calculation; for by virtue

of the factor $\mathbf{v} \times \boldsymbol{\omega}$, \mathbf{F}_g is perpendicular to the motion and therefore does no work, in analogy with magnetic forces in electrodynamics.

If, on the other hand, the array of coefficients had a symmetric contribution, we should have

$$(9) \quad \frac{d}{dt}(T+V) < 0$$

where the $<$ sign results from the assumption that the signs of the coefficients satisfy the physically necessary conditions corresponding to a damping of the motion. It is seen that (9) results not in conservation, but rather, as asserted, in dissipation of energy. An example (only one-dimensional, it must be admitted) of the dissipative character of an even array of coefficients is furnished by Eqs. (8) and (9) in the treatment of damped oscillations of Chapter II, § 19.

With Lord Kelvin we call the terms of an antisymmetric array of coefficients *gyroscopic terms*. The name suggests that they indicate an internal gyration of the system (in our case the earth) which has not been taken into account explicitly in setting up the problem, but has instead been incorporated in the choice of coordinates (in our case the ξ, η, ζ). Such gyroscopic terms play an important role in general laws concerning the stability of equilibria and motions.

We shall now proceed with the integration of Eqs. (5). Let us postulate a free fall from height h without initial velocity. We therefore require at $t=0$:

$$(10) \quad \begin{aligned} \xi = \eta = 0, \quad \zeta = h \\ \frac{d\xi}{dt} = \frac{d\eta}{dt} = \frac{d\zeta}{dt} = 0. \end{aligned}$$

From the first and third Eq. (5) we then have

$$(11) \quad \frac{d\xi}{dt} = 2\omega\eta \sin \phi, \quad \frac{d\zeta}{dt} + gt = 2\omega\eta \cos \phi.$$

Replacing these in the second Eq. (5), we obtain

$$(12) \quad \frac{d^2\eta}{dt^2} + 4\omega^2\eta = Ct, \quad C = 2\omega g \cos \phi.$$

The integral of this equation is found by the general rule laid down in connection with Eq. (19.4), viz., "particular solution of the inhomogeneous equation + general solution of the homogeneous equation." In the present case this leads to

$$\eta = \frac{C}{4\omega^2}t + A \sin 2\omega t + B \cos 2\omega t.$$

Conditions (10) require that we put

$$(13) \quad B=0, \quad 2\omega A = -\frac{C}{4\omega^2}, \text{ i.e.,} \\ \eta = \frac{C}{4\omega^2} \left(t - \frac{\sin 2\omega t}{2\omega} \right) = \frac{g \cos \phi}{2\omega} \left(t - \frac{\sin 2\omega t}{2\omega} \right).$$

According to the meaning of η , cf. (3), this is the *eastward deflection*.

ξ is the *southward deflection*. From (11) and (13) it satisfies

$$\frac{d\xi}{dt} = g \sin \phi \cos \phi \left(t - \frac{\sin 2\omega t}{2\omega} \right)$$

whose solution, with due regard for (10), is

$$(14) \quad \xi = g \sin \phi \cos \phi \left(\frac{t^2}{2} - \frac{1 - \cos 2\omega t}{4\omega^2} \right).$$

With the help of (13) and (10) we finally obtain from the second Eq. (11) the motion along the vertical,

$$(15) \quad \zeta = h - \frac{gt^2}{2} + g \cos^2 \phi \left(\frac{t^2}{2} - \frac{1 - \cos 2\omega t}{4\omega^2} \right).$$

ωt is a very small number of order of magnitude (time of fall) \div (1 day). We can therefore develop the solutions in powers of ωt . In lieu of (13), (14), and (15) we then obtain

$$\eta = \frac{gt^2}{3} \cos \phi \omega t, \quad \xi = \frac{gt^2}{8} \sin \phi \cos \phi (\omega t)^2 \\ \zeta = h - \frac{gt^2}{2} \left(1 - \frac{\cos^2 \phi}{3} (\omega t)^2 \right).$$

The eastward deflection is accordingly of the first, the southward deflection of the second order in ωt . The deviation from the law of freely falling bodies along the vertical caused by the earth's rotation is likewise only of the second order in ωt . The eastward deflection has been observed in several instances and found to be in agreement with theory; under favorable circumstances (deep mine shaft) it amounts to several centimeters.

Evidently these (observable or unobservable) deflections are due to the fact that the initial conditions (10) which lie at the very basis of both theory and experiment prescribe *rest with respect to the earth*. They hence imply a certain velocity in space, which is of the magnitude (earth's angular velocity) \cdot (distance from axis of earth). This velocity is somewhat different from the velocity with which the earth's surface moves away under the falling body. It is then clear that the body does not hit the earth at the exact vertical projection of its initial position,

§ 31. Foucault's Pendulum

Once more Eqs. (30.5) are in force, but with the added condition that the mass point have the constant distance l from the point of suspension of the pendulum. We write this condition in a form similar to that used for the spherical pendulum (18.1), i.e.,

$$(1) \quad F = \frac{m}{2}(\xi^2 + \eta^2 + \zeta^2 - l^2) = 0$$

and introduce the Lagrange multiplier associated with it. Eqs. (30.5) then read

$$\begin{aligned} \frac{d^2\xi}{dt^2} &= 2\omega \sin \phi \frac{d\eta}{dt} + \lambda \xi \\ (2) \quad \frac{d^2\eta}{dt^2} &= -2\omega \sin \phi \frac{d\xi}{dt} - 2\omega \cos \phi \frac{d\zeta}{dt} + \lambda \eta \\ \frac{d^2\zeta}{dt^2} + g &= 2\omega \cos \phi \frac{d\eta}{dt} + \lambda \zeta. \end{aligned}$$

We shall of course restrict ourselves to small oscillations. We therefore regard $\frac{\xi}{l}$ and $\frac{\eta}{l}$ as small quantities of the first order; from (1) it follows that $\frac{\zeta^2}{l^2} = 1$ up to quantities of the second order. More precisely, for points in the neighborhood of the rest position we can write

$$\zeta = -l(1 + \text{quantities of second order}),$$

since ζ is of course directed vertically upward. The third Eq. (12) then shows that up to quantities of the first order

$$(3) \quad g = -\lambda l, \text{ hence } \lambda = -\frac{g}{l}.$$

Once more we write down the first two Eqs. (2), neglecting the term in $\frac{d\zeta}{dt}$ because small of second order, and using the abbreviation

$$(4) \quad u = \omega \sin \phi,$$

to obtain

$$\begin{aligned} \frac{d^2\xi}{dt^2} - 2u \frac{d\eta}{dt} + \frac{g}{l}\xi &= 0 \\ (5) \quad \frac{d^2\eta}{dt^2} + 2u \frac{d\xi}{dt} + \frac{g}{l}\eta &= 0. \end{aligned}$$

It is convenient to consolidate them in complex form by multiplying the

second Eq. (5) by i , adding it to the first one, and, as on p. 142, Eq. (26.10), introducing the new variable

$$(6) \quad s = \xi + i\eta.$$

We obtain

$$(7) \quad \frac{d^2 s}{dt^2} + 2iu \frac{ds}{dt} + \frac{g}{l}s = 0,$$

which is a homogeneous linear differential equation of second order with constant coefficients. Note that it is the gyroscopic character of the middle terms of Eqs. (5) which made step (5) \rightarrow (7) possible.

Eq. (7) is solved by putting

$$s = A e^{i\alpha t}.$$

Substitution in (7) gives

$$\alpha^2 + 2u\alpha - \frac{g}{l} = 0,$$

a quadratic equation in α with the roots

$$(8) \quad \alpha_1 = -u + \left(u^2 + \frac{g}{l}\right)^{\frac{1}{2}} \quad \text{and} \quad \alpha_2 = -u - \left(u^2 + \frac{g}{l}\right)^{\frac{1}{2}}.$$

It follows that the general solution of (7) is

$$(9) \quad s = A_1 e^{i\alpha_1 t} + A_2 e^{i\alpha_2 t}.$$

The constants A_1 and A_2 are determined from the initial conditions. In agreement with the experimental arrangement we shall stipulate that these be

$$(10) \quad \xi = a, \quad \eta = 0, \quad \frac{d\xi}{dt} = \frac{d\eta}{dt} = 0 \quad \text{at } t = 0.$$

We therefore imagine that the bob is pulled by an amount a out of its plumb line position along the positive ξ -axis, i.e. (cf. Fig. 50), southward along the meridian, and then released without impulse. From (10) the initial values of our complex variables are

$$(10a) \quad s = a, \quad \frac{ds}{dt} = 0 \quad \text{at } t = 0.$$

Eq. (9) then gives

$$(11) \quad A_1 + A_2 = a,$$

$$(11a) \quad A_1 \alpha_1 + A_2 \alpha_2 = 0,$$

$$(11b) \quad A_1 = \frac{a}{2} \left[1 + \frac{u}{\left(u^2 + \frac{g}{l}\right)^{\frac{1}{2}}} \right], \quad A_2 = \frac{a}{2} \left[1 - \frac{u}{\left(u^2 + \frac{g}{l}\right)^{\frac{1}{2}}} \right].$$

Next we calculate the expression for $\frac{ds}{dt}$; it is somewhat less involved than that for s itself. Recalling (11a) we have

$$\frac{ds}{dt} = i\alpha_1 A_1 e^{-iut} \left[e^{i(u^2 + \frac{g}{l})^{\frac{1}{2}} t} - e^{-i(u^2 + \frac{g}{l})^{\frac{1}{2}} t} \right],$$

from which, according to (8) and (11b),

$$(12) \quad \frac{ds}{dt} = -\alpha \frac{g}{l} \frac{1}{(u^2 + \frac{g}{l})^{\frac{1}{2}}} e^{-iut} \sin \left((u^2 + \frac{g}{l})^{\frac{1}{2}} t \right).$$

We arrive at the following conclusions: whenever the sine factor vanishes, we have

$$\frac{ds}{dt} = 0 \quad \text{and hence} \quad \frac{d\xi}{dt} = \frac{d\eta}{ds} = 0.$$

This represents the occurrence of a turning point or cusp in the trajectory of the bob. According to our initial conditions (10), the first one of these occurs at $t=0$. If we put

$$(13) \quad T = \frac{2\pi}{(u^2 + \frac{g}{l})^{\frac{1}{2}}},$$

succeeding cusps occur at

$$t = \frac{T}{2}, t = T, t = \frac{3T}{2}, \dots$$

$t=T$ is the duration of a complete to-and-fro motion. Putting $u=0$ (that is, $\omega=0$) makes Eq. (13) agree with the period of oscillation of a simple pendulum without terrestrial rotation — as would be expected.

In order to see where the bob of our Foucault pendulum is located at $t=T$, we make use of (13) and (11) to obtain from (9)

$$s_{t=T} = A_1 e^{-i u T + 2\pi i} + A_2 e^{-i u T - 2\pi i} = (A_1 + A_2) e^{-i u T} = a e^{-i u T}.$$

The bob therefore has the same distance a from its rest position as it had at the outset of the motion, but its azimuth no longer coincides with the southward meridian, as initially, but has acquired a lag with respect to this direction given by the angle

$$uT = 2\pi \frac{u}{(u^2 + \frac{g}{l})^{\frac{1}{2}}} \cong 2\pi \left(\frac{l}{g} \right)^{\frac{1}{2}} \omega \sin \phi.$$

FIG. 50.
Foucault's pendulum. Bird's-eye view of the trajectory of the bob. Initial displacement to the south; westward deflection in a complete oscillation.

The bob is thus deflected westward, cf. Fig. 50. We can explain this by saying that for zero rotation of the earth the pendulum bob would pursue a straight south-north-south course. In our case, however, the Coriolis force, through its "pressure on the right bank," displaces the trajectory by an angle $\frac{1}{2}\omega T$ eastward while the bob is swinging out, $\frac{1}{2}\omega T$ westward while it is moving back.

Foucault's experiments of 1851 and those of his countless successors yielded only qualitative results; a quantitative investigation of all sources of error was carried out by H. Kamerlingh Onnes, later leading authority in the field of low temperatures and discoverer of superconductivity, in his Groningen thesis of 1879.

§ 32. Lagrange's Case of the Three-Body Problem

We cannot resist the temptation to conclude our analysis of relative motion with the proof of a famous principle enounced by Lagrange (Paris Academy, 1772): *The three-body problem can be solved in closed and elementary form if one assumes that the triangle formed by the three celestial bodies always remains similar to itself.* The masses of the three bodies are completely arbitrary.

The proof of this principle will show that

1. The plane through the three mass points is fixed in space.
2. The resultant of the Newtonian forces on each of the three points passes through their common mass center.
3. The triangle formed by them is equilateral.
4. The three points describe conic sections similar to each other, with the common mass center at one focus.

The proof given by Lagrange is rather involved. It can be simplified if, with Laplace, we assume from the start the first conclusion above. Carathéodory¹ has, however, shown that even without this assumption an elementary proof is possible. His starting point is our vector equation (29.4) resolved in orthogonal coordinates. We shall follow his proof with minor modifications.

We consider the plane S which passes through the three points P_1, P_2, P_3 (masses m_1, m_2, m_3) and therefore also through their center of mass O . Without spoiling the generality of the problem we can define the latter as being at rest. S therefore rotates about the fixed point O ; this rotation includes a component causing S to turn into itself about its normal at O . Call ω the total angular velocity. We imagine ourselves to be located on a frame fixed in S from which we observe the motion of the points P_k , in a way similar to that in which we observed the motion of Foucault's pendulum

¹ *Sitz. Bayr. Akad. Wiss.* 257 (1933).

from the earth. From O we measure the radius vectors \mathbf{r}_k to the points P_k ; \mathbf{v}_k and $\frac{d\mathbf{v}_k}{dt}$ are their velocities and accelerations as observed from S . Making use of the vector rule (24.7), we write down the differential equations (29.4) of the motion in the form

$$(1) \quad \frac{d\mathbf{v}_k}{dt} + 2\boldsymbol{\omega} \times \mathbf{v}_k + \boldsymbol{\omega}(\mathbf{r}_k \cdot \boldsymbol{\omega}) - \mathbf{r}_k \omega^2 + \dot{\boldsymbol{\omega}} \times \mathbf{r}_k = \frac{\mathbf{F}_k}{m_k}.$$

\mathbf{F}_k is the vector sum of the Newtonian gravitational forces acting at m_k . Thus, for example,

$$(2) \quad \frac{\mathbf{F}_1}{m_1} = \frac{Gm_2}{|\mathbf{r}_2 - \mathbf{r}_1|^3} \frac{\mathbf{r}_2 - \mathbf{r}_1}{|\mathbf{r}_2 - \mathbf{r}_1|} + \frac{Gm_3}{|\mathbf{r}_3 - \mathbf{r}_1|^3} \frac{\mathbf{r}_3 - \mathbf{r}_1}{|\mathbf{r}_3 - \mathbf{r}_1|}.$$

We fix a Cartesian coordinate system in S , with origin at O , and x, y , arbitrarily oriented, in the plane of S ; at O we erect the z -axis perpendicular to S . In Eulerian fashion we resolve $\boldsymbol{\omega}$ along these axes,

$$(3) \quad \boldsymbol{\omega} = (\omega_1, \omega_2, \omega_3).$$

Let the component ω_3 (rotation of S into itself) be determined by considering the direction of one of the vectors $\overrightarrow{OP_k}$ fixed in S . But we assumed that the triangle $P_1P_2P_3$ was to remain similar to itself; it follows that each of the other two vectors $\overrightarrow{OP_k}$ as well has a direction fixed in S . We can then write

$$(4) \quad \mathbf{r}_k = \lambda(t) (a_k, b_k, 0),$$

where a_k, b_k are the Cartesian components of P_k at some given initial time. The function $\lambda(t)$ determines the common change in scale of the vectors $\overrightarrow{OP_k}$ and hence also that of the triangle $P_1P_2P_3$: with $\dot{\lambda}$ and $\ddot{\lambda}$ the derivatives of λ , we obtain from (4) that

$$(4a) \quad \begin{aligned} \mathbf{v}_k &= \dot{\lambda}(t) (a_k, b_k, 0), \\ \frac{d\mathbf{v}_k}{dt} &= \ddot{\lambda}(t) (a_k, b_k, 0). \end{aligned}$$

It further follows that the resultant force \mathbf{F}_k of Eq. (1) has a vanishing z -component, and x - and y -components inversely proportional to λ^2 . We shall write this force in abbreviated form as

$$(5) \quad \frac{\mathbf{F}_k}{m_k} = \frac{1}{\lambda^2(t)} (L_k, M_k, 0).$$

Next we write down the z -component of Eq. (1) perpendicular to S ,

$$2\dot{\lambda}(\omega_1 b_k - \omega_2 a_k) + \lambda \omega_3 (a_k \omega_1 + b_k \omega_2) + \lambda (\dot{\omega}_1 b_k - \dot{\omega}_2 a_k) = 0,$$

or, factoring out a_k, b_k ,

$$(6) \quad \{-2\dot{\lambda}\omega_2 + \lambda(\omega_3\omega_1 - \dot{\omega}_2)\}a_k + \{2\dot{\lambda}\omega_1 + \lambda(\omega_3\omega_2 + \dot{\omega}_1)\}b_k = 0.$$

The two brackets $\{ \}$ are functions of t independent of k . Calling them $f(t)$ and $g(t)$, we obtain

$$(6a) \quad \frac{f(t)}{g(t)} = -\frac{b_k}{a_k}.$$

We have, however, assumed that the points P_k form a triangle, i.e., are not collinear. The three ratios b/a must therefore be unequal. In that case we can satisfy (6) only by putting $f=g=0$. Explicitly

$$(7) \quad \begin{aligned} 2\dot{\lambda}\omega_1 &= -\lambda(\omega_3\omega_2 + \dot{\omega}_1), \\ 2\dot{\lambda}\omega_2 &= \lambda(\omega_3\omega_1 - \dot{\omega}_2). \end{aligned}$$

Multiplication by ω_1 and ω_2 respectively, followed by addition, yields

$$\frac{2\dot{\lambda}}{\lambda} = -\frac{\omega_1\dot{\omega}_1 + \omega_2\dot{\omega}_2}{\omega_1^2 + \omega_2^2}$$

and, by quadrature,

$$(8) \quad \omega_1^2 + \omega_2^2 = \frac{C}{\lambda^2}, \quad C = \text{constant of integration}.$$

We proceed to write the x - and y -components of the differential Eq. (1). They are

$$\begin{aligned} \ddot{\lambda}a_k - 2\omega_3\dot{\lambda}b_k + \omega_1\lambda(a_k\omega_1 + b_k\omega_2) - \lambda a_k(\omega_1^2 + \omega_2^2 + \omega_3^2) - \dot{\omega}_3\lambda b_k &= \frac{L_k}{\lambda^2}, \\ \ddot{\lambda}b_k + 2\omega_3\dot{\lambda}a_k + \omega_2\lambda(a_k\omega_1 + b_k\omega_2) - \lambda b_k(\omega_1^2 + \omega_2^2 + \omega_3^2) + \dot{\omega}_3\lambda a_k &= \frac{M_k}{\lambda^2}, \end{aligned}$$

or, arranged in factored form,

$$(9) \quad \begin{aligned} \{\ddot{\lambda} - \lambda(\omega_2^2 + \omega_3^2)\}a_k - \{2\omega_3\dot{\lambda} + \lambda(-\omega_1\omega_2 + \dot{\omega}_3)\}b_k &= \frac{L_k}{\lambda^2}, \\ \{2\omega_3\dot{\lambda} + \lambda(\omega_1\omega_2 + \dot{\omega}_3)\}a_k + \{\ddot{\lambda} - \lambda(\omega_1^2 + \omega_3^2)\}b_k &= \frac{M_k}{\lambda^2}. \end{aligned}$$

The brackets $\{ \}$ of the first equation and similarly those of the second, when multiplied by λ^2 , must therefore each satisfy three linear equations with constant coefficients (independent of t). This is possible only if they are themselves constant. It follows that the difference of the first and fourth brackets and that of the third and second brackets each equal a constant divided by λ^2 . We then have

$$(10) \quad \omega_1^2 - \omega_2^2 = \frac{A}{\lambda^2}, \quad 2\omega_1\omega_2 = \frac{B}{\lambda^2}.$$

A suitable consolidation gives

$$(\omega_1 \pm i\omega_2)^2 = \frac{A \pm iB}{\lambda^2}$$

from which the absolute magnitude

$$(11) \quad \omega_1^2 + \omega_2^2 = \frac{D}{\lambda^2}, \quad D = (A^2 + B^2)^{\frac{1}{2}}$$

is obtained. A comparison with (8) would lead to

$$(11a) \quad \lambda = \frac{C}{D} = \text{const.}$$

unless both C and D were to vanish. Now according to (10) $\lambda = \text{const.}$ would make both ω_1 and ω_2 constant, so that, from (7), ω_3 would have to be zero. By suitable choice of the coordinates x, y one could even make $\omega_2 = 0$; the first Eq. (9) would then yield $L_k = 0$. In that case the three points P_k would have to be collinear, contrary to our hypothesis.

We must therefore put $C = D = 0$ and obtain from either (8) or (11) that

$$(12) \quad \omega_1 = \omega_2 = 0.$$

This proves statement 1, that *the plane S rotates with angular velocity ω_3 into itself; its normal is fixed in space.*

If we apply the equation of angular momentum to our system we see that the motion of the points m_k within the plane S cannot contribute to the areal velocity constant. This constant is hence directly determined by the angular velocity ω_3 of S . We must have

$$\text{const.} = \omega_3 \sum m_k |\mathbf{r}_k|^2 = \omega_3 \lambda^2 \sum m_k (a_k^2 + b_k^2).$$

For this we can write

$$(12a) \quad \lambda^2 \omega_3 = \gamma \quad (\gamma = \text{constant});$$

it follows that

$$(12b) \quad 2\dot{\lambda}\omega_3 + \lambda^2 \dot{\omega}_3 = 0.$$

By virtue of (12) and (12a, b) Eqs. (9) simplify to

$$(13) \quad \lambda^2 \ddot{\lambda} - \frac{\gamma^2}{\lambda} = \frac{L_k}{a_k} = \frac{M_k}{b_k}.$$

The requirement $\frac{L_1}{a_1} = \frac{M_2}{b_1}$ contained in them says that the moment of F_1 about O vanishes, for

$$(14) \quad |\mathbf{r}_1 \times \mathbf{F}_1| = \frac{1}{\lambda^2} (a_1 M_1 - b_1 L_1) = 0,$$

so that F_1 passes through the mass center O . The same holds for F_2 and F_3 . This is our assertion 2 which states that *the resultant of the forces acting at P_k passes through the mass center of the particles m_k .*

We can make use of (2) to write (14) more explicitly. We have at once

$$(15) \quad \frac{\mathbf{r}_1 \times \mathbf{F}_1}{m_1 G} = \frac{m_2 \mathbf{r}_1 \times \mathbf{r}_2}{|\mathbf{r}_2 - \mathbf{r}_1|^3} + \frac{m_3 \mathbf{r}_1 \times \mathbf{r}_3}{|\mathbf{r}_3 - \mathbf{r}_1|^3} = 0.$$

But from the definition of the mass center,

$$(16) \quad m_1 \mathbf{r}_1 + m_2 \mathbf{r}_2 + m_3 \mathbf{r}_3 = 0,$$

and therefore

$$m_2 \mathbf{r}_1 \times \mathbf{r}_2 + m_3 \mathbf{r}_1 \times \mathbf{r}_3 = 0.$$

Substitution into (15) yields

$$m_2 \mathbf{r}_1 \times \mathbf{r}_2 \left(\frac{1}{|\mathbf{r}_2 - \mathbf{r}_1|^3} - \frac{1}{|\mathbf{r}_3 - \mathbf{r}_1|^3} \right) = 0,$$

that is,

$$(17) \quad |\mathbf{r}_2 - \mathbf{r}_1| = |\mathbf{r}_3 - \mathbf{r}_1|.$$

Similarly we find

$$(17a) \quad |\mathbf{r}_3 - \mathbf{r}_2| = |\mathbf{r}_1 - \mathbf{r}_2|, \text{ etc.}$$

We have thus arrived at statement 3: *the triangle is equilateral.*

The quotients $\frac{L_k}{a_k}$ and $\frac{M_k}{b_k}$ occurring in (13) can each be determined. To this end, let us call λ the side of the triangle, where

$$\lambda^2 = (a_2 - a_1)^2 + (b_2 - b_1)^2 = (a_3 - a_2)^2 + (b_3 - b_2)^2 = \dots$$

According to (2) and (5) we then have

$$\frac{L_1}{a_1} = \frac{G}{\lambda^3} \{ m_2 (a_2 - a_1) + m_3 (a_3 - a_1) \}$$

and, in view of (16),

$$(18) \quad \frac{L_1}{a_1} = \frac{G}{\lambda^3} \{ -m_1 - m_2 - m_3 \}.$$

The right member of this equation is symmetric in the m_k and the coordinates a_k, b_k ; it therefore represents the value not only of $\frac{L_1}{a_1}$, but of $\frac{L_k}{a_k}$ and also of $\frac{M_k}{b_k}$. Substitution of this value in (13) yields

$$(19) \quad \lambda^2 \ddot{\lambda} - \frac{\gamma^2}{\lambda} = -\frac{G}{\lambda^3} (m_1 + m_2 + m_3).$$

This differential equation in λ describes the motion in time, i.e., the rhythm with which our equilateral triangle alternately expands and contracts.

There is, however, a simpler way to gain insight into this secular motion and at the same time into the form of the trajectories; we abandon the plane S and observe the motion from a plane S' coinciding with S , but fixed in space. In S' the only force acting on the mass point m_k is the resultant force F_k directed toward the mass center which is at rest; the fictitious forces (Coriolis, centrifugal, etc.) occurring in (1) drop out. From (5) and (18) the magnitude of F_k is

$$(20) \quad |F_k| = \frac{m_k}{\lambda^3} (L_k^2 + M_k^2)^{\frac{1}{2}} = - \frac{m_k G}{\lambda^3 s^3} (m_1 + m_2 + m_3) \frac{(a_k^2 + b_k^2)^{\frac{1}{2}}}{s}.$$

The only quantity in the right member that varies in time is λ^3 . With the help of (4) it can be expressed in terms of $|r_k|$,

$$\lambda^3 = \frac{|r_k|^3}{a_k^2 + b_k^2}.$$

Let us replace λ by this value in (20), define a new mass

$$(20a) \quad m'_k = m_k \frac{(a_k^2 + b_k^2)^{\frac{1}{2}}}{s^3}$$

and the total mass $M = m_1 + m_2 + m_3$. Instead of (20) we then obtain

$$|F_k| = - \frac{m'_k M G}{|r_k|^3}.$$

Each of our three mass points hence moves in space independently of the others, as if endowed with a mass m'_k , and attracted to a mass M at rest in O in a Newtonian manner. *It therefore describes a conic section with one focus at O .*

In order to be able to say something about the magnitude and mutual position of the three conic sections we must take into account the initial conditions implicit in the state of motion we have postulated. Let us for example consider the instant at which $\lambda = \lambda_{\text{extr}}$ when the distance

$$(21) \quad \lambda_{\text{extr}} (a_k^2 + b_k^2)^{\frac{1}{2}}$$

of all the m_k from O is an extremum. According to (4) the radial velocity in S is then equal to zero; the velocity in S' , i.e., in space, is given by the component ω_s of angular velocity multiplied by the distance (21); the factor $(a_k^2 + b_k^2)^{\frac{1}{2}}$ occurring in this distance is thus a *measure of the similarity* not only of the initial velocities and initial distances from the common mass center, but at the same time of the size of the three conic sections resulting

from these initial values. *With this, statement 4 is established.* The positions of the three conic sections are distinguished by the angles which the three radius vectors $\overrightarrow{OP_i}$ form with each other.

In the special case $m_1 = m_2 = m_3$, where the mass center coincides with the intersection of the medians of the equilateral triangle, the conic sections are congruent and displaced by 120° with respect to each other.

In addition to this motion in conic sections there is, according to Lagrange, a class of motions expressible in elementary form in which the three bodies are located on a rotating straight line. However we do not want to go into this here.

Let us finally point out that from the specialized three-body problem of Lagrange one can pass to a correspondingly specialized n -body problem. In the case of n equal masses and suitable initial velocities one then obtains n congruent Kepler ellipses, which are displaced by an angle $\frac{2\pi}{n}$ with respect to each other and traversed in the same rhythm. At one time this mode of motion was temporarily advanced for electrons to explain the L -spectra of X -rays [*Physikal. Zeits.* 19, 297 (1918)].

INTEGRAL VARIATIONAL PRINCIPLES OF MECHANICS AND LAGRANGE'S EQUATIONS FOR GENERALIZED COORDINATES

§ 33. *Hamilton's Principle*

We have already met a variational principle of mechanics, that of d'Alembert. This principle compares the state of a system at any given arbitrary instant with a neighboring state obtained from it by a virtual displacement. The principles which we are about to consider are *integral principles*. They differ from the former in that we shall be concerned with the successive states of the system during a finite interval of time, or, what amounts to the same thing, over a finite section of the trajectory. These states are then compared with certain corresponding virtual neighboring states.

The different integral principles with their various names are distinguished by the way in which the correspondence between the original states and their neighboring or varied states is established. They all have this in common: the quantity to be varied has the dimensions of *action*. They can therefore all be collected under the name "principles of Least Action¹."

While power, as we already know, is a quantity of dimensions Energy \times Time⁻¹, action has dimensions Energy \times Time. An example of this is the elementary quantum of action, or Planck's constant, which we shall encounter in § 45, i.e., the quantity

$$h = 6.624 \cdot 10^{-27} \text{ erg sec.}$$

We shall first deal with *Hamilton's principle*. It differs from that of Maupertuis, to be treated in § 37 (though historically the latter came first), in that here *the time is not varied*. This means that the system arrives at any given point of the actual trajectory, of coordinates x_k , at the same time as at the corresponding point of the varied trajectory, of coordinates $x_k + \delta x_k$. The following statement sums up this property of Hamilton's principle:

$$(1) \quad \delta t = 0.$$

¹ In English-speaking countries this usage is not common. We shall hence at once distinguish Hamilton's principle from the principle of least action (sometimes called the Principle of Maupertuis).—TRANSLATOR.

We must remark at this point that when we speak of the trajectory or path of the system, we do not mean the trajectory of a point of the system in a space of three dimensions, but rather a curve in a space of many dimensions, characteristic of the motion of the system as a whole. Thus, in the case of f degrees of freedom, this curve lies in the f -dimensional space of the coordinates $q_1 \dots q_f$ (cf. p. 48).

In addition to the condition (1) we demand that another restriction be imposed on the variations in Hamilton's principle; the end points O and P of the section of the trajectory under consideration and of its varied neighboring trajectory must coincide in space. Hence we have, for any coordinate x ,

$$(2) \quad \delta x = 0 \text{ at } t = t_0 \text{ and at } t = t_1.$$

The adjoining figure has been drawn to aid in visualizing symbolically, in three dimensions, the relation of the actual path (solid) to the virtual one (dashed). The displacement δq , resulting from the variations of the coordinates δx , is to be completely arbitrary except at the two end points, with the restriction that δq be continuous and differentiable in t . There is a one-to-one correspondence between any point on the real path and one on the varied path, obtained from the former by a displacement δq , and two such points belong to the same time t .

We shall now derive Hamilton's principle. We start out with the form (10.6) of d'Alembert's principle,

FIG. 51. Variation of the "trajectory" in Hamilton's principle. The time is not varied.

$$(3) \quad \sum_{k=1}^n \{ (m_k \ddot{x}_k - X_k) \delta x_k + (m_k \ddot{y}_k - Y_k) \delta y_k + (m_k \ddot{z}_k - Z_k) \delta z_k \} = 0.$$

We therefore consider a system of n discrete mass points which may, however, be coupled by either holonomic or non-holonomic forces of constraint of unspecified nature. It follows that the δx_k , δy_k , δz_k , which must of course satisfy these constraints, are not independent of each other; in the holonomic case of f degrees of freedom only f can be chosen arbitrarily. In the non-holonomic case they are related by differential conditions.

We shall at first take up a purely formal transformation of relation (3), by writing

$$(4) \quad \ddot{x}_k \delta x_k = \frac{d}{dt} (\dot{x}_k \delta x_k) - \dot{x}_k \frac{d}{dt} (\delta x_k),$$

where we shall at once ask ourselves what the meaning of an expression

such as $\frac{d}{dt}(\delta x_k)$ is. For this purpose we compare not only the actual path of the x_k with the virtual path of the $x_k + \delta x_k$, but also the velocity \dot{x}_k along the actual path with the velocity $\dot{x}_k + \delta \dot{x}_k$ along the virtual path *at the same instant* t . The latter velocity is defined by the identity

$$\frac{d}{dt}(x_k + \delta x_k) = \dot{x}_k + \frac{d}{dt}(\delta x_k).$$

We equate these two ways of writing the varied velocity and obtain

$$(5) \quad \frac{d}{dt}(\delta x_k) = \delta \dot{x}_k.$$

Let us introduce this result into (4),

$$(6) \quad \ddot{x}_k \delta x_k = \frac{d}{dt}(\dot{x}_k \delta x_k) - \dot{x}_k \delta \dot{x}_k = \frac{d}{dt}(\dot{x}_k \delta x_k) - \frac{1}{2} \delta (\dot{x}_k^2).$$

Similar equations hold of course for the coordinates y_k and z_k . Hence (3) can now be written in the form

$$(7) \quad \begin{aligned} \frac{d}{dt} \sum m_k (\dot{x}_k \delta x_k + \dot{y}_k \delta y_k + \dot{z}_k \delta z_k) = \\ \sum \frac{m_k}{2} \delta (\dot{x}_k^2 + \dot{y}_k^2 + \dot{z}_k^2) + \sum (X_k \delta x_k + Y_k \delta y_k + Z_k \delta z_k). \end{aligned}$$

The second term on the right is nothing else but the virtual work δW , that is, the work done by the external forces in our virtual displacement. On the other hand, the first term on the right is the variation of the kinetic energy T given by

$$T = \sum \frac{m_k}{2} (\dot{x}_k^2 + \dot{y}_k^2 + \dot{z}_k^2)$$

which occurs when we pass from the real to the virtual trajectory. Eq. (7) can therefore be simplified to

$$(8) \quad \frac{d}{dt} \sum m_k (\dot{x}_k \delta x_k + \dot{y}_k \delta y_k + \dot{z}_k \delta z_k) = \delta T + \delta W.$$

Before deriving some further conclusions from this, we shall digress for a moment to make some remarks about the relation (5). Let us write it down once more, in the form

$$(9) \quad \frac{d}{dt} \delta x = \delta \frac{dx}{dt}.$$

If we recall that t is not varied, and that $\delta t = 0$ implies $\delta dt = 0$, we can replace (9) by

$$(9a) \quad \frac{d \delta x}{dt} = \frac{\delta dx}{dt} \quad \text{or also} \quad d \delta x = \delta dx.$$

Eq. (9a), especially in the second form $d\delta = \delta d$, plays a fruitful if somewhat mysterious role in the older calculus of variations of the Euler type. We note that (9a) really says the same thing as the somewhat trivial Eq. (5) relating the time derivative of the virtual displacement to the virtual variation of velocity, except that (9a) contains the two assumptions that the time is not subject to variation and that the virtual displacement is continuous.

We now return to Eq. (8) and integrate it over t from t_0 to t_1 . The left-hand side vanishes because of (2) and we are left with

$$(10) \quad \int_{t_0}^{t_1} (\delta T + \delta W) dt = 0.$$

Owing to the type of variation embodied in Hamilton's principle, this can also be rewritten as

$$(11) \quad \delta \int_{t_0}^{t_1} T dt + \int_{t_0}^{t_1} \delta W dt = 0.$$

It would, however, be erroneous to replace the latter integral by $\delta \int W dt$; for while it is true that the virtual work δW and the amount of work done in dt , i.e., dW , have a well-defined meaning, this is not so for the work W itself. W is, in general, not a "state variable." It is a state variable only if dW is a perfect differential, that is, if the external forces satisfy those conditions which guarantee the existence of a potential energy V [cf. § 6, (3)]. In that case we can replace

$$\int \delta W dt \quad \text{by} \quad - \int \delta V dt = - \delta \int V dt$$

in Eq. (11), which then takes the classically simple form

$$(12) \quad \delta \int_{t_0}^{t_1} (T - V) dt = 0.$$

This is the equation one usually thinks of when one speaks of *Hamilton's principle*. It is valid, according to the statements of p. 46, for *conservative systems*. We can call equation (11) *Hamilton's principle generalized* to include non-conservative systems.

We now claim that Eqs. (12) or (11), respectively, contain the sum-total of mechanics, just as does d'Alembert's principle. This emphasizes the special significance of the energy-like expression $T - V$. In mechanics it is called the *Lagrangian function* (or *Lagrangian*, for short) and takes Eq. (12) into

$$(13) \quad \delta \int_{t_0}^{t_1} L dt = 0 \quad \text{where} \quad L = T - V.$$

In words, *the time integral of the Lagrangian is an extremum*. Helmholtz relied heavily on the variational principle in Hamiltonian form in his last works; he extended it to electrodynamics, and called L the *kinetic potential*. The name "free energy," as opposed to the "total energy" $T+V$, would be equally justified in view of its wide use in thermodynamics.

Hamilton's principle derives special value from the fact that it is totally independent of the choice of coordinates. In fact, T and V (as well as δW) are quantities of immediate physical significance, which can be expressed in any desired set of coordinates. We shall make use of this property in the following section.

Hertz was of the opinion that Hamilton's principle was valid only for holonomic systems. This error was corrected by O. Hölder (Göttinger Nachr. 1896).

Hamilton's principle goes counter to our need for cause-and-effect relationships, as do all the other variational principles involving action integrals. For here the sequence of events is determined not by the present state of the system, but is instead derived under equal consideration of both its past and future states. It seems then that the variation principles are *not causal*, but rather *teleological*. We shall come back to this point in § 37, where we shall deal with the historical origin of the principles. There we shall also briefly touch on the conversion of Hamilton's principle into forms useful in fields of physics other than mechanics.

§ 34. Lagrange's Equations for Generalized Coordinates

Let us consider an arbitrary mechanical system. We shall for the present assume that its parts are coupled by holonomic conditions only. The number of degrees of freedom of the system is f . We can then introduce f independent coordinates which determine the position of the system at any given instant. We shall call them, as on p. 49,

$$(1) \quad q_1, q_2, \dots, q_f.$$

These are our position coordinates. To them we add the "velocity coordinates"

$$(1a) \quad \dot{q}_1, \dot{q}_2, \dots, \dot{q}_f.$$

The q_k and \dot{q}_k together completely specify the state of the system at any instant.

Let us be more explicit: let the system be described for the moment by $n > f$ coordinates x_1, \dots, x_n , which need not necessarily be Cartesian. Let $n-f$ conditions hold between them, of the form

$$(2) \quad F_k(x_1, x_2, \dots, x_n) = 0, \quad k=f+1, f+2, \dots, n$$

We can then define q_k as some function F_k of x_1, \dots, x_n ,

$$(2a) \quad F_k(x_1, x_2, \dots, x_n) = q_k, \quad k=1, 2, \dots, f.$$

Let us denote the partial derivatives of F_k with respect to x_i by F_{ik} ; a differentiation of (2) and (2a) with respect to t then gives

$$(2b) \quad \sum_{i=1}^n F_{ik}(x_1, \dots, x_n) \dot{x}_i = \begin{cases} \dot{q}_k, & k=1, 2, \dots, f \\ 0, & k=f+1, \dots, n. \end{cases}$$

We can calculate from this the \dot{x}_i as linear functions of the \dot{q}_k , with coefficients that depend on the x_1, \dots, x_n , or, by virtue of (2) and (2a), on the q_1, \dots, q_f . The kinetic energy T , a homogeneous quadratic function of the \dot{x}_i , just as it would be were it expressed in Cartesian coordinates to begin with, again becomes a homogeneous quadratic function of the \dot{q}_k with coefficients that depend on the q_k . For the present we shall postulate that the potential energy V is a function of the q_k only, without, in principle, excluding the possibility of later making V a function of the \dot{q}_k as well. In this connection we may now complete the definition (33.13) of L by stating that

L is to be regarded as a function of the q_k and \dot{q}_k .

For the time being we shall exclude an explicit dependence of L on t .

It is in this sense that we now write down the variation of L , i.e., the difference between the values of L in the virtual varied state $q_k + \delta q_k$, $\dot{q}_k + \delta \dot{q}_k$ and in the original state q_k , \dot{q}_k :

$$(3) \quad \delta L = \sum_k \frac{\partial L}{\partial q_k} \delta q_k + \sum_k \frac{\partial L}{\partial \dot{q}_k} \delta \dot{q}_k.$$

This variation is now introduced into Hamilton's principle

$$(3a) \quad \int_{t_1}^{t_2} \delta L dt = 0.$$

This form differs from that in (33.13) in that we have written the variation under the integral sign, whereas we had previously put it in front. The two forms are, of course, equivalent by virtue of rule (33.1), which says that t and dt are not varied. In any case, Eq. (3a) corresponds to the formulation (33.10) in which we first encountered the principle.

We now carry out the integration over the time indicated by (3a) on the general term of the second sum of (3). For this purpose we alter the form of this term by a *partial integration*, a procedure which has been

characteristic of the whole calculus of variations ever since Euler²:

$$(4) \quad \int_{t_1}^{t_2} \frac{\partial L}{\partial \dot{q}_k} \delta \dot{q}_k dt = \int_{t_1}^{t_2} \frac{\partial L}{\partial \dot{q}_k} \frac{d}{dt} \delta q_k dt = \frac{\partial L}{\partial \dot{q}_k} \delta q_k \Big|_{t_1}^{t_2} - \int_{t_1}^{t_2} \frac{d}{dt} \frac{\partial L}{\partial \dot{q}_k} \delta q_k dt.$$

In the last member of this double equality the first term vanishes because of the conditions laid down in (33.2). The complete expression (3) for δL therefore yields

$$(4a) \quad \int_{t_1}^{t_2} \delta L dt = - \int_{t_1}^{t_2} \sum_k \left(\frac{d}{dt} \frac{\partial L}{\partial \dot{q}_k} - \frac{\partial L}{\partial q_k} \right) \delta q_k dt = 0.$$

Now the δq_k are independent of each other. We can therefore make all but one of them zero. This one we can also make zero everywhere along the "trajectory" of Fig. 51 except in the neighborhood of a single point, or, what amounts to the same thing, during a time interval Δt at an arbitrary time t . In order to satisfy (4a) we now require that

$$(5) \quad \left(\frac{d}{dt} \frac{\partial L}{\partial \dot{q}_k} - \frac{\partial L}{\partial q_k} \right) \int_{\Delta t} \delta q_k dt = 0.$$

But Δt is finite, and δq_k does not vanish during the interval Δt . Hence we must have, for any time t and any index k ,

$$(6) \quad \frac{d}{dt} \frac{\partial L}{\partial \dot{q}_k} - \frac{\partial L}{\partial q_k} = 0.$$

These are Lagrange's equations for generalized coordinates, or, as they are also called, *Lagrange's equations of the second kind*, specialized to the case so far considered in which the forces acting on the system have a potential and the internal constraints of the system are holonomic.

If one or the other of these assumptions is dropped, we arrive at an extended form of these equations; let us hence consider two cases.

The first case is that in which the forces are not derivable from a potential. In that case the form (33.11) of Hamilton's principle will have to be our starting point. We think of the virtual work δW of the external forces as expressed in terms of the virtual displacements δq_k , and are led to write

$$(7) \quad \delta W = \sum Q_k \delta q_k.$$

² In general we use the term "Euler's equation" of a given variational problem to designate an equation of type (6), and the derivation of (6) from (4) and (5) is typical of the derivation of Euler's equation in any such problem. We can therefore say that Lagrange's equations are the Euler equations for the variational problem characterized by the function L .

We shall call the coefficients Q_k here introduced the *generalized components of force* associated with the coordinates q_k . This is a formal extension of the force concept, which is of course admissible as a mathematical definition. Furthermore it is quite useful. Thus we can now restate the definition of the moment of a force about an axis given in (9.7) as follows: the moment of a force is the generalized force associated with the corresponding angle of rotation. It is clear that the quantities Q_k defined in (7) no longer possess vector character, nor need they in general have the dimensions of dynes any longer. From (7) it is seen that their dimensions depend instead on the dimension of the associated q_k . Thus moments of force must, as we already know, have dimensions of work, hence ergs, for the associated δq_k are angles and therefore dimensionless.

If we now introduce (7) in (33.11) and carry out the transformations indicated by Eqs. (4) and (5), we clearly obtain, in place of (6),

$$(8) \quad \frac{d}{dt} \frac{\partial T}{\partial \dot{q}_k} - \frac{\partial T}{\partial q_k} = Q_k.$$

We can write this in a somewhat more general form as

$$(8a) \quad \frac{d}{dt} \frac{\partial L}{\partial \dot{q}_k} - \frac{\partial L}{\partial q_k} = Q_k.$$

This is more general because now we can take into account the case where some of the forces acting are derivable from potentials, others not. We need only write the Q_k corresponding to the latter type of forces on the right side of (8a). The potential energy of the former, on the other hand, can be combined with the kinetic energy T to form the Lagrangian L of (8a).

Eqs. (8a) are then the *Lagrange equations for forces some of which are not derivable from potentials*.

If now we drop the second of the previously stated assumptions, i.e., postulate that the constraints of the system are in part non-holonomic, the introduction of the coordinates q_k is made invalid. For by definition non-holonomic conditions cannot be put in the form (2) and hence cannot be eliminated by proper choice of the q . We are then forced to introduce an excessive number of q , that is, a number greater than the number of degrees of freedom for infinitesimal motion. The latter is $f-r$ where f is the number of degrees of freedom for finite motion and r the number of non-holonomic conditions. These can be written as virtual conditions in a form similar to Eq. (7.4),

$$(9) \quad \sum_{k=1}^f F_{k\mu}(q_1, \dots, q_f) \delta q_k = 0, \quad \mu = 1, 2, \dots, r.$$

They imply a restriction on allowable variations δq_k . One takes this restriction into account by multiplying each of the Eqs. (9) by a Lagrangian multiplier λ_μ and then adding it under the integral of (8.13). One obtains, with the F in somewhat abbreviated notation,

$$\int_{t_0}^{t_1} (\delta L + \sum_{\mu=1}^r \lambda_\mu F_{k\mu} \delta q_k) dt = 0.$$

The Eulerian transformation proceeds as in (4), where instead of (4a) we obtain

$$(10) \quad \int_{t_0}^{t_1} \sum_k \left(\frac{d}{dt} \frac{\partial L}{\partial \dot{q}_k} - \frac{\partial L}{\partial q_k} - \sum_{\mu=1}^r \lambda_\mu F_{k\mu} \right) \delta q_k dt.$$

Here the δq_k are no longer independent of each other, but are connected through relations (9). One can, however, argue as on p. 67: of the bracketed () coefficients of δq_k in (10), r can be made to vanish by a suitable choice of the λ_μ . In the remaining sum over k , only $f-r$ of the q_k , all independent of each other, are left. The same line of reasoning as after (5) now forces us to the conclusion that the remaining brackets must vanish, too. We then obtain the complete system of f equations,

$$(11) \quad \frac{d}{dt} \frac{\partial L}{\partial \dot{q}_k} - \frac{\partial L}{\partial q_k} = \sum_{\mu=1}^r \lambda_\mu F_{k\mu}.$$

We can designate these as *Lagrange's equations of the mixed type*, since they fall halfway between Lagrange's equations of the first and second kind.

We may mention that this mixed type occurs not only when we are *unable* to eliminate some of the conditions (case of non-holonomic constraints), but also whenever we *do not wish* to eliminate them. For it can happen that we are interested in the force of constraint that a holonomic condition exerts on the system. This force, as it turns out, is represented by the λ_μ associated with the condition in question [just as in Eq. (18.7) dealing with the spherical pendulum], and can be obtained by integration of Eq. (11).

Evidently we can finally combine the types (11) and (8a), for the case that we simultaneously drop both assumptions stated after (6).

Instead of doing this, we shall lastly concern ourselves with the following question: how and under what assumptions can the principle of the conservation of energy be derived from Lagrange's equations (6)?

As already emphasized, above Eq. (3), L is a function of the q_k and the \dot{q}_k ; we further require, as earlier, that L not contain t explicitly. In that

case Eq. (8) is valid not only for the virtual changes δq , $\delta \dot{q}$, but also for the secular changes dq , $d\dot{q}$, so that we have

$$(12) \quad \frac{dL}{dt} = \sum_k \dot{q}_k \frac{\partial L}{\partial q_k} + \sum_k \ddot{q}_k \frac{\partial L}{\partial \dot{q}_k}.$$

On the other hand we emphasized at the same place that T is a homogeneous quadratic function^a of the \dot{q}_k . We can therefore apply the Euler rule

$$(13) \quad 2T = \sum_k \dot{q}_k \frac{\partial T}{\partial \dot{q}_k}$$

for homogeneous functions. Differentiation with respect to the time gives

$$(14) \quad 2 \frac{dT}{dt} = \sum_k \dot{q}_k \frac{d}{dt} \frac{\partial T}{\partial \dot{q}_k} + \sum_k \ddot{q}_k \frac{\partial T}{\partial \dot{q}_k}.$$

We now subtract (12) from (14). Because $L = T - V$, the left member becomes

$$\frac{dT}{dt} + \frac{dV}{dt}.$$

On the right the second terms cancel *provided* V is independent of \dot{q}_k . In that case, by means of Eq. (6), the first terms on the right cancel as well, so that we obtain

$$(14a) \quad \frac{dT}{dt} + \frac{dV}{dt} = 0$$

from which we conclude that

$$(15) \quad T + V = E.$$

The law of the conservation of energy is therefore a consequence of Lagrange's equations.

We must now examine the assumptions leading to this important conclusion.

a) From the meaning of T we can say that the kinetic energy is determined by the position and velocity of the system, hence by q and \dot{q} ; T could depend on t explicitly only as a result of the elimination of the equations

^a Even when this is not the case and L is instead assumed to be any desired function of the q_k and \dot{q}_k , a generalized conservation law of the form $H = \sum_k \frac{\partial L}{\partial \dot{q}_k} \dot{q}_k - L = \text{const.}$ can be given. In Chapter VIII we shall call the function H thus defined the "Hamiltonian"; the conservation law contained in Eq. (15c) is a special case of the above equation.

of constraint, in case the latter depend on t ⁴. Now we have already seen on p. 68 that such constraints do work on the system, and therefore upset the conservation of energy. It is then indeed necessary for the validity of the conservation law that T not contain the time explicitly.

b) The assumption that L does not depend explicitly on t therefore reduces to the assumption that V is independent of t . This condition, too, is necessary. Otherwise one would have to add the term

$$-\frac{\partial V}{\partial t}$$

on the right side of Eq. (12). This term would then reappear with opposite sign in the right-hand member of Eq. (14a). Instead of $T+V=\text{const.}$ we should then obtain

$$(15a) \quad \frac{d}{dt}(T+V) = \frac{\partial V}{\partial t},$$

that is, the law of the conservation of energy would be invalidated.

c) Suppose that V depends not only on the q_k but also on the \dot{q}_k . With the aid of (6) we obtain as the difference of the right members of (14) and (12)

$$(15b) \quad \sum \dot{q}_k \frac{d}{dt} \frac{\partial V}{\partial \dot{q}_k} + \sum \ddot{q}_k \frac{\partial V}{\partial \ddot{q}_k} = \frac{d}{dt} \sum \dot{q}_k \frac{\partial V}{\partial \dot{q}_k}.$$

This case does lead to a conservation law, which has, however, the unfamiliar form

$$(15c) \quad T+V - \sum \dot{q}_k \frac{\partial V}{\partial \dot{q}_k} = \text{const.}$$

One more conclusion can be drawn from the above which will be useful to us later. We shall calculate $L-2T = -(T+V)$, by using the expression (13) for $2T$ and reverting to the assumption that V is a function of only the q_k . We then arrive at

$$(T+V) = L - \sum \dot{q}_k \frac{\partial T}{\partial \dot{q}_k} = L - \sum \dot{q}_k \frac{\partial L}{\partial \dot{q}_k},$$

or

$$(16) \quad T+V = \sum \dot{q}_k \frac{\partial L}{\partial \dot{q}_k} - L.$$

The total energy $T+V$ can be calculated from the expression for the Lagrangian.

⁴ Sometimes such time-dependent conditions are called *rheonomous* (fluid) as opposed to time-independent conditions which are characterized as *scleronomous* (fixed, rigid).

The rather abstract developments of this section will come to life with the examples of the following section. To prepare ourselves for these we shall specialize the two expressions

$$\frac{\partial L}{\partial \dot{q}_k} \quad \text{and} \quad \frac{\partial L}{\partial q_k}$$

occurring in (6) for the simplest case, the motion of an isolated mass point expressed in Cartesian coordinates x, y, z . We have

$$T = \frac{m}{2} (\dot{x}^2 + \dot{y}^2 + \dot{z}^2), \quad \frac{\partial L}{\partial \dot{x}} = \frac{\partial T}{\partial \dot{x}} = m\dot{x}, \text{ etc.}$$

$$\frac{\partial L}{\partial x} = -\frac{\partial V}{\partial x} = X, \text{ etc.}$$

Since, according to this equation, $\frac{\partial L}{\partial \dot{x}}$ represents the x -coordinate of momentum, we shall, quite in general, call $\frac{\partial L}{\partial \dot{q}_k}$ the *component of generalized momentum belonging to q_k* . Since on the other hand $\frac{\partial L}{\partial x}$ furnishes the x -component of the force, we shall label the two terms resulting from $\frac{\partial L}{\partial q}$ as *q -components of generalized force*,

$$(17) \quad \frac{\partial T}{\partial q} - \frac{\partial V}{\partial q} = \frac{\partial T}{\partial q} - Q.$$

Q is an *external force* as in Eq. (7), whereas $\frac{\partial T}{\partial q}$ is a *fictitious Lagrange force* dependent on the way in which the q coordinate varies with position. In the case of Cartesian coordinates x, y, z where curves of constant q are parallel to each other, a given q_i is independent of the q_k ($k \neq i$) and the fictitious force vanishes.

§ 35. Examples Illustrating the Use of Lagrange's Equations

We have chosen examples which were treated earlier by elementary methods, in order to demonstrate the superiority of the Lagrange formalism.

(1) The Cycloidal Pendulum.

The obvious coordinate q in this case is the angle of rotation of the wheel generating the cycloids in Fig. 26. The Cartesian coordinates expressed in terms of this angle are, according to (17.2),

$$\begin{aligned} x &= a(\phi - \sin \phi), & \dot{x} &= a(1 - \cos \phi) \dot{\phi} \\ y &= a(1 + \cos \phi), & \dot{y} &= -a \sin \phi \dot{\phi}. \end{aligned}$$

From these we calculate

$$T = \frac{m}{2} (\dot{x}^2 + \dot{y}^2) = ma^2(1 - \cos \phi) \dot{\phi}^2$$

$$V = mgy = mga(1 + \cos \phi)$$

$$(1) \quad L = ma^2(1 - \cos \phi) \dot{\phi}^2 - mga(1 + \cos \phi).$$

This is all we need to know about the geometry and mechanics of our system. The Lagrange formalism automatically takes care of the rest:

$$\frac{\partial L}{\partial \dot{\phi}} = 2ma^2(1 - \cos \phi) \dot{\phi}, \quad \frac{\partial L}{\partial \phi} = ma^2 \sin \phi \dot{\phi}^2 + mga \sin \phi$$

$$\frac{d}{dt} \frac{\partial L}{\partial \dot{\phi}} = 2ma^2(1 - \cos \phi) \ddot{\phi} + 2ma^2 \sin \phi \dot{\phi}^2$$

or, when substituted into the differential equation (6),

$$(1 - \cos \phi) \ddot{\phi} + \frac{1}{2} \sin \phi \dot{\phi}^2 = \frac{g}{2a} \sin \phi.$$

Introduction of the half angle and division by $2 \sin \frac{1}{2} \phi$ simplifies this to

$$(2) \quad \sin \frac{\phi}{2} \ddot{\phi} + \frac{1}{2} \cos \frac{\phi}{2} \dot{\phi}^2 = \frac{g}{2a} \cos \frac{\phi}{2}.$$

It can easily be verified that the left member equals $-2 \frac{d^2}{dt^2} \cos \frac{1}{2} \phi$. Our differential equation (2) is therefore identical to the previous Eq. (17.6), by means of which we were able to prove the rigorously isochronous behavior of the cycloidal pendulum.

(2) The Spherical Pendulum

Here the angles θ and ϕ , polar angle and geographic longitude respectively on the sphere of radius l , are the given coordinates of the mass point. The line element is

$$ds^2 = l^2 (d\theta^2 + \sin^2 \theta d\phi^2)$$

so that the kinetic energy becomes

$$T = \frac{m}{2} l^2 (\dot{\theta}^2 + \sin^2 \theta \dot{\phi}^2).$$

As in (18.5a) the potential energy is $V = mgl \cos \theta$ and therefore

$$(3) \quad L = \frac{m}{2} l^2 (\dot{\theta}^2 + \sin^2 \theta \dot{\phi}^2) - mgl \cos \theta.$$

And now the automatic calculation along the Lagrange pattern sets in. After division by constant factors, the differential equations for θ and ϕ are

$$(4) \quad \ddot{\theta} - \sin \theta \cos \theta \dot{\phi}^2 - \frac{g}{l} \sin \theta = 0$$

$$\frac{d}{dt} (l^2 \sin^2 \theta \dot{\phi}) = 0.$$

The second of these equations is the law of conservation of areal velocity, in agreement with (18.8). Note that we have here avoided the calculation which necessarily preceded this equation in the earlier treatment. With the help of the areal velocity constant C of Eq. (18.8), the first of Eqs. (4) can be written

$$\ddot{\theta} = \frac{C^2}{l^2} \frac{\cos \theta}{\sin^3 \theta} + \frac{g}{l} \sin \theta.$$

The second term on the right is equivalent to the gravitational torque $|L| = mgl \sin \theta$, this being the generalized component of force associated with the angle $q = \theta$ in the sense of (34.7). The first term is a fictitious Lagrange force in the sense of (34.17); the origin of this force is the fact that the lines along which the angle θ is measured on a sphere do not run parallel but diverge from the pole.

It is instructive to apply to this example the extension of Lagrange's equations for which provision was made in Eq. (34.11) by introducing the excess coordinate r together with the θ and ϕ . Now r is of course fixed through the relation $r = l$; nevertheless we are interested in this coordinate because it will give us, by means of the multiplier λ , the pressure of the mass point on the surface of the sphere, or, what amounts to the same thing, the tension in the suspension cord of the pendulum. In order to obtain the pertinent differential equation we need only replace (3) by

$$(5) \quad L = \frac{m}{2} (\dot{r}^2 + r^2 \dot{\theta}^2 + r^2 \sin^2 \theta \dot{\phi}^2) - mgr \cos \theta$$

and form a third Lagrange equation to be added to the two of (4),

$$(6) \quad \frac{d}{dt} m\dot{r} - mr\dot{\theta}^2 - mr \sin^2 \theta \dot{\phi}^2 + mg \cos \theta = \lambda r.$$

We have put the quantity $F_{k\mu}$ occurring in (34.11) equal to r , for in order to obtain agreement with Eq. (18.1) we have written the condition $r = l$ in the form

$$F = \frac{1}{2} (r^2 - l^2) = 0.$$

If we set $r = l$ and $\dot{r} = \ddot{r} = 0$, it follows from (6) that

$$(7) \quad \lambda l = mg \cos \theta - ml(\dot{\theta}^2 + \sin^2 \theta \dot{\phi}^2).$$

This is in agreement with (18.6) if there we transform the rectangular coordinates to θ, ϕ . Such a calculation is once more avoided by the use of the Lagrange scheme.

(3) The Double Pendulum

Here the two angles ϕ and ψ of Fig. 38 are suitable coordinates q_k . In the notation of § 21 we write

$$(8) \quad \begin{aligned} X &= L \sin \phi, & x &= L \sin \phi + l \sin \psi \\ Y &= L \cos \phi, & y &= L \cos \phi + l \cos \psi. \end{aligned}$$

From these we get the following exact relations:

$$\begin{aligned} T &= \frac{M}{2} (\dot{X}^2 + \dot{Y}^2) + \frac{m}{2} (\dot{x}^2 + \dot{y}^2) \\ &= \frac{M+m}{2} L^2 \dot{\phi}^2 + \frac{m}{2} l^2 \dot{\psi}^2 + mLl \cos(\phi - \psi) \dot{\phi} \dot{\psi}, \end{aligned}$$

$$V = -MgY - mgy = -(M+m)gL \cos \phi - mgl \cos \psi.$$

The sign of the last expression is negative because (cf. Fig. 38) Y and y have been taken positive in the direction of the force of gravity. We shall here call Λ the Lagrangian formed from $T - V$ since we have used the letter L for the length of the pendulum suspension. We obtain

$$\begin{aligned} \frac{\partial \Lambda}{\partial \dot{\phi}} &= (M+m)L^2 \dot{\phi} + mLl \cos(\phi - \psi) \dot{\psi}, \\ \frac{\partial \Lambda}{\partial \dot{\psi}} &= ml^2 \dot{\psi} + mLl \cos(\phi - \psi) \dot{\phi}, \\ \frac{\partial \Lambda}{\partial \phi} &= -(M+m)gL \sin \phi - mLl \sin(\phi - \psi) \dot{\phi} \dot{\psi}, \\ \frac{\partial \Lambda}{\partial \psi} &= -mgl \sin \psi + mLl \sin(\phi - \psi) \dot{\phi} \dot{\psi}. \end{aligned}$$

In writing down the Lagrange equations from these relations we shall at once go over to small ϕ, ψ . $\dot{\phi}, \dot{\psi}$ are quantities of the same magnitude as ϕ, ψ ; their squares can therefore be neglected. The equations in question are then

$$(9) \quad \begin{aligned} \ddot{\phi} + \frac{g}{L} \phi &= -\frac{m}{M+m} \frac{l}{L} \ddot{\psi}, \\ \ddot{\psi} + \frac{g}{l} \psi &= -\frac{L}{l} \ddot{\phi}. \end{aligned}$$

These are identical with the Eqs. (21.3); we need merely switch back from coordinate angles ϕ , ψ to coordinate distances X , x by making use of the transformation equations (8) which, for small ϕ , ψ , simplify to

$$\phi = \frac{X}{L}, \quad \psi = \frac{x-X}{l}.$$

The identity is immediate for the second of Eqs. (9) and (21.3); the same is true of the first Eq. (9) and the first Eq. (21.3) provided we introduce for $\ddot{\psi}$ in the right member its value from the second Eq. (9). The discussion of the oscillation process following Eq. (21.3) is hence immediately applicable to our present Eqs. (9) and need not be repeated here.

In concluding we wish to emphasize that in the present purely formal treatment there was no mention whatever of the tension in the pendulum string l ; this tension is implicitly contained in the Lagrange equations of motion as an internal reaction of the system, as has already been stressed in the footnote on p. 112.

(4) The Heavy Symmetrical Top

The classical coordinates q_k of this problem are the Eulerian angles θ , ϕ and ψ [θ and ϕ have been introduced already in (25.4) and (26.5a)]. We shall define them and their corresponding angular velocities as follows (cf. Fig. 52):

1. θ is the angle between the vertical and the axis of the top; $\dot{\theta}$ is the angular velocity about the line of nodes which is perpendicular to both of these directions.
2. ψ is the angle which the line of nodes makes with a fixed direction in the horizontal plane, for instance the x -axis; $\dot{\psi}$ is the angular velocity about the vertical.
3. ϕ is the angle which the line of nodes makes with a fixed direction in the equatorial plane of the top, for example the X -axis; $\dot{\phi}$ is the angular velocity about the axis of symmetry of the top.

FIG. 52. Definition of the Eulerian angles θ , ϕ , ψ , and their sense. The labeling of the axes is in agreement with the systems of coordinates introduced on p. 139 (z =vertical, Z =axis of top, x =horizontal line fixed in space, X =line in the equatorial plane of the top, fixed in the top).

The $\dot{\theta}$, $\dot{\phi}$, $\dot{\psi}$ are *holonomic* but *curvilinear* components of the angular velocity vector ω , as opposed to the ω_1 , ω_2 , ω_3 which were *rectilinear* but *non-holonomic* components of rotational velocity. Table (10) below shows the direction cosines between both sets of components. The table also gives the sense of rotation of $\dot{\theta}$, $\dot{\phi}$, $\dot{\psi}$ (rule of right-handed screw):

(10)

	$\dot{\theta}$	$\dot{\phi}$	$\dot{\psi}$
ω_1	$\cos \phi$	0	$\sin \theta \sin \phi$
ω_2	$-\sin \phi$	0	$\sin \theta \cos \phi$
ω_3	0	1	$\cos \theta$

The first two columns follow in an obvious manner from what was said in 1 and 3. In order to understand the third column, note that the projection of the vertically oriented vector $\dot{\psi}$ in the equatorial plane is $\dot{\psi} \sin \theta$; this vector in turn is resolved in the equatorial plane into the two components indicated opposite ω_1 and ω_2 , viz., $\dot{\psi} \sin \theta \sin \phi$ and $\dot{\psi} \sin \theta \cos \phi$ respectively.

Notice that our table, unlike those in § 2, can be read only from left to right, not from top to bottom. From its rows we now obtain

$$\begin{aligned}
 \omega_1 &= \cos \phi \dot{\theta} + \sin \theta \sin \phi \dot{\psi}, \\
 \omega_2 &= -\sin \phi \dot{\theta} + \sin \theta \cos \phi \dot{\psi}, \\
 \omega_3 &= \dot{\phi} + \cos \theta \dot{\psi}.
 \end{aligned}
 \quad (11) \quad (11a) \quad \omega_1^2 + \omega_2^2 = \dot{\theta}^2 + \sin^2 \theta \dot{\psi}^2.$$

Putting $I_2 = I_1$, the expression (26.17) therefore becomes

$$(12) \quad T = \frac{I_1}{2} (\dot{\theta}^2 + \sin^2 \theta \dot{\psi}^2) + \frac{I_2}{2} (\dot{\phi} + \cos \theta \dot{\psi})^2.$$

By virtue of Eq. (25.6a) for the gravitational potential energy V we have

$$(13) \quad L = T - V = \frac{I_1}{2} (\dot{\theta}^2 + \sin^2 \theta \dot{\psi}^2) + \frac{I_2}{2} (\dot{\phi} + \cos \theta \dot{\psi})^2 - P \cos \theta,$$

$$P = mgs.$$

L is therefore *independent* of the position coordinates ϕ and ψ and depends only on their change with time. We say that ϕ and ψ are *cyclic coordinates*. The name has its origin in the dynamic behavior of a rotating wheel (Greek: $\kappaυκλoσ$) which is determined not by its instantaneous position but only by its speed of revolution. Hence

$$\frac{\partial L}{\partial \phi} = \frac{\partial L}{\partial \psi} = 0.$$

From Lagrange's equations the time derivatives of the quantities

$$\frac{\partial L}{\partial \dot{\phi}} \quad \text{and} \quad \frac{\partial L}{\partial \dot{\psi}}$$

must then vanish. At the end of the last section we called these quantities the generalized momenta associated with ϕ and ψ . From now on we shall always designate them by p . Thus we write in general

$$(14) \quad p_k = \frac{\partial L}{\partial \dot{q}_k}.$$

We can then assert that if the coordinates q_k are cyclic, the momenta p_k conjugate to cyclic coordinates are integrals of the motion (i.e., constants of integration). In our case we already know the significance of these constants from (25.6). We have

$$(15) \quad p_\phi = M'', \quad p_\psi = M'.$$

Previously, on p. 141, we lacked the expressions of these constants in terms of the position coordinates of the top. These can now be derived by application of the general rule (14):

$$(16) \quad \begin{aligned} p_\phi &= \frac{\partial L}{\partial \dot{\phi}} = I_3 (\dot{\phi} + \cos \theta \dot{\psi}), \\ p_\psi &= \frac{\partial L}{\partial \dot{\psi}} = I_1 \sin^2 \theta \dot{\psi} + I_3 \cos \theta (\dot{\phi} + \cos \theta \dot{\psi}). \end{aligned}$$

Combination of (15) and (16) results in

$$(17) \quad \begin{aligned} \dot{\phi} + \cos \theta \dot{\psi} &= \frac{M''}{I_3}, \\ I_1 \sin^2 \theta \dot{\psi} &= M' - M'' \cos \theta. \end{aligned}$$

Eqs. (17) exhaust the content of two of the Lagrange equations. The third one expresses the rate of change of

$$(18) \quad p_\theta = \frac{\partial L}{\partial \dot{\theta}} = I_1 \dot{\theta}$$

and becomes, if (17) is used to eliminate $\dot{\phi}$ and $\dot{\psi}$,

$$(19) \quad I_1 \ddot{\theta} = \frac{(M' - M'' \cos \theta)(M' \cos \theta - M'')}{I_1 \sin^3 \theta} + P \sin \theta.$$

The right-hand member, which comes from $\frac{\partial L}{\partial \theta}$, contains not only the gravitational effect familiar to us from (25.4), but in addition a fictitious force which is a consequence of the nature of the coordinate system used, as we know from p. 192.

Eq. (19) has the character of a generalized pendulum equation. We need not be detained with its integration, for we can avail ourselves of the integral of energy

$$(20) \quad T + V = E$$

which must be identical with the result of a first integration of (19). Let us once more eliminate the quantities $\dot{\phi}$ and $\dot{\psi}$ of Eq. (12) with the help of (17). Then (20) yields

$$(21) \quad \frac{I_1}{2} \left\{ \dot{\theta}^2 + \left(\frac{M' - M'' \cos \theta}{I_1 \sin \theta} \right)^2 \right\} + \frac{M''^2}{2I_2} + P \cos \theta = E.$$

Since Eq. (21) contains three constants of integration, namely M' , M'' , and E , it must be the general integral of first order for the problem of the top. Finally, just as in § 18 for the spherical pendulum, we replace θ and $\dot{\theta}$ by

$$\cos \theta = u; \quad \dot{\theta} \sin \theta = -\dot{u}.$$

We then obtain

$$(22) \quad \left(\frac{du}{dt} \right)^2 = U(u)$$

where

$$(23) \quad U(u) = \left(\frac{2E}{I_1} - \frac{M''^2}{I_1 I_2} - \frac{2P}{I_1} u \right) (1 - u^2) - \left(\frac{M' - M'' u}{I_1} \right)^2.$$

Since $U(u)$ is a polynomial of third degree in u , the time t must be given by an elliptic integral of the first kind, as in the case of the spherical pendulum:

$$(24) \quad t = \int \frac{du}{U^{1/2}}.$$

The azimuth angle ψ is given from Eq. (17) by an elliptic integral of the third kind (cf. p. 100),

$$(25) \quad \psi = \int \frac{M' - M'' u}{I_1 (1 - u^2)} \frac{du}{U^{1/2}}.$$

We can now repeat the considerations following Fig. 29 on p. 99, and arrive at the picture of Fig. 53. The trace of the axis of the top on a unit sphere oscillates back and forth between the two circles of latitude $u = u_2$ and $u = u_1$, which it touches. At the points of tangency, as

FIG. 53. Trace of the axis of the heavy symmetrical top on a sphere of unit radius.

At the points of tangency, as

shown in Fig. 53, the trace may either merely pass by, or make a loop; the loop may in turn degenerate into a cusp. During each oscillation the axis of the top advances by the same azimuth angle $\Delta\psi$, obtained from Eq. (25) by a complete elliptic integral of the third kind, similar to that in (18.15).

In particular, if the top is to describe a regular precession about the vertical, it is necessary that the parallel circles u_1 and u_2 become merged; the curve $U(u)$ of Fig. 29 (p. 99) must then touch the axis of abscissae from below. This shows that the regular precession of the heavy top is a particular form of motion (whereas, in the case of the top under no forces, it is the general form of motion).

If the two roots u_1 and u_2 do not coincide exactly, but only approximately, we still *seem* to have a uniform advance of the axis of the top about the vertical; on closer observation one notices, however, that *small nutations* are superposed on this uniform advance, giving rise to what we called a "pseudo-regular precession". This is the typical phenomenon that one observes in the usual experiments with tops: one first imparts the greatest possible angular momentum to the top about its axis by pulling a string off its rim, and then sets it point down in a socket pan, taking great care not to add a perceptible lateral impulse to the motion.

We explain this behavior as follows: in such an experiment the initial angular momentum M is close to the axis of symmetry; this also follows from the Poinsot method for the initial axis of rotation. Hence the axis of rotation describes at first a narrow circuit on the unit sphere of Fig. 43. The parallel circles $u=u_1$, $u=u_2$ touching this circuit are close neighbors and remain close during the entire course of the motion, as can be seen from our general illustration in Fig. 53. The angular momentum and hence also the angular velocity are at first very great; they, too, remain unchanged during the motion apart from frictional losses. The nutations are therefore very rapid and almost invisible. The top seems reluctant to yield to the influence of gravity, instead constantly "sidestepping" in a direction perpendicular to the force of gravitation. It is this paradoxical behavior which has for centuries attracted amateur and professional investigator alike to the theory of the spinning top.

§ 36. An Alternate Derivation of Lagrange's Equations

Even though the derivation of Lagrange's equations for generalized coordinates from Hamilton's principle is unsurpassed in clarity and brevity, we feel that it is somewhat artificial. The transformation properties of the various dynamic variables, which form the core of the Lagrange equations, are not brought to light. The following derivation will remedy this situation.

We focus our attention on a system of $\frac{n}{3}$ mass points (n being divisible by 3), subject to arbitrary constraints, chosen holonomic for the sake of simplicity. The number of constraints is equal to $n-f$, where f is the number of degrees of freedom of the system. Our notation will be that of Eq. (34.2). We shall number the coordinates, assumed orthogonal, $x_1, x_2 \dots x_n$; similarly we let $X_1, X_2 \dots X_n$ be the components of the external forces. Finally we shall call $\xi_1, \xi_2 \dots \xi_n$ the components of momentum of our mass points. We would have preferred to name them $p_1, p_2 \dots p_n$, as agreed to in (35.14); this notation must, however, be reserved for the generalized momenta. We have

$$(1) \quad \xi_i = m_i \dot{x}_i, \quad i=1, 2 \dots n,$$

where the m_i are of course equal in groups of three. The motion of our system is described by Lagrange's equations of the first kind (12.9) which are, in the present notation,

$$(2) \quad \frac{d\xi_i}{dt} = X_i + \sum_{\mu=f+1}^n \lambda_\mu \frac{\partial F_\mu}{\partial x_i}, \quad i=1, 2 \dots n.$$

We now introduce the generalized position coordinates $q_1, \dots q_f$, which can be and are to be chosen in such a way that, just as in (34.2), the $n-f$ conditions $F_\mu=0$ are identically satisfied. Then Eqs. (34.2b) must hold between the old and the new velocity coordinates; we solve these for the \dot{x} and write them as follows:

$$(3) \quad \dot{x}_i = \sum_{k=1}^f a_{ik} \dot{q}_k, \quad i=1, 2 \dots n.$$

The a_{ik} , called F_{ik} in (34.2b), are functions of the $x_1 \dots x_n$ and therefore also of the $q_1 \dots q_f$, as stressed in § 34. We see that whereas the old and new position coordinates are connected by an *arbitrary point transformation*, the velocity coordinates transform *linearly*, the coefficients depending on the position coordinates.

What is the transformation character of the *components of force*? We shall call the new force components Q_k and define them as in (34.7) by means of the invariance of virtual work, that is

$$(4) \quad \delta W = \sum_{i=1}^n X_i \delta x_i = \sum_{k=1}^f Q_k \delta q_k.$$

We now pass from virtual to real displacements and from these to the corresponding velocities. By virtue of (3), Eq. (4) becomes

$$(4a) \quad \sum_{k=1}^f Q_k \dot{q}_k = \sum_{i=1}^n X_i \sum_{k=1}^f a_{ik} \dot{q}_k.$$

The \dot{q}_k , unlike the \dot{x}_i , are independent of each other. Hence their coefficients on the right and left of (4a) must be equal, so that

$$(5) \quad Q_k = \sum_{i=1}^n a_{ik} X_i, \quad k=1, 2 \dots f.$$

This is the *transpose* of transformation (3); in (3) we sum over the k , in (5) over the i . Written explicitly,

$$\begin{aligned} \dot{x}_1 &= a_{11} \dot{q}_1 + a_{12} \dot{q}_2 \dots & Q_1 &= a_{11} X_1 + a_{21} X_2 + \dots \\ \dot{x}_2 &= a_{21} \dot{q}_1 + a_{22} \dot{q}_2 \dots & Q_2 &= a_{12} X_1 + a_{22} X_2 + \dots \end{aligned}$$

The transposition hence consists of an interchange of a_{ik} and a_{ki} . We say that *the components of force transform contravariantly*⁵ (or are "contragredient") to the velocity coordinates.

The *components of momentum transform like the components of force*, that is, covariantly to them. For we can think of the momenta as those impulsive forces which cause our mass points, initially at rest, to take on the required velocities. If we call the new momenta p_k , they can be expressed in terms of the old ξ_i by means of the relations

$$(6) \quad p_k = \sum_{i=1}^n a_{ik} \xi_i.$$

These are the defining equations for the p_k . The definition is rather clumsy, but can be converted quite readily to a more meaningful form. For this purpose let us consider, as on p. 186, the expressions for the kinetic energy as function of the \dot{q} on the one hand, and as function of the \dot{x} on the other. We shall distinguish the two expressions, wherever necessary, by writing

$$T_{\dot{q}} \text{ or } T_{\dot{x}}.$$

We then form

$$(7) \quad \frac{\partial T_{\dot{q}}}{\partial \dot{q}_k} = \sum_{i=1}^n \frac{\partial T_{\dot{x}}}{\partial \dot{x}_i} \left[\frac{\partial \dot{x}_i}{\partial \dot{q}_k} \right].$$

The bracket is to remind us that in differentiating with respect to \dot{q}_k we must keep the q_k as well as all \dot{q}_i ($i \neq k$) fixed. According to Eq. (3) the term in brackets is just a_{ik} . On the other hand the elementary expression

$$T_{\dot{x}} = \frac{1}{2} \sum m_i \dot{x}_i^2 \text{ evidently yields } \frac{\partial T_{\dot{x}}}{\partial \dot{x}_i} = \xi_i.$$

⁵ In the theory of general relativity it is customary to denote by a superscript (Q^k, p^k) those quantities which, like Q and the p (about to be defined), transform contravariantly (i.e., are "contragredient") to the \dot{q}_k . We believe, however, that this usage, so important in general relativity, can here be dispensed with,

Instead of (7) we then have

$$(8) \quad \frac{\partial T \dot{q}}{\partial \dot{q}_k} = \sum_{i=1}^n a_{ik} \dot{x}_i.$$

The right member is identical to that of (6). Hence the result:

$$(9) \quad p_k = \frac{\partial T \dot{q}}{\partial \dot{q}_k}$$

We can now assume that the external forces are derivable from a potential V independent of the \dot{q} , and introduce the Lagrangian $L = T - V$, so that (9) can be rewritten

$$(9a) \quad p_k = \frac{\partial L}{\partial \dot{q}_k}.$$

We have thus quite generally justified the definition of the p_k anticipated in (35.14).

We are now in a position to transform the equations of motion (2) to generalized coordinates. To this end we multiply them successively by the different a_{ik} ($k=1 \dots n$) and sum over i . By Eq. (5), the first term in the right member becomes

$$(10) \quad Q_k = - \frac{\partial V}{\partial q_k}.$$

In the second term on the right the factor of λ_μ is

$$(11) \quad \sum_{i=1}^n a_{ik} \frac{\partial F_\mu}{\partial x_i} \quad \text{for } \mu = f+1, \dots, n$$

Now Eq. (3) tells us that

$$(12) \quad a_{ik} = \frac{\partial x_i}{\partial \dot{q}_k}.$$

This becomes evident if one writes (3) in the equivalent form $dx_i = \sum a_{ik} d\dot{q}_k$, and holds all q except q_k fixed. Instead of (11) we can now also write

$$\sum_{i=1}^n \frac{\partial F_\mu}{\partial x_i} \frac{\partial x_i}{\partial \dot{q}_k} = \frac{\partial F_\mu}{\partial \dot{q}_k}.$$

But according to (34.2) it is precisely for $\mu = f+1, \dots, n$ that the F_μ have been made identically zero by our choice of the q_k , so that the partial derivatives of the F_μ with respect to the q_k vanish as well. Hence the right member of our equation reduces to (10).

The left member,

$$\sum_i a_{ik} \frac{d\xi_i}{dt},$$

is transformed into

$$(13) \quad \frac{d}{dt} \sum_i a_{ik} \xi_i - \sum_i \xi_i \frac{da_{ik}}{dt} = \frac{dp_k}{dt} - \sum_i \xi_i \frac{d}{dt} \frac{\partial x_i}{\partial q_k},$$

where we have made use of (6) and (12). The last sum can be written in the form

$$\sum_i m_i \dot{x}_i \frac{\partial x_i}{\partial q_k} = \frac{\partial}{\partial q_k} \frac{1}{2} \sum_i m_i \dot{x}_i^2 = \frac{\partial T}{\partial q_k},$$

where the index q of T is to remind us that T must be converted to a function of the q, \dot{q} before the differentiation with respect to q_k is carried out. The right side of (13) will then become

$$(13a) \quad \frac{dp_k}{dt} - \frac{\partial T}{\partial q_k}.$$

Since it is to be equal to (10), we finally obtain

$$(14) \quad \frac{dp_k}{dt} = \frac{\partial T}{\partial q_k} - \frac{\partial V}{\partial q_k} = \frac{\partial L}{\partial q_k}.$$

Referring back to (9a) we see that this is identical with the Lagrange equation in form (34.6), or, if we do not assume the existence of a potential energy, with that in the form (34.8).

We have thus convinced ourselves that we need not have recourse to Hamilton's principle to derive the Lagrange equations; we need merely make a thorough study of the transformation properties of the dynamic variables involved.

§ 37. The Principle of Least Action

In the conclusion to § 33 we spoke of the *teleological* character of our integral principles. "Teleological" means "shaped by a purpose," "directed toward an end." "Among all possible motions, Nature chooses that which reaches its goal with the minimum expenditure of action." This statement of the principle of least action may sound somewhat vague, but is completely in keeping with the form given it by its discoverer.

In the formulation of the principle not only teleological but also theological beliefs played a role. Maupertuis recommended his principle with the assertion that it best expressed the wisdom of the Creator. Leibniz, too, must have had such arguments in mind, as shown by the title of his *Theodicee* (justification of God).

Maupertuis published his principle in the year 1747. He was referred to a letter of Leibniz of the year 1707 (the original of this letter has been lost); he nevertheless defended his priority with passion, even throwing his weight as president of the Berlin Academy into the dispute. The principle acquired a mathematically definite form only later in the hands of Euler and especially Lagrange.

In the formulation of the principle of least action given above two things are not clear.

1. What is meant by the word "action"? Clearly not the same entity as in Hamilton's principle, for we are dealing with a formulation which, though related to that of Hamilton, is yet distinct from it.

2. What is meant by the phrase, "all possible motions"? It is quite essential to define precisely the class of all motions to be considered for comparison; only thus shall we be able to choose from this class the real motion as the most purposeful or favorable.

Regarding 1: Leibniz took the product $2T dt$ as his element of action. In what is to follow we, too, shall designate by *action integral* the quantity*

$$(1) \quad S = 2 \int_{t_1}^{t_2} T dt.$$

Maupertuis, who, like Descartes, regarded the momentum mv as basic in mechanics, took $mv ds$ to be the element of action. It is clear, however, that the definitions of Leibniz and Maupertuis are equivalent in the case of the single mass point, since

$$(2) \quad 2T dt = mv \cdot v dt = mv ds.$$

This equality carries over to arbitrary mechanical systems, provided that by action we understand the sum of the $m_k v_k ds_k$ for all the mass points of the system.

Regarding 2: in Hamilton's principle we had restricted the sum total of motions to be compared by means of conditions (1) and (2) of § 33. Here we shall keep (2), but alter (1). Instead of $\delta t = 0$ we shall now require that

$$(3) \quad \delta E = 0.$$

We shall therefore compare only trajectories of the same energy E as that of the real trajectory under investigation. This condition implies of course that our principle is now valid only for motions in which energy is conserved,

* The factor of 2 is of course unimportant as far as the minimum property of S is concerned. It is, however, convenient, especially for the formulations of § 44. Incidentally Leibniz was still in doubt as to whether he should take mv^2 or, as we nowadays do, $\frac{1}{2}mv^2$ as "live force."

i.e., motions caused by forces which have a potential. If we call the potential energy of the real path V , that of the varied paths $V + \delta V$, we must have because of (3),

$$(4) \quad \delta T + \delta V = 0, \quad \delta V = -\delta T, \quad \delta L = \delta T - \delta V = 2\delta T.$$

To visualize the change in the state of affairs caused by condition (3) we recall Fig. 51. There two points related by a variation δq belonged to the same time t . This is now no longer the case. The time of the varied point is $t + \delta t$ rather than t (cf. Fig. 54). Hence our varied path does not reach the end point at time $t = t_1$, but, according to the way our figure is drawn, at a later time. On the varied path a point Q is reached at a time $t = t_1$, whereas on the original path the corresponding point (also labeled Q) is reached at an earlier time $t_1 - \delta t_1$.

We now repeat the calculations of § 33. Eqs. (3) and (4) of that section remain valid, but Eq. (5) must be altered because, as stressed there, it is valid only for $\delta t = 0$. We find the condition replacing (5) by forming

$$(5) \quad \delta \dot{x} = \frac{d(x + \delta x)}{d(t + \delta t)} - \frac{dx}{dt}.$$

Let us transform the quotient of differentials on the right by writing

$$(6) \quad \frac{\frac{d(x + \delta x)}{dt}}{\frac{d(t + \delta t)}{dt}} = \frac{\frac{dx}{dt} + \frac{d}{dt}\delta x}{1 + \frac{d}{dt}\delta t} = \frac{dx}{dt} + \frac{d}{dt}(\delta x) - \dot{x} \frac{d}{dt}(\delta t) + \dots,$$

where we have neglected products in small quantities of order higher than the first. From (5) we therefore have

$$\delta \dot{x} = \frac{d}{dt}(\delta x) - \dot{x} \frac{d}{dt}(\delta t),$$

or

$$(7) \quad \frac{d}{dt}(\delta x) = \delta \dot{x} + \dot{x} \frac{d}{dt}(\delta t).$$

If we introduce this in (33.4), we have, with index k arbitrary,

$$(8) \quad \ddot{x}_k \delta x_k = \frac{d}{dt}(\dot{x}_k \delta x_k) - \dot{x}_k \delta \dot{x}_k - \dot{x}_k^2 \frac{d}{dt}(\delta t).$$

FIG. 54. Variation of the "trajectory" in the principle of least action. Since the energy is not varied, point q of the original path and $q + \delta q$ of the varied path belong to different times t and $t + \delta t$. To the endpoint P on the real path is assigned the point Q on the varied one.

Eq. (8) is valid for coordinates y and z as well as x . Therefore (33.3), rather than leading to (33.8) as before, yields in this instance

$$(9) \quad \frac{d}{dt} \sum m_k (\dot{x}_k \delta x_k + \dot{y}_k \delta y_k + \dot{z}_k \delta z_k) = \delta T + 2T \frac{d}{dt} (\delta t) + \delta W.$$

Here we make use of (4) to put

$$(9a) \quad \delta W = -\delta V = +\delta T,$$

thereby giving as the right member of (9)

$$(10) \quad 2\delta T + 2T \frac{d}{dt} (\delta t).$$

Let us now integrate (9) from t_0 to t_1 . In this process the left member vanishes because of condition (33.2); we then obtain, using (10),

$$(11) \quad 2 \int_{t_0}^{t_1} \delta T dt + 2 \int_{t_0}^{t_1} T d\delta t = 0.$$

This, however, is nothing but

$$(12) \quad 2\delta \int_{t_0}^{t_1} T dt = 0$$

or, recalling (1),

$$(12a) \quad \delta S = 0.$$

This concludes the explicit proof of the principle of least action, as envisaged by Maupertuis.

Let us subject the transition from (11) to (12) to some further scrutiny. In Hamilton's principle the two symbols

$$\delta \int T dt \quad \text{and} \quad \int \delta T dt$$

could be used interchangeably because of the condition $\delta t = 0$; use of this was made for instance in the transition from Eq. (33.10) to (33.11). From our present viewpoint the expressions are, however, different in character, as comparison of Eqs. (11) and (12) above will show.

In particular, let us consider a motion under no forces. In that case $T = E$, so that, with the help of (3), Eq. (12) gives

$$(13) \quad \delta \int_{t_0}^{t_1} dt = \delta(t_1 - t_0) = 0.$$

This is the *principle of least time* (principle of "earliest arrival") which Fermat formulated and applied to the refraction of light, after Heron, in ancient times, had treated the reflection of light in a similar fashion.

In the case of a single free mass point we can put $v = \text{const.}$ instead of $T = E$ and write in place of (12),

$$(14) \quad \delta \int v dt = \delta \int ds = 0.$$

This is the principle of the "shortest path." It determines the trajectory of a free mass point, for instance on a curved surface or — as in general relativity — in a manifold of arbitrary curvature. Such a trajectory is called a *geodesic*. We shall come back to this point in § 40.

In his celebrated Königsberg *Vorlesungen über Dynamik* of 1842 (published by Clebsch) Jacobi justified the necessity for completely eliminating the time t from the principle of least action. This is possible, because

$$T = E - V = \frac{1}{2} \sum m_k v_k^2 = \frac{1}{2} \frac{\sum m_k ds_k^2}{dt^2}$$

and therefore

$$dt = \left(\frac{\sum m_k ds_k^2}{2(E - V)} \right)^{\frac{1}{2}}.$$

Instead of (12) we can then require that

$$(15) \quad \delta \int [2(E - V)]^{\frac{1}{2}} [\sum m_k ds_k^2]^{\frac{1}{2}} = 0.$$

With E fixed, the variation here concerns only the spatial properties of the trajectory of the system; there is no longer any mention of the passage of time during the motion.

Let us come back once more to the teleological aspect of the principles of Hamilton and of least action. Notice that the "least action" may, under certain circumstances, also be a "greatest action"; for in demanding that $\delta \dots = 0$ we do not necessarily obtain a minimum, but rather in general only an *extremum*. We see this most simply in the example of the geodesics on the surface of a sphere, which are arcs of great circles. Suppose that initial point O and endpoint P lie on a specified hemisphere. Then the arc of a great circle connecting them directly is indeed shorter than all arcs lying in planes through O and P but not containing the center of the sphere. Yet the complementary arc, which proceeds from O to P in the opposite direction, traversing the hemisphere not containing the two endpoints, is also a geodesic; and this line is longer than all other arcs of circles which join O to P over this hemisphere. We therefore conclude that in general we do not need to think of the integral principles as demonstrating the "purposefulness" of Nature; they merely constitute an unusually impressive mathematical formulation of an extremal property common to the laws of dynamics.

Maupertuis claimed that his principle was generally valid for all laws of nature. Nowadays we are more inclined to accord this property to Hamilton's principle. We mentioned on p. 185 that Helmholtz made this principle the basis of his studies in electrodynamics. Since that time

integral variational principles of Hamiltonian form have been used in the most diverse fields.

In volume II we shall have direct recourse to this principle in order to gain deeper understanding of the concept of fluid pressure. A special advantage of this procedure will be that we shall obtain not only the differential equations—in this case partial differential equations—of the problem, but also the boundary conditions which the solutions of these equations must satisfy. The same turns out to be true for other problems with continuous mass distributions (capillarity, vibrating membrane, etc.). In many cases it is first necessary to look for the Lagrangian L of the problem at hand before L can be used in the variational principle. Such a case, for instance, is the motion of an electron in a magnetic field; there the force acting is not derivable from a potential V . Relativistic problems form another case; there one should not use the expression for the kinetic energy derived in (4.10) to build the Lagrangian. Instead the expression

$$(16) \quad m_0 c^2 \int (1 - \beta^2)^{\frac{1}{2}} dt$$

must be used as the kinetic contribution to the action principle. The Eulerian derivation of this term leads directly to the relativistic momentum \mathbf{p} of (3.19) and therefore also to the law of the velocity-dependent electron mass. In general, especially outside of mechanics, the search for the Lagrange function L which leads (via the variational principle) to given differential laws is an arduous problem for the solution of which there are no universally valid rules. The previously mentioned problem of the electron in a magnetic field was solved in a simple manner by Larmor and Schwarzschild. A separation of L into a kinetic and a potential contribution according to the pattern $L = T - V$ is then in general no longer feasible.

It is to be emphasized that the quantity under the integral of (16) is nothing but the element of *proper time* (2.17), which was recognized by Minkowski as the simplest invariant of the special theory of relativity; Einstein furthermore generalized it in the form of a world line element in the general theory of relativity. In the form (16) Hamilton's principle therefore automatically satisfies the invariance requirement of relativity theory. In this property Planck⁷ saw the "most brilliant success which Hamilton's principle has achieved."

⁷ Cf. the instructive article in *Die Kultur der Gegenwart*, Part III, § III, 1, p. 701 (B. G. Teubner, Leipzig 1915).

CHAPTER VII

DIFFERENTIAL VARIATIONAL PRINCIPLES OF MECHANICS

§ 38. Gauss' Principle of Least Constraint

Gauss was not only a very eminent mathematician, but also an astronomer and geodesist, and, as such, a passionate calculator of numerical results. It was he who founded the method of least squares, which he evolved with successively greater depth in three extensive treatises. If, as happened now and then, he was asked (against his will) to deliver a lecture at the University of Goettingen, his preferred topic was always the method of least squares.

His brief paper of 1829 entitled "On a New General Fundamental Principle of Mechanics"¹ is concluded with the characteristic sentence, "It is quite remarkable that Nature modifies free motions incompatible with the necessary constraints in the same way in which the calculating mathematician uses least squares to bring into agreement results which are based on quantities connected to each other by necessary relations."

Gauss called his new fundamental principle the *principle of least constraint*. He defined the measure of constraint as follows: consider a mass point of the system, and form the product of its mass by the "square of the deviation of this point from free motion." The sum of this product over all mass points of the system defines the constraint. Let us number the mass points and their rectangular coordinates as on p. 66. We then have

$$(1) \quad Z = \sum_{k=1}^{3n} m_k \left(\ddot{x}_k - \frac{X_k}{m_k} \right)^2$$

as the measure of the constraint of a system of n mass points; for the "free motion" which would occur were the internal constraints neglected is given by

$$\ddot{x}_k = \frac{X_k}{m_k}.$$

Thus the quantity contained in the parenthesis of (1) is indeed the "deviation from free motion" caused by the constraint on the k^{th} mass point.

¹ *Crelle's Journal f. Math.* 4, 232 (1829); *Werke* 5, 23.

It can (cf. p. 61) also be called the "lost force" divided by the mass, so that instead of (1) we can write

$$(2) \quad Z = \sum_{k=1}^{3n} \frac{1}{m_k} (\text{lost force})_k^2.$$

Notice that here the lost forces and reciprocal masses play the same role as the errors and weights in the calculation of errors.

We must now define what is meant by the expression "least constraint," that is, we must indicate what quantities are to be kept fixed and what quantities are to be varied in the calculation of $\delta Z = 0$.

We shall keep *fixed*

a) the instantaneous state of the system, i.e., the position and velocity of each of its mass points. We must therefore put

$$(3) \quad \delta x_k = 0, \quad \delta \dot{x}_k = 0.$$

b) the constraints to which the system is subject. If we take these in the holonomic form $F_i(x_1, x_2, \dots) = 0$, we must, in the variation δZ , take into account the secondary condition

$$(4) \quad \sum_{k=1}^{3n} \frac{\partial F_i}{\partial x_k} \delta x_k = 0, \quad i = 1, 2, \dots, r,$$

where r is the number of conditions, $3n - r = f$ therefore the number of degrees of freedom of the system. Let us differentiate Eq. (4) twice with respect to t . This yields terms in δx , $\delta \dot{x}$ and $\delta \ddot{x}$. Because of (3) we need keep only those in $\delta \ddot{x}$, that is,

$$(4a) \quad \sum_{k=1}^{3n} \frac{\partial F_i}{\partial x_k} \delta \ddot{x}_k = 0.$$

c) the forces acting on the system and, of course, the masses, so that we have

$$(5) \quad \delta X_k = 0, \quad \delta m_k = 0.$$

The remaining quantity \ddot{x}_k is then the only one to be *varied*.

Taking the secondary conditions (4a) into account by the method of Lagrange's undetermined multipliers, we obtain from (1)

$$(6) \quad \delta Z = 2 \sum_{k=1}^{3n} \left\{ m_k \ddot{x}_k - X_k - \sum_{i=1}^r \lambda_i \frac{\partial F_i}{\partial x_k} \right\} \delta \ddot{x}_k = 0.$$

Only $f = 3n - r$ of the $\delta \ddot{x}_k$ are independent. As on p. 66 we can, however, choose our λ_i in such a way as to make r of the $\{ \}$ vanish, so that only

f terms are left in (6). The $\delta\ddot{x}_k$ of these remaining f terms can now be treated as independent. It follows that their f associated $\{ \}$ must vanish. We therefore arrive at Lagrange's equations of the first kind in the form (12.9).

Clearly the proof extends without change to non-holonomic constraints. Thus we are indeed confronted by a "new general fundamental principle of mechanics," as claimed by Gauss in the title of his paper. This fundamental principle is fully equivalent to d'Alembert's principle. Like the latter it is a *differential* principle in that it deals only with the present behavior of the system, not its future or past behavior. Here we do not need the rules of the calculus of variations, but only those of the ordinary differential calculus in the determination of the maxima and minima.

§ 39. Hertz's Principle of Least Curvature

Strictly speaking this principle is but a special case of that of Gauss. Nevertheless Hertz was able to call his principle, if not new, at least completely general; the reason for this is that he succeeded in replacing all forces by means of connections between the system in question and other systems interacting with it (cf. p. 5). Hertz was hence able to restrict himself to *systems under no forces*. In order to give the principle its sought-for geometric interpretation, he found himself obliged, moreover, to assume all masses to be multiples of a *unit mass*, say of atomic origin. The factor m_k in Gauss' expression (38.1) then becomes 1, while X_k becomes 0. It follows that (38.1) goes over to

$$(1) \quad Z = \sum_{k=1}^N \ddot{x}_k^2.$$

Here we have indicated by means of the upper index N of the summation that the number of unit masses of the system to be summed has been augmented in an unspecified manner by a suitable number of unit masses corresponding to the interacting systems coupled to the given system.

Let us change (1) by writing

$$\frac{d^2 x_k}{ds^2} \text{ in place of } \ddot{x}_k, \text{ where } (2) \quad ds^2 = \sum_{k=1}^N dx_k^2.$$

This is permitted because of the special form of the principle of energy. This principle is a consequence of Lagrange's equations of the first kind, and hence also of the principle of least constraint. For our present specialization the principle of energy can be written

$$\frac{1}{2} \sum_{k=1}^N \left(\frac{dx_k}{dt} \right)^2 = E$$

or, more concisely,

$$\left(\frac{ds}{dt}\right)^2 = \text{const.}$$

A division of (1) by the square of this constant yields thus the quantity

$$(3) \quad K = \sum_{k=1}^N \left(\frac{d^2 x_k}{ds^2}\right)^2.$$

Hertz calls ds the *element of line*, $K^{\frac{1}{2}}$ the *curvature* of the trajectory described by the system, and postulates

$$(4) \quad \delta K = 0.$$

Every free system remains in a state of rest or of uniform motion along a path of least curvature.

The mode of expression (cf. Art. 309 of Hertz's book cited earlier) is chosen so as to recall Newton's formulation of the first law.

The mathematical treatment of postulate (4) follows that of Gauss and, on the basis of the conditions of variation stipulated under (a) and (b) on p. 211, evidently leads to Lagrange's equations of the first kind for a system under no forces (with $m_k = 1$).

What justifies Hertz in calling ds the "line element" and $K^{\frac{1}{2}}$ the "curvature"? Evidently these concepts are to be interpreted in a poly-dimensional sense. We are not in three dimensions, but in an N -dimensional Euclidean space of coordinates x_1, x_2, \dots, x_N . In this space the element of line is indeed given by (2). We shall now discuss the cases of two and three dimensions in order to show that the square of the curvature of a trajectory is quite generally given by (3).

According to Eq. (5.10) we have, in the space of coordinates x_1, x_2 ,

$$(5) \quad K = \frac{1}{\rho^2} = \left(\frac{\Delta\epsilon}{\Delta s}\right)^2.$$

From Fig. 4b, $\Delta\epsilon$ is the angle between two neighboring tangents to the path whose points of contact with the path are a distance Δs apart. These tangents have direction cosines

$$(6) \quad \frac{dx_1}{ds}, \quad \frac{dx_2}{ds} \quad \text{and} \quad \frac{dx_1}{ds} + \frac{d^2 x_1}{ds^2} \Delta s, \quad \frac{dx_2}{ds} + \frac{d^2 x_2}{ds^2} \Delta s, \quad \text{respectively.}$$

Now these direction cosines are at the same time the coordinates of the two points formed by the intersection of a unit circle about the origin of coordinates with two radii drawn from the origin parallel to the tangents; moreover the angle $\Delta\epsilon$ is measured by the arc of distance between these two points of intersection. According to (6) we therefore have

$$\Delta\epsilon^2 = \left[\left(\frac{d^2x_1}{ds^2} \right)^2 + \left(\frac{d^2x_2}{ds^2} \right)^2 \right] \Delta s^2$$

and from (5),

$$(7) \quad K = \left(\frac{d^2x_1}{ds^2} \right)^2 + \left(\frac{d^2x_2}{ds^2} \right)^2.$$

In the space of the three coordinates x_1, x_2, x_3 , $\Delta\epsilon$ is once again the angle between neighboring tangents to the three-dimensional trajectories. The unit circle is now replaced by a unit sphere through the center of which parallels to the two tangents are to be drawn. The distance between their points of intersection with the surface of the sphere measures $\Delta\epsilon$ in units of arc:

$$\Delta\epsilon^2 = \left[\left(\frac{d^2x_1}{ds^2} \right)^2 + \left(\frac{d^2x_2}{ds^2} \right)^2 + \left(\frac{d^2x_3}{ds^2} \right)^2 \right] \Delta s^2.$$

From (5) we thus obtain an expression for K which now has three terms.

The generalization to a space of N dimensions and to the equation (3) of N terms is now obvious.

With this we must conclude our report on the mechanics of Hertz. As mentioned on p. 5, his is an interesting and stimulating idea, carried out with great logic; because of the complicated replacement of forces by connections it has, however, borne little fruit.

§ 40. A Digression on Geodesics

We define as geodesics of an arbitrary curved surface the trajectories of mass points under no forces (hence no friction) constrained to move on the surface. Let the mass of a particle be equal to 1, and the equation of the surface $F(x, y, z) = 0$.

The principle of least action states that these geodesics are also the shortest possible lines or, more generally (cf. p. 208) lines whose lengths are extrema. Since conservation of energy holds, the velocity along the path is constant. By choosing the constant of energy properly we can put the velocity equal to 1 and therefore replace $\frac{d}{dt}$ by $\frac{d}{ds}$.

We obtain the basic definition of geodesics if we describe our trajectories by Lagrange's equations of the first kind. Written vectorially, these are, in our case,

$$(1) \quad \dot{v} = \lambda \text{ grad } F.$$

\dot{v} has the direction of the principal normal to the trajectory if, as in our case, $v = \text{const.}$ so that $\dot{v} = 0$ (cf. § 5, beginning of (3)); it follows (of. same place) that \dot{v} lies in the osculating plane. $\text{grad } F$, on the other hand, has

the direction of the normal to the surface, since for any translation (dx, dy, dz) on the surface we have

$$\frac{\partial F}{\partial x} dx + \frac{\partial F}{\partial y} dy + \frac{\partial F}{\partial z} dz = 0,$$

so that the direction

$$\frac{\partial F}{\partial x} : \frac{\partial F}{\partial y} : \frac{\partial F}{\partial z}$$

is indeed normal to that of the displacement. Eq. (1) therefore contains the basic definition of geodesics which states that *the principal normal of a geodesic coincides with the normal to the surface*, or equivalently, *the osculating plane of a geodesic contains the normal to the surface*.

We now appeal to the principle of least curvature. According to it the geodesic has a smaller curvature than neighboring paths; the neighboring paths are, according to conditions (38.3), restricted to pass through the same point with the same tangent as the geodesic at the point considered. We obtain the total class of these neighboring paths by passing through the tangent in question all possible skew planes and determining their intersections with the surface; the plane containing the normal to the surface furnishes the geodesic. According to Hertz's principle these skew sections have a greater curvature than the normal section, or, equivalently, a smaller radius of curvature.

This fact is in agreement with Meusnier's theorem in the differential geometry of surfaces, which states that the radius of curvature of an oblique section equals the projection of the radius of curvature of the normal section on the plane of the oblique section. We thus recognize in Meusnier's theorem a quantitative expression of the general content of the principle of least curvature.

Let us finally apply Lagrange's equations of the second kind to our geodesics. We thereby enter the sphere of thought of Gauss' great treatise of 1827 ("Disquisitiones generales circa superficies curvas"), which, extended to four dimensions, is also the sphere of thought of the general theory of relativity.

While Lagrange introduces arbitrary curvilinear coordinates q , Gauss uses as coordinates on the surface two arbitrary families of curves which cover the surface with a "grid." As customary, we shall call them

$$(2) \quad u = \text{const.}, \quad v = \text{const.}$$

In these coordinates Gauss writes the line element ds in the form

$$(3) \quad ds^2 = E du^2 + 2F du dv + G dv^2.$$

The "first differential parameters" E , F and G are to be thought of as

functions of u and v . They are connected with the rectangular coordinates x, y, z of the points on the surface by the relations

$$E = \left(\frac{\partial x}{\partial u}\right)^2 + \left(\frac{\partial y}{\partial u}\right)^2 + \left(\frac{\partial z}{\partial u}\right)^2, \quad G = \left(\frac{\partial x}{\partial v}\right)^2 + \left(\frac{\partial y}{\partial v}\right)^2 + \left(\frac{\partial z}{\partial v}\right)^2,$$

$$F = \frac{\partial x}{\partial u} \frac{\partial x}{\partial v} + \frac{\partial y}{\partial u} \frac{\partial y}{\partial v} + \frac{\partial z}{\partial u} \frac{\partial z}{\partial v}.$$

The square of the line element divided by $2dt^2$ is the expression of the kinetic energy T of our (unit) mass point moving on the surface. We can thus transform the Lagrange equations for generalized coordinates to Gaussian notation by forming

$$p_u = \frac{\partial T}{\partial \dot{u}} = E\dot{u} + F\dot{v}$$

$$2\frac{\partial T}{\partial u} = \frac{\partial E}{\partial u}\dot{u}^2 + 2\frac{\partial F}{\partial u}\dot{u}\dot{v} + \frac{\partial G}{\partial u}\dot{v}^2.$$

If, finally, we put $\frac{ds}{dt}$ in place of $\frac{d}{dt}$, the differential equation of the geodesics is, according to the method of Lagrange,

$$(4) \quad \frac{d}{ds} \left(E \frac{du}{ds} + F \frac{dv}{ds} \right) = \frac{1}{2} \left\{ \frac{\partial E}{\partial u} \left(\frac{du}{ds} \right)^2 + 2 \frac{\partial F}{\partial u} \frac{du}{ds} \frac{dv}{ds} + \frac{\partial G}{\partial u} \left(\frac{dv}{ds} \right)^2 \right\}$$

for the u -coordinate. We need not write down the corresponding differential equation for the v -coordinate; by virtue of the principle of energy (in our case $\frac{ds}{dt} = 1$) it must be identical to (4).

Gauss derives Eq. (4) in Art. 18 of the cited treatise by means of the principle of the shortest path. Here we merely wanted to point out the fact that Gauss' method of general surface parameters (2) is equivalent to Lagrange's method of the mechanics of systems. Both methods are invariant with respect to an arbitrary transformation of coordinates and depend only on the intrinsic properties of the surface or of the mechanical system respectively.

CHAPTER VIII
THE THEORY OF HAMILTON
§ 41. *Hamilton's Equations*

In Lagrange's equations our independent variables were the q_k and \dot{q}_k . In Hamilton's equations, which we shall now derive in two different ways, the q_k and p_k are the independent variables; the latter is defined by Eq. (36.9a). Whereas the characteristic function of Lagrange's equations was the "free energy" $T - V$, regarded as function of the q_k and \dot{q}_k , in Hamilton's equations the characteristic function is the total energy $T + V$, regarded as function of the q_k and p_k . This function we call the Hamiltonian function or simply the *Hamiltonian*, and we designate it by $H(q, p)$ just as we called the free energy the Lagrangian and designated it by $L(q, \dot{q})$. Between H and L there exists relation (34.16), which we shall write

$$(1) \quad H = \sum p_k \dot{q}_k - L,$$

using the definition of the p_k .

Let us at once extend the basis of the theory by recalling the last part of § 37: we shall drop the decomposition of L into a kinetic and a potential contribution and, in addition, permit an explicit dependence on t . According to p. 190, such a dependence may arise if either the equations of constraint or the defining equations for the coordinates contain the time. We then write the Lagrangian in the generalized form

$$(1a) \quad L = L(t, q, \dot{q}).$$

Let us keep Eq. (1) as our definition of the Hamiltonian associated with L ,

$$(1b) \quad H = H(t, q, p)$$

although H then loses the meaning of total energy. As before, the p_k are given by the relation

$$(1c) \quad p_k = \frac{\partial L}{\partial \dot{q}_k}.$$

If we take Hamilton's principle

$$(1d) \quad \delta \int_{t_1}^{t_2} L dt = 0$$

as our fundamental principle of mechanics, we obtain Lagrange's equations

just as in § 34—in spite of the new extended meaning of L . For purposes of the following we shall write these equations in the form

$$(1e) \quad \dot{p}_k = \frac{\partial L}{\partial q_k}.$$

(1) Derivation of Hamilton's Equations from Lagrange's Equations

Let us write down the total differentials of H and L :

$$(2) \quad dH = \frac{\partial H}{\partial t} dt + \sum \frac{\partial H}{\partial q_k} dq_k + \sum \frac{\partial H}{\partial p_k} dp_k,$$

$$(2a) \quad dL = \frac{\partial L}{\partial t} dt + \sum \frac{\partial L}{\partial q_k} dq_k + \sum \frac{\partial L}{\partial \dot{q}_k} d\dot{q}_k,$$

and, by means of Lagrange's equations (1e) and the definition (1c) of the p_k , transform dL to

$$(2b) \quad dL = \frac{\partial L}{\partial t} dt + \sum \dot{p}_k dq_k + \sum p_k d\dot{q}_k.$$

Let us, on the other hand, form the total differential of (1) with the help of (2b):

$$(3) \quad dH = \sum \dot{q}_k dp_k + \sum p_k d\dot{q}_k - \frac{\partial L}{\partial t} dt - \sum \dot{p}_k dq_k - \sum p_k d\dot{q}_k.$$

Cancelling of the last term on the right against the second term yields

$$(3a) \quad dH = - \frac{\partial L}{\partial t} dt - \sum \dot{p}_k dq_k + \sum \dot{q}_k dp_k.$$

This expression for dH must, of course, be identical to that of Eq. (2). If we equate the coefficients of dt , we obtain

$$(3b) \quad \frac{\partial H}{\partial t} = - \frac{\partial L}{\partial t}.$$

Comparison of the coefficients of dq_k and dp_k yields

$$(4) \quad \dot{p}_k = - \frac{\partial H}{\partial q_k}, \quad \dot{q}_k = \frac{\partial H}{\partial p_k}.$$

These relations, exhibiting an amazing symmetry, are "Hamilton's ordinary differential equations" or, for short, *Hamilton's equations*.

Incidentally, they first occurred in the much earlier "*Mécanique analytique*" of Lagrange (Sec. 5, § 14), where they were, however, derived and put to use only for the special case of small vibrations.

(2) Derivation of Hamilton's Equations from Hamilton's Principle

In the light of (1) we write this principle in the form

$$\begin{aligned}
 (5) \quad & -\delta \int L dt = \delta \int [H(t, q, p) - \sum p_k \dot{q}_k] dt \\
 & = \sum_k \int \left(\frac{\partial H}{\partial q_k} \delta q_k + \frac{\partial H}{\partial p_k} \delta p_k - \dot{q}_k \delta p_k - p_k \delta \dot{q}_k \right) dt = 0,
 \end{aligned}$$

where we can transform the last term in the parenthesis by partial integration,

$$(6) \quad - \int_{t_0}^{t_1} p_k \delta \dot{q}_k dt = \int_{t_0}^{t_1} \dot{p}_k \delta q_k dt - p_k \delta q_k \Big|_{t_0}^{t_1}.$$

The integrated term vanishes because of the way in which the variation is carried out in Hamilton's principle. Substitution of (6) in (5), followed by collection of terms in δq_k and δp_k , yields

$$(7) \quad \sum_k \int \left(\left\{ \frac{\partial H}{\partial q_k} + \dot{p}_k \right\} \delta q_k + \left\{ \frac{\partial H}{\partial p_k} - \dot{q}_k \right\} \delta p_k \right) dt = 0.$$

If it were permitted to treat the δq_k and the δp_k as independent variations, one would be justified in putting the factors of δq_k and δp_k separately equal to 0 for every value of the index k , and so obtain Hamilton's equations (4). This, however, is not allowed; for while q_k and p_k enter in H as independent variables, they are related in time through Eq. (1c), a fact which might conceivably cause our Eq. (7) to be satisfied identically. We notice, however, that a partial differentiation of (1) with respect to p_k (q_k being held constant) causes the second $\{ \}$ of (7) to vanish identically. We conclude, therefore, that the first $\{ \}$ must vanish as well.

One of the reasons why we derived Hamilton's equations in the second way is that we wish now to make an important remark connected with it.

We know that Lagrange's equations are invariant under arbitrary "point transformations," i.e., that they keep their form if we replace the q_k by a new set of coordinates Q_k connected with the former by relations of the type

$$(8) \quad Q_k = f_k(q_1, q_2, \dots, q_f).$$

The associated P_k are then given by

$$(8a) \quad P_k = \frac{\partial L}{\partial \dot{Q}_k} = \sum_i \frac{\partial L}{\partial \dot{q}_i} \frac{\partial \dot{q}_i}{\partial \dot{Q}_k} = \sum_i p_i a_{ik},$$

that is, by linear functions of the p_i whose coefficients a_{ik} are functions of the q_k , just as in (36.3).

We shall now show that Hamilton's equations are invariant under the much more general transformations

$$\begin{aligned}
 (9) \quad & Q_k = f_k(q, p) \\
 & P_k = g_k(q, p),
 \end{aligned}$$

where the f_k and g_k are arbitrary functions of the two sets of variables q_k and p_k —arbitrary, that is, to within a restriction to be mentioned below. In particular, the g_k need no longer be linear in the p_k .

Let us suppose that Eqs. (9) are solved for the q, p in terms of the Q, P [we must of course require that Eqs. (9) be so constituted that this is possible] and are substituted in the expression $H(q, p)$. Let us call \bar{H} this new transformed Hamiltonian. We then have

$$(10) \quad H(q, p) = \bar{H}(Q, P).$$

Let us, moreover, compare the quantity $\sum p_k \dot{q}_k$ occurring in (5) with $\sum P_k \dot{Q}_k$. It is easy to see that the two expressions would be equal in a transformation (8), (8a). We now require that this equality be maintained in a general transformation (9), apart from an additive term. The latter we require to be a complete time derivative of a function F' of the q and p , or, alternatively, of a function F of the q and Q ¹. We hence put

$$(11) \quad \sum p_k \dot{q}_k = \sum P_k \dot{Q}_k + \frac{d}{dt} F(q, Q)$$

with arbitrary F . This is the restriction on transformation (9) mentioned above.

In the substitution of Eqs. (10) and (11) in (5) the additional term $\frac{dF}{dt}$ vanishes in the integration and subsequent variation, since δq and δQ vanish at the endpoints; Eq. (5) then retains its earlier form, becoming

$$\delta \int (\bar{H}(Q, P) - \sum P_k \dot{Q}_k) dt = 0.$$

Furthermore, nothing is changed in our transformations (6) and (7); we conclude that Hamilton's equations remain valid in the new variables. In complete correspondence to our Eqs. (4) we now have

$$(12) \quad \dot{P}_k = - \frac{\partial \bar{H}}{\partial Q_k}, \quad \dot{Q}_k = \frac{\partial \bar{H}}{\partial P_k}.$$

Transformations (9), as subjected to restriction (11), are called *canonical transformations* or² *contact transformations*. The reason for the latter name

¹ If F' is originally given as a function of q and p , we can of course solve for p from the first Eq. (9) and substitute it in F' , thus obtaining a new function F of q and Q .

² The terms are not entirely synonymous, their difference being one of definition. We need not be detained with this difference, but remark that under suitable conditions either of the two transformations can be shown to be a special case of the other. Cf., for instance, Whittaker, *Analytical Dynamics* (Dover), Chapter XI, or Osgood, *Mechanics* (Macmillan), Chapter XIV.—TRANSLATOR.

is a geometric one. Let us consider a hypersurface in the f -dimensional space of the q_1, q_2, \dots, q_f , given by

$$(13) \quad z = z(q_1, \dots, q_f);$$

the quantities

$$p_k = \frac{\partial z}{\partial q_k}$$

determine the position of the tangent plane to the hypersurface and can, for this reason, be interpreted as the coordinates of this plane. We require that there exist a condition

$$(14) \quad dz = \sum_{k=1}^f p_k dq_k$$

between the coordinates of the point q_k and those of the plane p_k . This condition insures the "union of lineal elements," i.e., the continuity of the coordinates p_k as we pass from an arbitrary point of coordinates q_k to a neighboring point. Let us now introduce new coordinates Q_k, P_k by means of Eq. (9) and calculate (13) in terms of these new coordinates. Let the result be

$$z = Z(Q, P).$$

We now demand that this new expression again represent a hypersurface touched by the planes of coordinates P at the points determined by the Q . From (14) we must therefore have

$$(15) \quad dZ = \sum_{k=1}^f P_k dQ_k,$$

or, with ρ a factor of proportionality,

$$(16) \quad dZ - \sum P_k dQ_k = \rho (dz - \sum p_k dq_k).$$

Thus the contact between the surface and its tangent plane at a given point has been preserved in a transformation of the point. Let us compare condition (16) with Eq. (11), which, when multiplied by dt , can be written

$$(16a) \quad \sum p_k dq_k = \sum P_k dQ_k + dF.$$

If we put $dF = dz - dZ$ in (16a) and $\rho = 1$ in (16), the two conditions are in agreement. This may constitute adequate justification for the name "contact transformation."

In transformations of the generality of Eqs. (9) the meaning of the P_k as components of momentum is obscured. For this reason we prefer to

call the P_k, Q_k *canonical variables*; P_k and Q_k are then said to be *canonically conjugate*. Because Hamilton's equations are invariant under transformations (9) [with restriction (11)], they are often called *Hamilton's canonical equations*.

It is to this invariance under canonical transformations that Hamilton's equations owe their special significance in astronomical perturbation theory. They also play an important role in the statistical mechanics of Gibbs, a topic which we shall discuss in Vol. V.

We conclude our treatment of Hamilton's equations with a remark dealing with the principle of energy.

In agreement with Eq. (2) we have, quite generally,

$$\frac{dH}{dt} = \frac{\partial H}{\partial t} + \sum_k \left(\frac{\partial H}{\partial q_k} \dot{q}_k + \frac{\partial H}{\partial p_k} \dot{p}_k \right).$$

According to (4), the parenthesis vanishes for all k . We then obtain, in general,

$$(17) \quad \frac{dH}{dt} = \frac{\partial H}{\partial t}.$$

If, in particular, H does not depend *explicitly* on t , we arrive at the *conservation law*

$$(18) \quad \frac{dH}{dt} = 0, \quad H = \text{const.}$$

This law is more general than that of the conservation of energy, for, according to (1) and (1c), it states that

$$(18a) \quad \sum \frac{\partial L}{\partial \dot{q}_k} \dot{q}_k - L = \text{const.}$$

where L must not depend explicitly on t , but otherwise can be quite arbitrary. It is this conservation law to which we alluded in footnote 3 of Chapter VI. Eq. (18a) leads to the *conservation of energy* if L can be split up into two contributions, a kinetic one homogeneous of second degree in the \dot{q}_k , and a potential one independent of the \dot{q}_k .

§ 42. Routh's Equations and Cyclic Systems

In Eqs. (10) and (11) of § 34 we considered a "mixed type" of equation resulting from a combination of Lagrange equations of the first and the second kind. We shall now become acquainted with a mixed type of equation arising from a combination of Lagrange's equations of the second

kind with those of Hamilton. The new equations bear the name of Routh³ who, for several decades, dominated the study of mechanics in Cambridge as "coach" and examiner in the "tripos." Somewhat later Helmholtz⁴ developed the same equations as the basis of his theory of monocyclic and polycyclic systems, a theory which he intended to use in the solution of the fundamental problems of thermodynamics.

We subdivide the degrees of freedom of the system into two groups. One group, containing $f-r$ degrees of freedom, can be described by Lagrange's position and velocity coordinates

$$q_1, q_2, \dots, q_{f-r}; \quad \dot{q}_1, \dot{q}_2, \dots, \dot{q}_{f-r},$$

and the other, containing r degrees of freedom, is to be represented in terms of Hamilton's canonical variables

$$q_{f-r+1}, q_{f-r+2}, \dots, q_f; \quad p_{f-r+1}, p_{f-r+2}, \dots, p_f.$$

Instead of the Lagrangian L or the Hamiltonian H we now construct a Routh function R , which is to be a function of the $2f$ variables enumerated above and, for the sake of generality, of the time as well:

$$(1) \quad R(t, q_1, q_2, \dots, q_f; \quad \dot{q}_1, \dot{q}_2, \dots, \dot{q}_{f-r}, p_{f-r+1}, \dots, p_f).$$

R is to be defined by the equation

$$(2) \quad R = \sum_{k=f-r+1}^f p_k \dot{q}_k - L(t, q_1, \dots, q_f; \dot{q}_1, \dots, \dot{q}_f).$$

We see that for $r=f$, R transforms to the Hamiltonian (41.1); for $r=0$, where the summation on the right vanishes, it goes over into the Lagrangian (apart from sign). Evidently we could have replaced definition (2) of R by the equivalent condition

$$(2a) \quad R = H(t, q_1, \dots, q_f; p_1, \dots, p_f) - \sum_{k=1}^{f-r} p_k \dot{q}_k.$$

We now proceed as in Eqs. (41.2) to (41.4). We form the total differential of R , on the one hand from (1),

³ In this connection we wish to mention the two volumes of Routh's *Treatise on the Dynamics of a System of Rigid Bodies*; I, Elementary Part, II, Advanced Part. It is a collection of problems of unique variety and richness. Routh first developed his form of the dynamical equations in the prize article *A Treatise of Stability of a Given State of Motion* (1877).

⁴ *Berliner Akad.* (1884) and *Crelle's Journal f. Math.* 97.

$$(3) \quad dR = \frac{\partial R}{\partial t} dt + \sum_{k=1}^f \frac{\partial R}{\partial q_k} dq_k + \sum_{k=1}^{f-r} \frac{\partial R}{\partial \dot{q}_k} d\dot{q}_k + \sum_{k=f-r+1}^f \frac{\partial R}{\partial p_k} dp_k,$$

and on the other, from (2),

$$(3a) \quad dR = \sum_{k=f-r+1}^f \dot{q}_k dp_k + \sum_{k=f-r+1}^f p_k d\dot{q}_k - dL,$$

For dL we can use the expression (41.2b), which we shall, for greater clarity, decompose into

$$(3b) \quad dL = \frac{\partial L}{\partial t} dt + \sum_{k=1}^f \dot{p}_k dq_k + \sum_{k=1}^{f-r} p_k d\dot{q}_k + \sum_{k=f-r+1}^f p_k d\dot{q}_k.$$

Substitution in (3a) causes the last term of (3b) to cancel against the middle term of (3a), so that we are left with

$$(4) \quad dR = -\frac{\partial L}{\partial t} dt - \sum_{k=1}^f \dot{p}_k dq_k - \sum_{k=1}^{f-r} p_k d\dot{q}_k + \sum_{k=f-r+1}^f \dot{q}_k dp_k.$$

A term-by-term comparison with (3) yields the relation

$$\frac{\partial R}{\partial t} = -\frac{\partial L}{\partial t}$$

and the scheme of equations given below:

for $k=1, 2, \dots, f-r$	for $k=f-r+1, f-r+2, \dots, f$
$\dot{p}_k = -\frac{\partial R}{\partial q_k}$ $p_k = -\frac{\partial R}{\partial \dot{q}_k}$	$\dot{p}_k = -\frac{\partial R}{\partial q_k}$ $\dot{q}_k = +\frac{\partial R}{\partial p_k}$

The $f-r$ equations on the left are of the Lagrange type with $L = -R$, whereas the r equations on the right are of the Hamiltonian type with $H = R$.

The application of these equations to cyclic systems, which Routh had in mind when he formulated them, proceeds as follows: we assume that the coordinates of the second group are cyclic, so that, from p. 197, they do not occur in the Lagrangian; in that case neither do they occur in the Routh function. The associated p_k are then constant [from the upper equation of the right group of Routh's equations (5) or, as remarked on p. 198, from Lagrange's equations]. We can now replace these constant values of

the p_k , and, with the help of Eq. (41.1c), those of the (generally not constant) associated \dot{q}_k in Eq. (2). We thus obtain a Routh function which depends only on the $f-r$ coordinates of the first group of q_k and \dot{q}_k . For these coordinates the left group of Eq. (5) above is valid. We have, therefore, reduced the problem to $f-r$ equations of the Lagrange type.

Routh used his method chiefly in the difficult problems of the stability of given states of motion. Let us instead illustrate the method with a reasonably simple example, that of the symmetrical top. The cyclic coordinates of this doubly cyclic problem are the Eulerian angles ϕ and ψ ; according to Eqs. (35.15) to (35.17), we have

$$\begin{aligned} p_\phi \ddot{\phi} + p_\psi \ddot{\psi} &= M'' \left(\frac{M''}{I_3} - \cos \theta \frac{M' - M'' \cos \theta}{I_1 \sin^2 \theta} \right) + M' \frac{M' - M'' \cos \theta}{I_1 \sin^2 \theta} \\ &= \frac{M''^2}{I_3} + \frac{(M' - M'' \cos \theta)^2}{I_1 \sin^2 \theta}; \end{aligned}$$

by virtue of (35.13) the Routh function then becomes

$$\begin{aligned} R &= \frac{M''^2}{I_3} + \frac{(M' - M'' \cos \theta)^2}{I_1 \sin^2 \theta} - \frac{I_1}{2} \dot{\theta}^2 - \frac{(M' - M'' \cos \theta)^2}{2I_1 \sin^2 \theta} - \frac{M''^2}{2I_3} + P \cos \theta \\ &= -\frac{I_1}{2} \dot{\theta}^2 + \Theta(\theta), \quad \Theta = \frac{M''^2}{2I_3} + \frac{(M' - M'' \cos \theta)^2}{2I_1 \sin^2 \theta} + P \cos \theta. \end{aligned}$$

With $q_k = \theta$, the lower equation in the left group of our present Eqs. (5) then yields

$$p_k = I_1 \dot{\theta}$$

and the upper equation of the same group gives

$$(6) \quad I_1 \ddot{\theta} = -\frac{\partial \Theta}{\partial \theta},$$

which is, of course, in agreement with the "generalized pendulum equation" (35.19). This example may serve to illustrate the usefulness of Routh's method, particularly for problems more difficult than the one presented.

In 1891 Boltzmann gave a series of lectures on Maxwell's electromagnetic theory at the University of Munich. He devoted his first lectures to the detailed consideration of a doubly cyclic mechanical system in order to illustrate the mutual inductive effect between two electrical circuits. The carefully worked mechanical model, consisting mainly of two pairs of beveled gears with centrifugal governors, is preserved in the museum of our Institute. To us it seems much more complicated than Maxwell's theory which it was intended to illustrate. Hence we shall not use it to clarify this theory, but instead take advantage of it in an exercise on the differential of an automobile, to which it is similar in its essential features.

Let us finally generalize the mathematical formalism which led us from Lagrange's to Hamilton's and to Routh's equations. We consider a function Z of two variables (or two sets of variables) x and y , and let

$$(7) \quad dZ(x, y) = X dx + Y dy.$$

If we wish to replace x, y by X, Y as independent variables, it is convenient to consider, instead of Z , the "modified function"

$$(8) \quad U(X, Y) = xX + yY - Z(x, y).$$

Indeed a differentiation of (8) at once gives, in view of (7),

$$(9) \quad dU(X, Y) = x dX + y dY.$$

Eqs. (7) and (9) are identical to the "reciprocity relations"

$$(10) \quad \begin{aligned} \frac{\partial Z}{\partial x} &= X, & \frac{\partial Z}{\partial y} &= Y, \\ \frac{\partial U}{\partial X} &= x, & \frac{\partial U}{\partial Y} &= y. \end{aligned}$$

If, on the other hand, we wish to replace only one of the original variables, say y , by its "canonically conjugate" Y , we shall have to "modify" (8) to

$$(11) \quad V(x, Y) = yY - Z,$$

which yields

$$(12) \quad dV(x, Y) = -X dx + y dY$$

with the "reciprocity relations"

$$(13) \quad \frac{\partial V}{\partial x} = -X, \quad \frac{\partial V}{\partial Y} = y.$$

The transition from Z to U can be compared with that from Lagrange to Hamilton, that from Z to V with the transition from Lagrange to Routh.

Such a change of independent variables and the attendant modification of the characteristic function is called a *Legendre transformation* and plays an extensive role in analysis. We have mentioned it chiefly in order to be able to refer to it in our study of thermodynamics (Vol. V).

§ 43. The Differential Equations for Non-Holonomic Velocity Parameters

Whereas the differential equations considered so far were all modeled after those of Lagrange for generalized coordinates, the theory of the spinning top brought us in contact with equations of an entirely different, much simpler structure, viz., Euler's Eqs. (26.4) for the angular velocities ω_1 ,

ω_1 and ω_3 . Let us determine what relation they bear to Lagrange's equations.

The difference between the two types stems from the fact that the $\omega_1, \omega_2, \omega_3$ are not holonomic coordinates like the θ, ψ, ϕ , but linear functions of these which are not integrable with respect to t . The connection between them is given by Eq. (35.11). Let us immediately consider the unsymmetrical top with kinetic energy

$$(1) \quad T = \frac{1}{2}(I_1 \omega_1^2 + I_2 \omega_2^2 + I_3 \omega_3^2),$$

and for brevity restrict ourselves to the case of a top under no forces.

We start out with Lagrange's equation for the ϕ -coordinate

$$(2) \quad \frac{d}{dt} \frac{\partial T}{\partial \dot{\phi}} - \frac{\partial T}{\partial \phi} = 0.$$

According to (35.11)

$$\begin{aligned} \frac{\partial \omega_1}{\partial \dot{\phi}} &= \frac{\partial \omega_2}{\partial \dot{\phi}} = 0, & \frac{\partial \omega_3}{\partial \dot{\phi}} &= 1, \\ \frac{\partial \omega_1}{\partial \phi} &= \omega_2, & \frac{\partial \omega_2}{\partial \phi} &= -\omega_1, & \frac{\partial \omega_3}{\partial \phi} &= 0, \end{aligned}$$

so that, in view of (1),

$$\begin{aligned} \frac{\partial T}{\partial \dot{\phi}} &= I_1 \omega_1 \frac{\partial \omega_1}{\partial \dot{\phi}} + I_2 \omega_2 \frac{\partial \omega_2}{\partial \dot{\phi}} + I_3 \omega_3 \frac{\partial \omega_3}{\partial \dot{\phi}} = I_3 \omega_3, \\ \frac{\partial T}{\partial \phi} &= I_1 \omega_1 \frac{\partial \omega_1}{\partial \phi} + I_2 \omega_2 \frac{\partial \omega_2}{\partial \phi} + I_3 \omega_3 \frac{\partial \omega_3}{\partial \phi} = (I_1 - I_2) \omega_1 \omega_2. \end{aligned}$$

From (2) we then have

$$(3) \quad I_3 \frac{d\omega_3}{dt} = (I_1 - I_2) \omega_1 \omega_2.$$

This is the third Euler Eq. (26.4).

A similar calculation for the θ -coordinate yields

$$\begin{aligned} \frac{\partial \omega_1}{\partial \dot{\theta}} &= \cos \phi, & \frac{\partial \omega_2}{\partial \dot{\theta}} &= -\sin \phi, & \frac{\partial \omega_3}{\partial \dot{\theta}} &= 0, \\ \frac{\partial \omega_1}{\partial \theta} &= \dot{\psi} \cos \theta \sin \phi, & \frac{\partial \omega_2}{\partial \theta} &= \dot{\psi} \cos \theta \cos \phi, & \frac{\partial \omega_3}{\partial \theta} &= -\dot{\psi} \sin \theta. \end{aligned}$$

From (1) we obtain

$$\begin{aligned} \frac{\partial T}{\partial \dot{\theta}} &= I_1 \omega_1 \cos \phi - I_2 \omega_2 \sin \phi, \\ \frac{\partial T}{\partial \theta} &= (I_1 \omega_1 \sin \phi + I_2 \omega_2 \cos \phi) \dot{\psi} \cos \theta - I_3 \omega_3 \dot{\psi} \sin \theta. \end{aligned}$$

Lagrange's equation

$$(4) \quad \frac{d}{dt} \frac{\partial T}{\partial \dot{\phi}} - \frac{\partial T}{\partial \phi} = 0$$

hence becomes

$$(5) \quad \begin{aligned} 0 = & I_1 \frac{d\omega_1}{dt} \cos \phi - I_1 \frac{d\omega_2}{dt} \sin \phi \\ & - I_1 \omega_1 \sin \phi (\dot{\phi} + \dot{\psi} \cos \theta) - I_2 \omega_2 \cos \phi (\dot{\phi} + \dot{\psi} \cos \theta) \\ & + I_3 \omega_3 \dot{\psi} \sin \theta. \end{aligned}$$

But according to (35.11),

$$\dot{\phi} + \dot{\psi} \cos \theta = \omega_3, \quad \dot{\psi} \sin \theta = \omega_1 \sin \phi + \omega_2 \cos \phi,$$

so that the second and third lines of (5) can be written

$$(I_2 - I_1) \omega_2 \omega_1 \sin \phi - (I_2 - I_3) \omega_2 \omega_3 \cos \phi$$

and, together with the first line,

$$(6) \quad 0 = \left\{ I_1 \frac{d\omega_1}{dt} - (I_2 - I_3) \omega_2 \omega_3 \right\} \cos \phi - \left\{ I_2 \frac{d\omega_2}{dt} - (I_3 - I_1) \omega_3 \omega_1 \right\} \sin \phi.$$

Finally the Lagrange Equation

$$\frac{d}{dt} \frac{\partial T}{\partial \dot{\psi}} - \frac{\partial T}{\partial \psi} = 0$$

becomes, after suitable transformation of variables and in view of (3),

$$(7) \quad 0 = \left\{ I_1 \frac{d\omega_1}{dt} - (I_2 - I_3) \omega_2 \omega_3 \right\} \sin \phi - \left\{ I_2 \frac{d\omega_2}{dt} - (I_3 - I_1) \omega_3 \omega_1 \right\} \cos \phi.$$

It follows from (6) and (7) that both $\{\}$ must necessarily vanish, so that we obtain the first and second Euler equations (26.4).

The transformation which we have carried out for one specific example can be performed quite generally⁵ in the case of an arbitrary number of non-holonomic velocity parameters defined as linear (or more general) functions of real velocity coordinates. If, as in the case of the rigid body, the kinetic energy takes an especially simple form when expressed in terms of these parameters, such transformations can be of signal value for the integration of the equations of motion; they can also be useful in that they may satisfy non-holonomic conditions. Boltzmann found it necessary

⁵ Cf., in particular, G. Hamel, *Math. Ann.* 59 (1904), and *Sitzungsber. der Berl. Math. Ges.* 37 (1938). Furthermore, *Encykl. d. Math. Wiss.* IV.2, Art. Prange No. 3 and ff.

to introduce the components of momentum corresponding to non-holonomic velocities in the kinetic theory of gases. He called these components "momentoids."

§ 44. The Hamilton-Jacobi Equation

At the beginning of the previous century the most burning question of theoretical physics was, "wave theory or corpuscular theory of light?" The wave theory was founded by Huygens and, at the time mentioned, found its confirmation in Thomas Young's discovery of the phenomenon of interference. The corpuscular theory, on the other hand, had Newton's seemingly authoritative backing. W. R. Hamilton, astronomer and profound mathematical thinker, was just then engaged in a study of the paths of light rays in optical instruments. The results of these studies* began to appear in print in 1827, at about the time at which the two greatest advocates of wave optics, Fraunhofer and Fresnel, died at almost the same early age. Hamilton's work on general dynamics, the results of which we shall briefly summarize in this section, came somewhat later, but it is intimately related to his investigations in ray optics†.

Let us add parenthetically that as a result of Planck's discovery of the elementary quantum of action the above-mentioned question must now be posed differently. We no longer ask, "waves or corpuscles?" but state, "waves *as well as* corpuscles!" It seems at first sight impossible to reconcile these apparently contradictory concepts; actually they are complementary rather than contradictory aspects both of optics and of dynamics. Their reconciliation, as Schrödinger has recognized, results from a logical extension of Hamilton's ideas and leads to *wave or quantum mechanics*.

Ray optics is the mechanics of light particles; in optically inhomogeneous media the paths of these particles are by no means straight lines, but are determined by Hamilton's ordinary differential equations or Hamilton's principle which is equivalent to them. From the viewpoint of wave optics, on the other hand, the rays of light are given by the orthogonal[‡] trajectories of a system of wave surfaces or wave fronts. According to Huygens' principle, these wave fronts are parallel surfaces. Hamilton under-

* Treatises on ray optics, *Trans. Roy. Irish Acad.* 1827, with supplements of 1830 and 1832. His work on dynamics appeared in the *Trans. Roy. Soc. London* 1834 and 1835.

† In the formulation by Jacobi this connection was lost. It was newly worked out in 1891 by F. Klein (*Naturforscher-Ges. in Halle; Ges. Abhandl.*, Vol. II, pp. 601, 603).

‡ This is true of optically isotropic media. In anisotropic media such as crystals the orthogonality between ray and wave front is no longer an ordinary Euclidean one, but a non-Euclidean, generalized tensor orthogonality.

took to represent the family of wave surfaces by a (perforce partial) differential equation and to extend this method to the polydimensional space of the q_k of an arbitrary mechanical system. As we shall see, the family of wave surfaces is then given by $S = \text{const.}$, where S is the least action function of Eq. (37.1). The trajectories orthogonal to the surfaces are determined by the equation

$$(1) \quad p_k = \frac{\partial S}{\partial q_k}.$$

(1) Conservative Systems

For the moment we deal with a mechanical system in which energy is conserved and can be resolved into a kinetic part T and a potential part V . T , V and H are hence not explicitly dependent on t .

We start out with Eq. (37.9), and replace δW in the right member by

$$-\delta V = \delta(T - E) = \delta T - \delta E.$$

The right member of (37.9) then becomes

$$(2) \quad 2\delta T + 2T \frac{d}{dt} \delta t - \delta E.$$

Next we transform the left member of the same equation to generalized coordinates p , q ,

$$(3) \quad \frac{d}{dt} \sum p_k \delta q_k.$$

Equating (3) and (2) yields

$$(4) \quad 2\delta T + 2T \frac{d}{dt} \delta t - \delta E = \frac{d}{dt} \sum p_k \delta q_k.$$

We integrate (4) with respect to t between the limits 0 and t to obtain

$$(5) \quad \delta S - t \delta E = \sum p \delta q - \sum p_0 \delta q_0,$$

where S is defined by Eq. (37.1) and p_0 and δq_0 refer to the lower limit $t=0$ of the integration, p and δq to its upper limit t .

Eq. (5) indicates that we must regard the action integral S as a function of the initial position q_0 , the final position q and the energy E , i.e., that we are to use the arbitrarily assigned total energy E as variable in place of the time t :

$$(6) \quad S = S(q, q_0, E).$$

According to (5), the motion as a function of time is then given by

$$(7) \quad t = \frac{\partial S}{\partial E}.$$

where q_0 and q are held fixed. If, instead, we keep E fixed and vary either q or q_0 , (5) yields

$$(8) \quad p = \frac{\partial S}{\partial q}, \quad p_0 = - \frac{\partial S}{\partial q_0}.$$

The first of these relations is in agreement with our assertion (1); as for the second, we shall soon transform it to a more convenient form.

It must be admitted that we have not gained much in the way of knowledge of the motion as long as S is not known in the form (6). Let us, however, recall the equation of energy

$$H(q, p) = E,$$

where we substitute the value of p from Eq. (8) to obtain

$$(9) \quad H\left(q, \frac{\partial S}{\partial q}\right) = E.$$

We regard (9) as the determining equation for the characteristic function S . It is called "Hamilton's partial differential equation" or the *Hamilton-Jacobi equation* for conservative systems. With T homogeneous of second degree in the p (V can be assumed independent of the p), it is of *second degree and first order*.

Let us suppose that we have found a *complete integral* of this equation, i.e., a solution that contains a number of assignable constants equal to the number of degrees of freedom of the problem. Call these constants

$$\alpha_1, \alpha_2, \dots, \alpha_f.$$

Since S itself does not occur in (9), it is determined by (9) only up to an additive constant. One of the above constants of integration, say α_1 , is, therefore, in excess and can be replaced by an additive constant which remains unassigned. We may replace α_1 by our energy parameter E , so that the complete integral can be written in the form

$$(10) \quad S = S(q, E, \alpha_2, \alpha_3, \dots, \alpha_f) + \text{const.}$$

The classic method used to arrive at such a complete solution is that of *separation of variables*—a method often, but not always, applicable. We shall deal with this method in § 46. In § 45 we shall show how Eq. (10) leads to a knowledge of the motion of the system.

(2) Dissipative Systems

We shall now adopt the general viewpoint that the Lagrangian L and hence the Hamiltonian H depend on t . In general it is then impossible to decompose L and H into T and V ; if, in particular, a potential energy V does exist, it will have to depend on the time. This case is important for

the perturbation problems of astronomy and quantum mechanics. There exists then no energy principle, hence no total energy constant E . It follows that we cannot use the principle of least action, but must revert to Hamilton's principle. Consequently we define a characteristic function S^* , given by the integral occurring in Hamilton's principle,

$$(11) \quad S^* = \int_{t_0}^t L dt,$$

and regard S^* as function of the initial and final positions and of the *time of travel* t ,

$$(12) \quad S^* = S^*(q, q_0, t).$$

This is to be compared to Eq. (6) where the constant total energy E (non-existent in the present case) took the place of t .

Let us now form $\frac{dS^*}{dt}$, first by means of (11),

$$(13) \quad \frac{dS^*}{dt} = L,$$

next by means of (12),

$$(14) \quad \frac{dS^*}{dt} = \sum \frac{\partial S^*}{\partial q_k} \dot{q}_k + \frac{\partial S^*}{\partial t} = \sum p_k \dot{q}_k + \frac{\partial S^*}{\partial t}.$$

The relation analogous to (8) used here,

$$(15) \quad p_k = \frac{\partial S^*}{\partial q_k},$$

is easily verified. Merely differentiate (11) with respect to q_k and recall Eq. (41.1e).

In view of the general definition (41.1) of H , the comparison of (13) and (14) now yields

$$(16) \quad \frac{\partial S^*}{\partial t} + H = 0;$$

from Eq. (15) we have, therefore,

$$(17) \quad \frac{\partial S^*}{\partial t} + H\left(q, \frac{\partial S^*}{\partial q}, t\right) = 0.$$

This is the *Hamilton-Jacobi equation in general form*. It includes our earlier Eq. (9) as a special case. To show this, let us assume, as in (a), that H is independent of t . From (17) it follows that S^* is linear in t . Hence we put

$$S^* = at + b$$

and conclude from (16) that $-a=H$, i.e., equal to the energy constant E which now exists; b proves to be identical to our former characteristic function S . Thus Eq. (17) reduces to the special form (9) in this case.

The remarks made in (a) concerning the integration of (9) apply equally well to the more general Eq. (17). The complete integral of the latter now contains $f+1$ constants, one of which is again additive. Instead of (10) we can then write

$$(18) \quad S^* = S^*(q, t, \alpha_1, \alpha_2, \dots, \alpha_f) + \text{const.}$$

§ 45. Jacobi's Rule on the Integration of the Hamilton-Jacobi Equation

We stated in connection with Eqs. (44.8) that the second of these did not lend itself to ready integration. The reason for this is that we integrated our partial differential equation, not in the form (44.6), but in the forms (44.10) and (44.18), respectively. In Eq. (44.7),

$$(1) \quad t = \frac{\partial S}{\partial H},$$

on the other hand, we had obtained an equation describing, very directly, *the motion in time*. We shall now prove that if we differentiate S with respect to the constants of integration $\alpha_2, \alpha_3, \dots, \alpha_f$ instead of E , we obtain equations

$$(2) \quad \beta_k = \frac{\partial S}{\partial \alpha_k}, \quad k=2, 3, \dots, f$$

which describe *the geometric configuration of the path of the system, provided that we regard the β_k as a second set of constants of integration*. This is Jacobi's rule for the case (a). In the case (b) it takes the even simpler form

$$(3) \quad \beta_k = \frac{\partial S^*}{\partial \alpha_k}, \quad k=1, 2, \dots, f.$$

Here we have f equations of uniform structure which give both the *temporal* and the *spatial course of the motion of the system*.

We can introduce the same simplicity into case (a) by formally writing

$$(3a) \quad \beta_1 = \frac{\partial S}{\partial \alpha_1},$$

where we have put $t = \beta_1$ and $E = \alpha_1$.

We shall restrict our proof to case (a). Let us recall the definition (41.11) of a contact transformation, which we shall write, for purposes of the following,

$$(4) \quad dF(q, Q) = \sum p_k dq_k - \sum P_k dQ_k.$$

Let us compare this with the total differential of the characteristic function (44.10),

$$dS(q, E, \alpha) = \sum_{k=1}^f \frac{\partial S}{\partial q_k} dq_k + \frac{\partial S}{\partial E} dE + \sum_{k=2}^f \frac{\partial S}{\partial \alpha_k} d\alpha_k,$$

which becomes, with substitution from (44.8) and (2), (3a) of this section,

$$(5) \quad dS(q, \alpha) = \sum_{k=1}^f p_k dq_k + \sum_{k=1}^f \beta_k d\alpha_k.$$

This equation agrees with (4) if we identify

$$(6) \quad F \text{ with } S, \quad Q_k \text{ with } \alpha_k, \quad P_k \text{ with } -\beta_k.$$

Now we know that, by means of a transformation $q_k, p_k \rightarrow Q_k, P_k$ satisfying condition (4), we pass from Hamilton's equations (41.4)

$$\dot{p}_k = -\frac{\partial H}{\partial q_k}, \quad \dot{q}_k = \frac{\partial H}{\partial p_k}$$

to Eqs. (41.12),

$$\dot{P}_k = -\frac{\partial \bar{H}}{\partial Q_k}, \quad \dot{Q}_k = \frac{\partial \bar{H}}{\partial P_k}.$$

In view of (6) these become, in our case,

$$(7) \quad -\dot{\beta}_k = -\frac{\partial \bar{H}}{\partial \alpha_k}, \quad \dot{\alpha}_k = -\frac{\partial \bar{H}}{\partial \beta_k}.$$

But from (41.10),

$$\bar{H}(Q, P) = H(q, p),$$

or, by virtue of (6),

$$\bar{H}(\alpha, -\beta) = E = \alpha_1.$$

It follows that

$$(9) \quad \frac{\partial \bar{H}}{\partial \alpha_k} = \begin{cases} 1 & \text{for } k=1, \\ 0 & \text{for } k>1; \end{cases} \quad \frac{\partial \bar{H}}{\partial \beta_k} = \begin{cases} 0 & \text{for } k=1, \\ 0 & \text{for } k>1. \end{cases}$$

Thus Eqs. (7) become

$$(10) \quad \dot{\beta}_k = \begin{cases} 1 & \text{for } k=1, \\ 0 & \text{for } k>1; \end{cases} \quad \dot{\alpha}_k = \begin{cases} 0 & \text{for } k=1, \\ 0 & \text{for } k>1. \end{cases}$$

These equations tell us nothing new regarding the α_k ; they merely confirm that the α_k are constants of integration. The same can be said of the

equation for β_1 ; from $\dot{\beta}_1=1$ we simply have $\beta_1=t$ (to within an additive constant of no importance), nothing new in view of Eq. (3a). Eqs. (10) for β_k with $k>1$, on the other hand, furnish the proof of Jacobi's rule; they state that, like the α_k , the β_k are integration constants.

The proof can be extended without important changes to the case (b) provided we make the definition of a contact transformation somewhat more general. Since we do not need this result in the following, we shall not be detained by it.

§ 46. Classical and Quantum-Theoretical Treatment of the Kepler Problem

In this section we wish to show how the Hamilton-Jacobi method of integration leads unambiguously and directly to the solution of the planetary problem of astronomy. We shall, furthermore, discover with surprise that the same method is made to order for the requirements of atomic physics and leads in a natural way to the (older) quantum theory.

We begin with the Lagrangian of the two-body problem with fixed sun M , expressed in polar coordinates,

$$(1) \quad L = \frac{m}{2} (\dot{r}^2 + r^2 \dot{\phi}^2) + G \frac{mM}{r}$$

from which we calculate the momenta

$$(1a) \quad p_r = m\dot{r}, \quad p_\phi = mr^2\dot{\phi}.$$

Substitution of these in (1) and a change of sign in the potential energy yield the Hamiltonian

$$(1b) \quad H = \frac{1}{2m} \left(p_r^2 + \frac{1}{r^2} p_\phi^2 \right) - G \frac{mM}{r}$$

and, from (44.9), the Hamilton-Jacobi equation

$$(2) \quad \left(\frac{\partial S}{\partial r} \right)^2 + \frac{1}{r^2} \left(\frac{\partial S}{\partial \phi} \right)^2 = 2m \left(E + G \frac{mM}{r} \right).$$

Let us apply in this example the method of "separation of variables" mentioned on p. 231.

We try a solution of the differential equation (2) of the form

$$(3) \quad S = R + \Phi$$

in which R depends only on r and Φ only on ϕ . If we replace the right member of (2) by the general function $f(r, \phi)$, we obtain

$$(3a) \quad \left(\frac{dR}{dr}\right)^2 + \frac{1}{r^2} \left(\frac{d\Phi}{d\phi}\right)^2 = f(r, \phi).$$

In general, such a relation does not hold. If, however, f is independent of ϕ , as in our case, we need merely put $\frac{d\Phi}{d\phi}$ equal to a constant, say C (called the "separation constant"). R is then determined by the equation

$$(4) \quad \left(\frac{dR}{dr}\right)^2 = f(r) - \frac{C^2}{r^2},$$

which is solved by quadrature, yielding a complete integral. The assumption that f is independent of ϕ is evidently equivalent to the fact that in our case ϕ is cyclic, that is, it does not occur explicitly in the differential equation. We see that the method of separation of variables is based on special symmetry properties of the given differential equation, symmetry properties which are often, though by no means always, realized.

We now follow the general pattern of § 45, put $C = \alpha_2$ and separate (2) into

$$(5) \quad \frac{\partial S}{\partial \phi} = \alpha_2$$

$$(6) \quad \frac{\partial S}{\partial r} = \left[2m \left(E + G \frac{mM}{r} \right) - \frac{\alpha_2^2}{r^2} \right]^{\frac{1}{2}}.$$

Eq. (5) is the law of conservation of angular momentum, that is, Kepler's second law; the separation constant α_2 is the constant angular momentum, essentially identical to the areal velocity constant used in Eq. (6.2). Eq. (6) gives the variable radial momentum.

To calculate the characteristic function S , we integrate (5) and (6) and form (3). Replacing E by α_1 , we obtain

$$(7) \quad S = \int_{r_0}^r \left[2m \left(\alpha_1 + G \frac{mM}{r} \right) - \frac{\alpha_2^2}{r^2} \right]^{\frac{1}{2}} dr + \alpha_2 \phi + \text{const.}$$

The lower limit of integration can be chosen arbitrarily since it merely affects the magnitude of the additive constant.

Let us, for the present, focus our attention on the geometric trajectory, i.e., on Kepler's first law. To do this we follow (45.2) and form

$$(8) \quad \beta_2 = \frac{\partial S}{\partial \alpha_2} = -\alpha_2 \int_{r_0}^r \left[2m \left(\alpha_1 + G \frac{mM}{r} \right) - \frac{\alpha_2^2}{r^2} \right]^{-\frac{1}{2}} \frac{dr}{r^2} + \phi.$$

It is evidently convenient to introduce $s = \frac{1}{r}$ instead of r as variable of integration and to rewrite (8)

$$(9) \quad \begin{aligned} \beta_2 - \phi &= \alpha_2 \int_{s_0}^s \left[2m \left(\alpha_1 + GmMs \right) - \alpha_2^2 s^2 \right]^{-\frac{1}{2}} ds \\ &= \int_{s_0}^s \frac{ds}{[(s - s_{\min})(s_{\max} - s)]^{\frac{1}{2}}}. \end{aligned}$$

Here s_{\min} and s_{\max} are the reciprocals of the distances from sun to aphelion and perihelion. Comparison of the two integrals yields

$$(10) \quad \begin{aligned} s_{\min} s_{\max} &= -\frac{2m\alpha_1}{\alpha_2^2} \\ s_{\min} + s_{\max} &= \frac{2Gm^2 M}{\alpha_2^2}. \end{aligned}$$

Now we wish to obtain (9) in convenient trigonometric form; the transformation

$$(11) \quad s = \frac{s_{\min} + s_{\max}}{2} + \frac{s_{\max} - s_{\min}}{2} u,$$

suggests itself. It takes $s = s_{\max}$ into $u = +1$ and $s = s_{\min}$ into $u = -1$. From (9) we then have

$$(12) \quad \beta_2 - \phi = \int_{u_0}^u \frac{du}{(1-u^2)^{\frac{1}{2}}}$$

and, making the assignable lower limit of integration equal to 1,

$$(13) \quad \phi - \beta_2 = \cos^{-1} u, \quad u = \cos(\phi - \beta_2).$$

Finally we return from u to s via (11) and take note that, according to p. 42, Fig. 7,

$$s_{\min} = \frac{1}{a(1+\epsilon)}, \quad s_{\max} = \frac{1}{a(1-\epsilon)},$$

so

$$s = \frac{1}{a(1-\epsilon^2)} + \frac{\epsilon}{a(1-\epsilon^2)} u.$$

From (13) we then obtain the equation of an ellipse in the familiar form

$$(14) \quad s = \frac{1}{r} = \frac{1 + \epsilon \cos(\phi - \beta_2)}{a(1-\epsilon^2)},$$

where the constant β_2 can be absorbed into the definition of ϕ .

For experimental reasons the astronomer is interested not so much in the geometrical form of the trajectory as in the motion as a function of time. Here again the Hamilton-Jacobi method gives the answer in the most systematic fashion, namely, by means of Eq. (45.1),

$$t = \frac{\partial S}{\partial H} = \frac{\partial S}{\partial \alpha_1},$$

from which we obtain, after substitution of the variable s ,

$$(15) \quad t = -\frac{m}{\alpha_2} \int_{s_0}^s \frac{ds}{s^2 [(s-s_{\min})(s_{\max}-s)]^{\frac{1}{2}}}.$$

With this equation we complete our former treatment in § 6, where the position of the planet as a function of time was left undetermined. With the help of the "eccentric anomaly" of Problem I.16 as the new variable of integration [its symbol u should not be confused with the auxiliary u in Eq. (11)] equation (15) can be solved by elementary integration and leads directly to the celebrated Kepler equation

$$nt = u - \epsilon \sin u$$

mentioned in the cited problem.

It is well-known that two- and several-body problems play a central role in modern atomic physics as well. In the hydrogen atom the electron moves about the nucleus, the proton, like a planet about the sun. Here, too, the Hamilton-Jacobi method has proved of surprising value. It literally shows us the point at which *quantum numbers* must be introduced.

In the older quantum theory, whenever the k th degree of freedom was separable from the remaining ones, one defined a *phase integral* (also called "action variable") of the k th degree of freedom given by

$$(16) \quad J_k = \int p_k dq_k.$$

The integral was to be taken over the whole range of values of the variable q_k . One then asked that J_k be an integral multiple of Planck's elementary quantum of action (cf. p. 181),

$$(16a) \quad J_k = n_k h.$$

With p_k in (16) expressed in terms of the characteristic function S , one obtains

$$(17) \quad \int \frac{\partial S}{\partial q_k} dq_k = \Delta S_k = n_k h.$$

ΔS_k is the k th "modulus of periodicity" of the function S , i.e., the change suffered by S when q_k runs through a complete cycle of its values.

The electron of a hydrogen atom has coordinates $q_1 = \phi$ and $q_2 = r$. The differential equation (2) for S and its solution (7) can be transferred directly from astronomy to atomic physics, provided we replace the gravitational potential energy by the Coulomb energy $-\frac{e^2}{r}$.

Since the range of the coordinate ϕ extends from 0 to 2π , we obtain from (7) and (17)

$$(18) \quad \Delta S_\phi = 2\pi \alpha_\phi = n_\phi \hbar.$$

n_ϕ is the *azimuthal quantum number*; α_ϕ , as we know, is identical to the azimuthal moment of momentum p_ϕ .

The range of values of the r -coordinates extend from r_{\min} to r_{\max} and back. Eqs. (7) and (17) therefore yield

$$(19) \quad \Delta S_r = 2 \int_{r_{\min}}^{r_{\max}} \left[2m \left(E - \frac{e^2}{r} \right) - \frac{n_\phi^2 \hbar^2}{4\pi^2 r^2} \right]^{\frac{1}{2}} dr = n_r \hbar.$$

n_r is the *radial quantum number*. The quadrature is best performed by complex integration in the r -plane; once this is done, (19) becomes

$$(20) \quad -n_\phi \hbar + 2\pi i \frac{me^2}{(2mE)^{\frac{1}{2}}} = n_r \hbar.$$

The energy of the hydrogen electron in the quantum state $n = n_r + n_\phi$ is, therefore,

$$(21) \quad E = - \frac{2\pi^2 m e^4}{\hbar^2 n^2}.$$

It is negative because the energy was set equal to zero for infinite electron-proton distance (see the above expression for the potential energy).

Eq. (21), together with Bohr's postulate of the radiation of energy in quantum jumps, led to the first understanding of the hydrogen spectrum (the so-called Balmer series) and from there to the modern theory of spectral lines in general.

Present-day developments of atomic theory have gone beyond the description of electronic orbits here presented. As mentioned at the beginning of § 44, investigations following Hamilton's line of thought have resulted in a more profound wave-mechanical conception of atomic processes.

PROBLEMS

Chapter I

I.1. *Elastic collision*¹. n equal masses M are placed in contact with each other along a straight line. Two masses M , both having velocity v , collide with the row of n masses from the left. Evidently the laws of momentum and energy are satisfied if the two masses on the left transfer their velocities to the last two masses on the right. Show that these laws cannot be satisfied if only one mass is expelled on the right, or if the two last masses on the right are set in motion with different velocities v_1, v_2 .

I.2. *Elastic collision with unequal masses*. Let the last mass m on the right be smaller than the remaining masses. Let a mass M collide from the left with velocity v_0 . Show from the principles of energy and momentum that it is impossible for m to be the only mass set in motion. If it is assumed that only two masses are set in motion, what must be their velocities?

I.3. *Elastic collision with unequal masses*. Let the last mass M' on the right be greater than the remaining ones. Make the same assumptions as in Problem 2, taking notice, however, that the next-to-last mass on the right transfers its momentum toward the left. What is the velocity of M' and of the first mass M at the left end of the row? What happens if M' is very large?

I.4. *Inelastic collision between an electron and an atom*. An electron m , of velocity v , collides centrally with an atom M initially at rest. The atom is excited and is raised from its ground state to an energy level E units above it. What is the minimum initial velocity v_0 that the electron must have?

You will find one quadratic equation each for the final velocities v of the electron and V of the atom. The minimum value v_0 results from the requirement that the radical occurring in the solutions for v and V be real. The value of v_0 is somewhat higher than would be expected if only the conservation of energy were called into play, although the difference is not observable because the ratio $M/m \geq 2000$ is very high.

¹It is essential that the student carry out the experiments described in Problems I.1 to I.3 himself. This can be done with coins on a smooth support, with elastic spheres so suspended on strings that they touch in the position of rest, or finally with marbles in a trough.

If the colliding particle is of the same, or approximately the same, mass as the struck one, the required minimum energy is about twice that expected from conservation of energy alone.

1.5. Rocket to the moon. A rocket with continuous exhaust shoots vertically upward. Let the exhaust velocity be a relative to the rocket and $\mu = -\dot{m}$ be the mass expelled per second, and assume both constant in time. Assume that the motion occurs under constant gravitational acceleration g , friction being neglected. Set up the equation of motion and integrate it under the assumption that the initial velocity of the rocket on the surface of the earth is zero. If $\mu = \frac{1}{100}$ of the initial mass m_0 and $a = 2000$ meter \cdot sec $^{-1}$, what height has the rocket reached at $t = 10, 30, 50$ sec.?

1.6. Water drop falling through saturated atmosphere. A spherical water droplet falls, without friction and under the influence of gravity, through an atmosphere saturated with water vapor. Let its initial radius ($t = 0$) be c , its initial velocity, v_0 . As a result of condensation the water drop experiences a continuous increase in mass proportional to its surface; as will be shown, its radius then increases linearly with time. Integrate the differential equation of the motion by introducing r instead of t as independent variable. Show that for $c = 0$ the velocity increases linearly with time.

1.7. Falling chain. A chain lies pushed together at the edge of a table, except for a piece which hangs over it, initially at rest. The links of the chain start moving one at a time; neglect friction. The energy written in the usual form is here no longer an integral of the motion. Instead, the impulsive (Carnot) energy loss must be taken into account in writing the balance of energy.

1.8. Falling rope. A rope of length l slides over the edge of a table. Initially a piece x_0 of it hangs without motion over the side of the table. Let x be the length of rope hanging vertically at time t . The rope is assumed to be perfectly flexible. Show that the principle of energy in the form $T + V = \text{const.}$ gives an integral of the motion.

1.9. Acceleration of moon due to earth's attraction. The moon's distance to the earth is about 60 earth radii. Assume that the lunar orbit is a circle, once traversed in 27 days, 7 hours and 43 minutes. From this the acceleration of the moon toward the earth (centripetal acceleration) can be calculated. Comparison of this value with that from Newton's law of gravitation gave the first confirmation of this law.

1.10. The torque as a vector quantity. Consider a rectangular coordinate system (x, y, z) , with \mathbf{r} the radius vector of the point of application of a force \mathbf{F} . We now pass to a second coordinate system (x', y', z') , obtained from the former by rotation. Show that the moment of force \mathbf{F} about the origin of the first coordinate system transforms like a vector, i.e., like

$\mathbf{r} = (x, y, z)$. To prove this one must assume that both coordinate systems are of similar sense (both right-handed or both left-handed).

I.11. *The hodograph of planetary motion.* From Eq. (6.5) with $A=0$, the hodograph of planetary motion is given by

$$\xi = \dot{x} = -\frac{GM}{O} \sin \phi, \quad \eta = \dot{y} = +\frac{GM}{O} \cos \phi + B,$$

where M is the mass of the sun, O the angular momentum constant, ϕ the true anomaly (cf. Fig. 6). Show that the trajectory is a hyperbola or ellipse, depending on whether the "pole" $\xi=\eta=0$ of the hodograph is excluded from or included by the hodograph. Also describe the limiting cases of parabola and circle in terms of the position of this pole.

I.12. *Parallel beam of electrons passing through the field of an ion. Envelope of the trajectories.* A source located at infinity shoots off electrons (charge e , mass m) along parallel paths with constant initial velocity v_0 . An ionized atom A (charge E , mass M) is fixed at the origin. If e and E have the same sign, what area surrounding A is never touched by the electrons?

Take the y -axis as the direction of the incident particles; treat the problem as plane. It will be easiest to write the trajectory of an electron in polar coordinates with A as pole of the coordinate system and focus of the hyperbolic trajectory. The boundary of the above-mentioned area is obtained as the envelope of the electronic trajectories. Because of $M \gg m$ one can consider A to be at rest.

Show that if e and E have opposite signs, the envelope of trajectories seems to yield the same boundary, but that it is now devoid of physical meaning.

I.13. *Elliptical trajectory under the influence of a central force directly proportional to the distance.* Consider a mass m under the influence of a force directed toward a fixed point O (center of force)

$$\mathbf{F} = -k\mathbf{r}$$

($\mathbf{r} = \vec{Om}$, $k = \text{const.}$). Show that the following three laws hold for the motion of m :

1. m describes an ellipse with O as center.
2. The radius vector \mathbf{r} sweeps out equal areas in equal times.
3. The period T is independent of the shape of the ellipse, depending only on the force law, i.e., the values of k and m .

I.14. *Nuclear disintegration of lithium* (Kirchner, Bayer. Akad. 1933). If a hydrogen nucleus (proton, mass m) collides with velocity v_p with a nucleus of Li^7 (lithium of atomic weight 7), the latter splits into two α -particles (mass $m_\alpha = 4m_p$). These two α -particles fly off in almost (but

not exactly) diametrically opposite directions. Assume that the α -particles fly off symmetrically with respect to the line of collision, and with equal velocities, and calculate the angle 2ϕ between them. Notice that in addition to the kinetic energy E_p of the proton, there occurs another energy E liberated as a result of the mass defect, which is greatly in excess of E_p , and is likewise transmitted to the two α -particles. Thus the final answer for $\cos\phi$ contains not only m_p and m_α , but also the kinetic energy E_p of the proton, and E .

In the units customary in atomic physics, $E=14\cdot10^6$ ev (electron-volt). In an experiment $E_p=0.2\cdot10^6$ ev; what are the values of v_α and 2ϕ ?

I.15. *Central collisions between neutrons and atomic nuclei; effect of a block of paraffin.* Neutrons are slowed down but little by a lead plate 50 cm thick; a layer of paraffin about 20 cm deep, on the other hand, absorbs them completely. This can easily be understood if one remembers that in a central collision the kinetic energy of the neutron (mass $m=1$) is completely transferred to one of the hydrogen nuclei of the paraffin (proton mass $M_1=1$); whereas the amount of energy transferred in a central collision with a lead nucleus (mass $M_2=206$) is hardly worth mentioning. Draw a curve showing the kinetic energy which the initially motionless atomic nucleus (of mass M) receives from the neutron (mass m) in a central collision, as a function of the ratio M/m .

I.16. *Kepler's equation.* The secular variation of the motion of the planet in its orbit is determined, in differential form, by the principle of angular momentum. In order to obtain the secular variation in integral form, one can, following Kepler, proceed as follows (Fig. 55).

Draw a circle about the center of the ellipse with the major axis as diameter. We now associate a point K on the circle with the planet located at point E of the ellipse at the time t . If we take the principal axes of the ellipse as coordinate axes, point K has the same abscissa as E . Whereas E is given by its polar coordinates r, ϕ (pole S), K is determined by polar coordinates a, u (pole M). Thus with the true anomaly ϕ we associate

FIG. 55. Kepler's construction of the eccentric anomaly u and its connection with the true anomaly ϕ .

the *eccentric anomaly* u (as in the text, we count both from aphelion in the direction of motion, at variance with astronomical usage, where the anomalies are counted from perihelion, though, of course, also in the direction of motion of the planet).

The coordinates x and y of the planet E can be expressed, on the one hand, in terms of r and ϕ , and on the other, in terms of one of the semi-axes of the ellipse and the eccentric anomaly u , so that, with K given, E is also given. The course of the motion of point K on the circle is then determined by the celebrated Kepler equation

$$nt = (u - \epsilon \sin u).$$

Here ϵ is the eccentricity of the elliptical trajectory, and $n = \left(\frac{GM}{a^3}\right)^{\frac{1}{2}} = \frac{C}{ab}$, where a , b are the semi-axes, G the gravitational constant, M the mass of the sun, C the areal velocity constant.

In order to derive Kepler's equation, start out with the polar equation of the ellipse, referred to S as pole and the ray SA (aphelion) as polar axis,

$$r = \frac{p}{1 - \epsilon \cos \phi}$$

where p is the "parameter" $a(1 - \epsilon^2)$. Now use the transformation relations referred to above to introduce u in place of ϕ , and obtain the equation

$$r = a(1 + \epsilon \cos u).$$

Differentiation of these two equations, elimination of r and ϕ , introduction of the principle of angular momentum and of Eq. (6.8) finally yield Kepler's equation by an integration, provided we stipulate that at $t=0$ the planet is at aphelion.

Chapter II

II.1. Non-holonomic conditions of a rolling wheel. A sharp-edged wheel, of radius a , rolls without sliding on a rough plane support (think, for example, of a hoop rolling on an even road). Its instantaneous position is determined by assigning values to

1. coordinates x , y of the point of contact of the wheel with the support, referred to a rectangular coordinate system x , y , z whose xy -plane coincides with the support;
2. angle θ between axle of wheel and z -axis;
3. angle ψ formed between the tangent to the wheel (intersection of the plane of the wheel with that of the support) and the x -axis;

4. angle ϕ that the radius toward the instantaneous point of contact of the wheel makes with an arbitrary fixed radius, this angle to be counted positive, say, in the direction of rotation.

In finite motion the wheel therefore has five degrees of freedom. The mobility of the wheel is, however, restricted by the condition of pure rolling (without slipping) brought about by the static friction between wheel and support; indeed, with the wheel moving along its instantaneous direction, the distance δs moved along the direction of the tangent must equal $a\delta\phi$. By projecting this equation on the coordinate axes we then obtain the conditions of constraint

$$(1) \quad \delta x = a \cos \psi \delta\phi, \quad \delta y = a \sin \psi \delta\phi$$

which the displacements δx , δy and $\delta\phi$ must satisfy.

Hence the rolling wheel has only three degrees of freedom in infinitesimal motion.

Show that conditions (1) cannot be reduced to equations between the coordinates themselves. To do this, show that the existence of an equation $f(x, y, \phi, \psi) = 0$ [θ does not occur in (1)] is incompatible with conditions (1).

II.2. *Approximate design of a flywheel for a double-acting one-cylinder steam engine* (cf. also § 9 (4)). A double-acting piston engine is one in which steam is introduced alternately on both sides of the piston, so that work is done during both strokes of a cycle.

Let us assume, for simplicity, that the steam pressure remains constant during each stroke (full pressure or Diesel cycle), and let us, moreover, suppose that the connecting rod is of infinite length. The variable torque as a function of crank angle ϕ transmitted from the piston to the crank shaft is then given by

$$L = L_0 \sin \phi$$

for the half-cycle in which the crank moves from the backward to the dead forward position [cf. Eq. (9.5)]. Here L_0 is a constant; ϕ is counted in the sense of rotation from the dead backward position. During the second half-cycle, from forward to dead backward position, under the same assumptions as made above (viz., 1. double-acting engine, 2. operation under full pressure, 3. infinite connecting rod), the torque changes according to the same law, provided ϕ is now measured in the sense of rotation from the dead forward position.

Let the load on the engine be given by the constant torque W , corresponding to a power of N HP with n r.p.m. Thus the driving torque L is variable, while the load torque W is constant. As a result the angular velocity of the engine fluctuates between a maximum value ω_{\max} and a minimum value ω_{\min} , its mean value ω_m being given approximately by

$$\omega_m = \frac{\omega_{\max} + \omega_{\min}}{2}.$$

It is the purpose of the flywheel to prevent the relative fluctuation, that is the degree δ of unbalance of the engine, given by

$$\delta = \frac{\omega_{\max} - \omega_{\min}}{\omega_m},$$

from exceeding a given limit. How great must the moment of inertia of the flywheel be if the inertial effect of the moving masses (piston, piston rod, cross head, connecting rod and crank) is neglected?

II.3. Centrifugal force under increased rotation of the earth. How fast must the earth rotate and how long would the day be in order that centrifugal force and gravity just cancel at the equator?

II.4. Poggendorff's experiment. From one end of the beam of a balance we suspend a weightless pulley which can rotate without friction. A string U passes over the pulley; on one side the string carries the weight P , on the other, the weight $P+p$, where p is a small additional weight, just as in Atwood's machine. Initially p is fastened to the axle of the pulley by means of a thread u . On the other side of the balance these weights are suitably equilibrated in a pan. The thread u is then burned.

(a) With what acceleration do the weights P and $P+p$ rise and fall, respectively?

(b) Is the beam of the balance displaced in this process?

(c) What is the tension in the string U ?

II.5. Accelerated inclined plane. An inclined plane is moved in a vertical direction according to a given dependence on the time. Investigate the motion of a body of mass m sliding down the plane without friction; in particular, consider the case that the inclined plane is moved with the constant accelerations $+g$ and $-g$.

II.6. Products of inertia for the uniform rotation of an unsymmetrical body about an axis. An unsymmetrical body rotates uniformly about an axis whose ends rest in bearings A and B . What reactions A and B must be exerted by the bearings? Calculate them from d'Alembert's principle; show that they result from the total centrifugal force applied at the center of gravity and from the resultant moment of the centrifugal forces acting on the individual mass elements.

From p. 55 we know the reactions caused by the weight of the body alone; we can therefore omit their effect here.

II.7. Theory of the Yo-yo. A disk-shaped body of mass M and moment of inertia I is provided with a deep symmetrical groove in the median plane

perpendicular to its axis. A string is wound on the shaft of radius r in the groove. The loose end of the string is held in the hand. One then lets the body fall, with the string taut at all times. As the body descends, it acquires a rotational acceleration until the string is unwound. Then follows a transition stage, not to be considered in detail here, the result of which is that the body shifts from one side of the string to the other. The string now winds around the shaft in the opposite sense, and the body climbs with rotational deceleration, and so on. What is the string tension

(a) in descent?

(b) in ascent?

Assume that r is so small compared to the distance of the axis from the loose end of the string that the string can at all times be considered to be vertical.

II.8. *Particle moving on the surface of a sphere.* A mass point moves on the outside of the upper half of a sphere. Let its initial position z_0 and initial velocity v_0 be arbitrary, except that the latter is to be tangential to the surface of the sphere. The motion is to be frictionless, occurring solely under the influence of gravity. At what height does the mass point leave the sphere?

Chapter III

III.1. *Spherical pendulum with infinitesimal oscillations.* In general, the nodal points of the trajectory of a spherical pendulum advance during the course of the motion. For sufficiently small oscillations, however, the nodal points must be fixed, for we are then dealing with an harmonic elliptical motion. Estimate in what order the advance $\Delta\phi$ of the nodal points vanishes with vanishing area of the ellipse.

III.2. *Position of the resonance peak of forced, damped oscillations.* In a forced oscillation with damping the maximum amplitude of oscillation lies, not at $\omega = \omega_0$ as in the case of no damping, but at a value below ω_0 (cf. Fig. 33) depending on the amount of damping.

Find for what value of ω $|C|$ is a maximum.

[Show that the maximum of the velocity amplitude $|C|\omega$ (or of the time average of the kinetic energy) occurs exactly at $\omega = \omega_0$.]

III.3. *The galvanometer.* A galvanometer is connected through a switch with a direct-current source of constant EMF E . At time $t=0$, the switch is closed. After a sufficiently long time the galvanometer deflection reaches its final value α_∞ . What is its motion between the initial position of rest, $\alpha=0$, $\dot{\alpha}=0$, and the final position, $\alpha=\alpha_\infty$?

Three effects have to be taken into account. First, an external torque proportional to the electric current and hence to the *EMF* acts on the galvanometer of moment of inertia I . Second, there acts a damping torque proportional to the angular velocity, which tends to slow down the motion. Third, the torsion in the suspension acts as a restoring torque and is proportional to the deflection α . Let ρ be the factor of proportionality of the damping torque, ω_0^2 that of the restoring torque.

Distinguish and explain graphically the three cases

- (a) weak damping ($\rho < \omega_0$),
- (b) aperiodic ("critical") damping ($\rho = \omega_0$),
- (c) strong damping ($\rho > \omega_0$).

III.4. *Pendulum under forced motion of its point of suspension.*

(a) A particle is suspended from an inextensible string and oscillates without damping under the influence of gravity. The point of suspension is moved along a straight horizontal line according to some given law of displacement $\xi = f(t)$.

What are the equations of motion of the system, the mass of the string being neglected? Derive them either from d'Alembert's principle or from Lagrange's equations of the first kind.

The equations of motion become considerably simplified if we pass to small oscillations, i.e., retain terms of only the first order.

If we make the additional assumption that the displacements of the point of suspension are harmonic in time, the equations of motion can easily be integrated. As the pendulum is set moving, say by a motion of the point of suspension, its proper frequency is excited; the amplitude of this proper frequency is gradually damped out (though we shall neglect damping in the analysis), thus leading to a steady state of oscillation with the same frequency as that forced on the point of suspension. Show that when the motion has thus become stationary, suspension point and mass m move in the same sense below the resonance frequency, in opposite senses above it.

(b) Make a similar analysis of the case in which the point of suspension is subjected to a vertical displacement η , with special emphasis on the case that the acceleration of the point is constant. What is the period of oscillation if the point of suspension is displaced with accelerations $+g$ and $-g$?

III.5. *Practical arrangement of coupled pendulums, sketched in Fig. 56.*

Between two fixed supports A and B is stretched a weightless, flexible and elastic wire. Its tension S is regulated by an adjustable weight G attached to the loose end of the wire hanging over the angle iron B . Two pendulums are suspended *bifilarly* at points C and D which divide the

segment AB into three, let us say, equal parts. The bifilar suspensions, indicated as simple suspensions in the sketch, enable the pendulums to swing out with good accuracy in a transverse direction, i.e., normal to the plane of the drawing. By increasing G the coupling between the two pendulums is made weaker (not stronger, as might at first be thought!). In what is to follow, we shall assume the coupling to be weak, which means that S is large compared with the weight of the pendulum bobs. We further suppose the angles of deflection ϕ_1 and ϕ_2 of the pendulums with

FIG. 56. Wire $AODB$ is held taut by the weight G . It is deformed into $A34B$ or, for the opposite deflection, into $A3'4'B$, the deflection being caused not only by the gravitational action on masses m_1 and m_2 , but also by the inertial effects of the pendulums. The latter are labeled 1 and 2, are of lengths l_1 and l_2 , and suspended bifilarly, so that they swing out normally to the plane of the drawing (the bifilar suspensions are not shown in the figure). ϕ_1 and ϕ_2 are the instantaneous deflections from the vertical.

respect to the vertical to be small. (Refer to Fig. 56 for notation; $3'$ and $4'$ are the deflections of the points of suspension C and D symmetrically opposite to 3 and 4.) These angles are then approximated by

$$\sin \phi_1 = \phi_1 = \frac{x_2 - x_3}{l_1}, \quad \cos \phi_1 = 1$$

$$\sin \phi_2 = \phi_2 = \frac{x_3 - x_4}{l_2}, \quad \cos \phi_2 = 1.$$

With neglect of the y -component of the small oscillations we have for m_1 and similarly for m_2 ,

$$(1) \quad m_1 g = S_1 \cos \phi_1 = S_1 \quad m_2 g = S_2 \cos \phi_2 = S_2$$

$$(2) \quad m_1 \ddot{x}_1 = -S_1 \sin \phi_1 = -\frac{m_1 g}{l_1} (x_3 - x_1), \quad m_2 \ddot{x}_2 = -S_2 \sin \phi_2 = -\frac{m_2 g}{l_2} (x_4 - x_2).$$

At the points of suspension C and D , S_1 and S_2 respectively must, at any instant, be in equilibrium with the tension S ; the latter is altered negligibly little by S_1 and S_2 . This yields two more conditions between x_1 , x_2 , x_3 and x_4 . We can solve these for x_3 and x_4 and substitute them in (2). We then

obtain the simultaneous differential equations of coupled pendulums. Verify that these are indeed in agreement with Eqs. (20.10).

III.6. The oscillation quencher. A system capable of oscillating in the x -direction (mass M , proportionality constant of the restoring force, K) is coupled by means of a spring (constant k) to a mass m , in such a way that m , too, can oscillate in the x -direction. We require that when an external force $P_x = c \cos \omega t$ acts on the mass M , this mass M stay at rest. What conditions must be satisfied by the system (m, k)?

Chapter IV

IV.1. Moments of inertia of a plane mass distribution. Prove that for any plane mass distribution the moment of inertia about the "polar" axis (perpendicular to the plane) equals the sum of the moments of inertia about two mutually perpendicular "equatorial" axes (in the plane of the mass distribution, intersecting in the polar axis). Specialize the foregoing to a circular disk.

IV.2. Rotation of a top about its principal axes. According to Fig. 46a, b, the rotations of an unsymmetrical top about the axes of the largest and smallest moments of inertia are stable, that about the axis of the intermediate moment of inertia is unstable. Prove this analytically. Start out with Euler's equations of motion and put the angular velocity about the axis of rotation $\omega_1 = \text{const.} = \omega_0$. Angular velocities ω_2 and ω_3 about the other two principal axes are initially zero, but, due to a perturbation, acquire values different from zero. If we suppose the perturbation small, the first Euler equation states that to a first approximation ω_1 remains unchanged, $= \omega_0$. From the other two equations one obtains a system of two linear differential equations of first order in ω_2 and ω_3 . Put $\omega_2 = ae^{\lambda t}$ and $\omega_3 = be^{\lambda t}$ with arbitrary constants a and b , and substitute in the two equations. The discussion of the resulting quadratic equation for λ yields the proof of the above assertion.

IV.3. High and low shots in a billiard game. Follow shot and draw shot. A billiard ball is hit with horizontal cue in its median plane, i.e., without "English." At what height h above the center must the cue hit the ball so that pure rolling (no slipping) will ensue? Work out a theory of balls struck high and low, taking into account the kinetic friction between ball and cloth. By how much does the velocity of the center of mass grow in a high shot during the total time friction is acting, and by how much does it decrease in a low shot? What time elapses before only pure rolling remains?

The same method can be used to explain the phenomena taking place on collision with another ball, i.e., follow and draw shots.

IV.4. *Parabolic motion of a billiard ball.* How must a ball be struck so that the initial motion of its center of gravity and the axis of rotation are not normal to each other? Show that the direction of the force of friction is constant as long as the ball slides. What is the trajectory of the center of the ball? After what time does pure rolling ensue?

Chapter V

V.1. *Relative motion in a plane.* A plane rotates with variable angular velocity ω about its normal at one of its points O .

What forces in addition to the centrifugal force must be applied to a mass point so that its equations of motion in the rotating plane take on the same form as in the inertial frame of a spatially fixed plane? It will be convenient to introduce complex variables $x+iy$ in the spatially fixed plane, $\xi+i\eta$ in the rotating plane.

V.2. *Motion of a particle on a rotating straight line.* A mass point moves without friction on a straight line which in its turn rotates with constant angular velocity ω about a fixed horizontal axis intersecting, and perpendicular to, the straight line. Calculate the motion on the rotating straight line as a function of time, and show that the force of constraint (guiding force) and the component of the gravitational attraction along this force just balance the Coriolis force.

V.3. *The sleigh as the simplest example of a non-holonomic system* [after C. Carathéodory, *Z. angew. Math. Mech.* 13, 71 (1933)]. The sleigh is regarded as a rigid plane system with three degrees of freedom in finite motion, one degree in infinitesimal motion. (Cf. the rolling wheel in Problem II.1, which had five degrees of freedom in finite motion, three in infinitesimal motion.)

Neglect the sliding friction on the snow, or, alternatively, think of it as permanently compensated by the pull of a horse. One must, however, take into account the friction F exerted laterally by the snow tracks against the runners of the sleigh, for it prevents any lateral motion of these. Let this friction be concentrated at one point of application O .

An $\xi\eta$ -system is fixed in the sleigh. The ξ -axis runs horizontally along the center line of the runners and passes through the center of mass G with coordinates $\xi=a$, $\eta=0$, and the η -axis passes horizontally through the point of application of F . In the horizontal plane of the snow we fix an xy -system. Let ϕ be the angle between the axes of ξ and x , $\omega=\dot{\phi}$ the

instantaneous angular velocity of the sleigh about the vertical; M is the mass of the sleigh, I its moment of inertia about the vertical through the mass center; u, v are the components of the velocity of the point O ($\xi=\eta=0$) along ξ and η .

(a) Derive the three simultaneous differential equations for the quantities u, v, ω with F as external force, using the method of complex variables of Problem V.1.

(b) Simplify them by introducing the non-holonomic condition $v=0$ and determine F from them.

FIG. 57. Trajectory of a sleigh for various values of k , after Carathéodory.

(c) Integrate them by introducing, instead of ϕ , an auxiliary angle proportional to ϕ .

(d) Verify that the kinetic energy of the sleigh is constant (because F does no work).

(e) Show that, with suitable choice of the time scale, the trajectory of point O in the xy -plane possesses a cusp at $t=0$ and asymptotically approaches straight lines for $t=\pm\infty$, as shown by the curves of Fig. 57 borrowed from Carathéodory.

Chapter VI

VI.1. Example illustrating Hamilton's principle. Calculate the value of Hamilton's integral between the limits $t=0$ and $t=t_1$

(a) for the real motion of a falling particle, $z=\frac{1}{2}gt^2$;

(b) for two fictitious motions $z=ct$ and $z=at^3$, where the constants c and a must be so determined that initial and end positions coincide with those of the real path, in agreement with the rules of variation in Hamilton's

principle. Show that the integral has a smaller value for the real motion (a) than for the fictitious ones (b).

VI.2. *Once more the relative motion in a plane and the motion on a rotating straight line.* Treat Problems V.1 and V.2 by means of the Lagrange method.

VI.3. *Once more the free fall on the rotating earth and Foucault's pendulum.* Verify that these problems, too, can be treated by Lagrange's method without knowledge of the laws of relative motion. This procedure is interesting and simpler in thought than that of Chapter V; it does, however, require a careful inspection of the numerous small terms occurring; only *after* the differentiations $\frac{d}{dt} \frac{\partial}{\partial \dot{q}}$ and $\frac{\partial}{\partial q}$ have been carried out should the usual approximations of large terrestrial radius and small angular velocity be made; until then, *all* terms must be carried.

Start out with ordinary spherical polar coordinates r, θ, ψ , where r is measured from the earth's center. Next compare these with coordinates ξ, η, ζ introduced in Fig. 49. Let R be the earth's radius, θ_0, ψ_0 the coordinates of the projection on the earth of the initial position of the freely falling body or of the point of suspension of the pendulum. We then have the following relations between coordinates r, θ, ψ and ξ, η, ζ of the falling or oscillating particle m ,

$$(1) \quad \xi = R(\theta - \theta_0), \quad \eta = R \sin \theta (\psi - \psi_0), \quad \zeta = r - R,$$

with

$$(2) \quad \psi_0 = \omega t, \quad \theta_0 = \frac{\pi}{2} - \phi = \text{colatitude}.$$

From this

$$\dot{\xi} = R\dot{\theta}, \quad \dot{\eta} = R \sin \theta (\dot{\psi} - \omega) + \frac{\cos \theta}{\sin \theta} \eta \dot{\theta}, \quad \dot{\zeta} = \dot{r}$$

and, conversely,

$$(3) \quad r\dot{\theta} = \left(1 + \frac{\zeta}{R}\right) \dot{\xi},$$

$$r \sin \theta \dot{\psi} = \left(1 + \frac{\zeta}{R}\right) \dot{\eta} + \omega R \left(1 + \frac{\zeta}{R}\right) \sin \theta - \frac{\cos \theta}{\sin \theta} \left(1 + \frac{\zeta}{R}\right) \frac{\eta}{R} \dot{\xi}, \quad \dot{r} = \dot{\zeta},$$

where the angle θ occurring on the right must, according to (1), be regarded as a function of ξ .

These values are to be replaced in the expression

$$T = \frac{m}{2} (\dot{r}^2 + r^2 \dot{\theta}^2 + r^2 \sin^2 \theta \dot{\psi}^2)$$

for the kinetic energy, which becomes, as a result, a function of $\dot{\xi}$, $\dot{\eta}$, $\dot{\zeta}$, ξ , η and ζ . If we denote the terms later to be dropped by \dots , we can, for instance, calculate from T

$$(4) \quad \frac{\partial T}{\partial \dot{\xi}} = m \left(1 + \frac{\zeta}{R}\right)^2 \dot{\xi} - m \frac{\cos \theta}{\sin \theta} \left(1 + \frac{\zeta}{R}\right) \frac{\eta}{R} \left\{ \dots + \omega R \left(1 + \frac{\zeta}{R}\right) \sin \theta + \dots \right\}$$

$$(5) \quad \frac{d}{dt} \frac{\partial T}{\partial \dot{\xi}} = m \ddot{\xi} - m \omega \cos \theta \dot{\eta} + \dots$$

$$(6) \quad \frac{\partial T}{\partial \xi} = \frac{1}{R} \frac{\partial T}{\partial \theta} = + m \omega \cos \theta \dot{\eta} + \dots$$

As our potential energy we can take

$$(7) \quad V = mg(r - R) = mg\zeta.$$

Verify that in this manner we obtain Eqs. (30.5) for the free fall and Eqs. (31.2) for Foucault's pendulum, from which follow the results developed earlier.

VI.4. "Wobbling" of a cylinder rolling on a plane support. A circular cylinder of radius a has an inhomogeneous mass distribution, so that the center of mass G has the distance s from the axis of the cylinder. The cylinder rolls on a horizontal plane under the influence of gravity. Let m be the mass of the cylinder, I its moment of inertia about an axis through the mass center parallel to its axis of symmetry. Investigate the motion with the help of Lagrange's method, introducing the angle ϕ rotated through as generalized coordinate q . In calculating the kinetic energy, put the point of reference

(a) in the center of mass,

(b) in the geometrical center,

of the cylinder and verify that in both cases the same differential equation in ϕ results.

Show by means of the "method of small oscillations" that the equilibrium of the cylinder is stable with G in the lowest, and unstable with G in the highest position.

VI.5. Differential of an automobile. If the driven wheels of an automobile are not to slide, they must be able to turn at different speeds on a curve. This is achieved by the differential (Fig. 58). The engine drives the driving wheel (Ω) in which axle A is fixed. Two bevel gears (ω) sit on A in such a way that they can rotate independently about A . They, in turn, are in mesh with the pair of bevel gears (ω_1 , ω_2) on which they may roll (cf. Fig. 58, left) as A turns.

The axle of the rear wheels of an automobile is cut at the center (Fig. 58, right). Fixed to the left end of its right half is the bevel gear (ω_1), to the right end of its left half, the bevel gear (ω_2). The two halves of the rear

FIG. 58. The differential of an automobile, at the same time a model (after Boltzmann) for the induction effect of two coupled circuits. Left: view along rear axle of vehicle. Right: side view of this axle.

axle are therefore coupled by the differential in such a way that they can turn with different angular velocities.

Set up the kinematic relations between angular velocities Ω , ω , ω_1 and ω_2 . Next make use of the principle of virtual work to derive the condition of equilibrium between the driving torque L acting on (Ω) and the torques L_1 and L_2 acting on (ω_1) and (ω_2).

What is the equation of motion of the system? Let I_1 and I_2 be the moments of inertia of (ω_1) and (ω_2), I that of the pair of gears (ω) about the axis of A , I' that of (ω) about the axis of the driving wheel. Neglect the contribution of (Ω) to I' .

If one rear wheel is accelerated, for instance by decreasing friction, the other wheel is retarded, even if driving torque and frictional torque remain equal there.

HINTS FOR SOLVING THE PROBLEMS

Almost all numerical calculations occurring in these problems can be carried out to sufficient accuracy by means of a slide rule. Let us call express attention to this useful tool for quick approximate calculations.

I.1. The proof that $v_1=v_2=v$ can be derived either algebraically or geometrically. In the latter case use v_1 and v_2 as rectangular coordinates in a plane diagram.

I.2. The velocities of the expelled masses are, respectively,

$$\frac{2M}{M+m}v_0 \quad \text{and} \quad \frac{M-m}{M+m}v_0.$$

I.3. Here we obtain the formulas of I.2 with a change of sign.

I.4. Verify that the quadratic equation for V leads to the same minimum value v_0 as that for v .

I.5. The differential equation to be integrated is

$$m\dot{v} - \mu a = -mg.$$

With the independent variable $m=m_0-\mu t$ instead of t one obtains

$$v = -a \ln\left(1 - \frac{\mu}{m_0}t\right) - gt$$

and, by an additional integration (z =height above earth's surface),

$$(1) \quad z = \frac{am_0}{\mu} \left\{ \left(1 - \frac{\mu}{m_0}t\right) \ln\left(1 - \frac{\mu}{m_0}t\right) + \frac{\mu}{m_0}t \right\} - \frac{1}{2}gt^2.$$

For small t we obtain, by neglecting higher terms in t ,

$$(2) \quad z = \left(\frac{\mu a}{m_0} - g\right) \frac{t^2}{2}.$$

The numerical calculation with equation (1) yields

$t = 10$	30	50 sec
$z = 0.54$	5.65	18.4 km

I.6. Since water has specific gravity 1, the mass of the drop is $m = \frac{4}{3}\pi r^3$, i.e., $dm = 4\pi r^2 dr$. In condensation, on the other hand, with α a factor of proportionality, $dm = 4\pi r^2 \alpha dt$; it follows that $dr = \alpha dt$. In terms of r the differential equation is then

$$\alpha \frac{d}{dr}(r^2 v) = r^2 g.$$

By virtue of the initial condition $v=v_0$ for $r=c$ its solution is

$$v = \frac{g}{\alpha^2} + \frac{c^2}{r^2} \left(v_0 - \frac{g}{\alpha^2} \right);$$

for $c=0$ and $v_0=0$ we have, respectively,

$$v = \frac{g}{\alpha^2}, \quad v = \frac{g}{\alpha^2} \left(1 - \frac{c^2}{r^2} \right).$$

I.7. Let x be the instantaneous length of chain hanging down. With the mass of the chain per unit length put equal to 1, the equation of motion is

$$\frac{d}{dt}(x\dot{x}) = x\ddot{x} + \dot{x}^2 = gx.$$

Since its integration is somewhat difficult—after the substitution $x=u^2$ it leads to an elliptic integral—we shall be satisfied with expressing the quantities \dot{T} , \dot{V} and \dot{Q} (Carnot energy loss per unit time) in terms of x , \dot{x} and \ddot{x} and showing that by the equation of motion we have

$$\dot{T} + \dot{V} + \dot{Q} = 0, \text{ and hence, } \dot{T} + \dot{V} \neq 0.$$

I.8. Our equation of motion is $\ddot{x} = gx$. This linear differential equation with constant coefficients has a solution of the form (3.24b). The validity of the principle of energy can be read off either in differential form from the equation of motion, or in integrated form from its solution

$$x = a(e^{\alpha t} + e^{-\alpha t}), \quad \alpha^2 = \frac{g}{l}, \quad a = \frac{x_0}{2}.$$

I.9. The numerical data given in the problem permit the calculation of the centripetal acceleration of the moon in msec^{-2} . For the radius r of the earth we can take the original definition of the meter, $r = \frac{2}{\pi} 10^7 \text{m}$.

The law of gravitation, on the other hand, yields $\frac{g}{80^2}$ as the centripetal acceleration after the gravitational constant G has been eliminated by means of g as on p. 20. The two numerical values thus obtained are in satisfactory agreement.

I.10. Set up the transformation equations for the coordinates as in (2.5), but with $\alpha_0 = \beta_0 = \gamma_0 = 0$. The components of the transformed moment L' are found to be linear expressions of the components of L with coefficients equal to the cofactors of the transformation scheme. For the latter we have the relations

$$\rho\gamma_1 = \begin{vmatrix} \alpha_2 & \alpha_3 \\ \beta_2 & \beta_3 \end{vmatrix}, \quad \rho\gamma_2 = \begin{vmatrix} \alpha_3 & \alpha_1 \\ \beta_3 & \beta_1 \end{vmatrix}, \dots$$

to be proved from the orthogonality conditions. Here $\rho = \pm 1$, according as the transformed system has the same sense ("unimodular transformation") as the original system, or the opposite sense.

I.11. From Eqs. (6.8) we have [according to Fig. 7 and Eq. (6.5), B is negative]

$$\epsilon = \frac{-B}{\frac{GM}{O}} = \frac{|B|}{\frac{GM}{O}}.$$

It follows that for the ellipse ($\epsilon < 1$) $\frac{GM}{O} > |B|$, for the hyperbola ($\epsilon > 1$) $\frac{GM}{O} < |B|$. Now $R = \frac{GM}{O}$ is the radius of the hodograph circle, $|B|$ the distance of the center from the pole. From this the assertion made in the statement of the problem follows at once.

The table below, in which

$$v_0 = \frac{GM}{O} + |B|$$

signifies the magnitude of the planet's velocity at perihelion, shows how the limiting cases of the circle and the parabola fit into the scheme.

Planetary Trajectory	ϵ	$ B $	Hodograph	v_0
circle	$= 0$	$= 0$	center at pole	$= \frac{GM}{O}$
ellipse	< 1	$< R$	hodograph includes pole	$< \frac{2GM}{O}$
parabola	$= 1$	$= R$	hodograph passes through pole	$= \frac{2GM}{O}$
hyperbola	> 1	$> R$	hodograph excludes pole	$> \frac{2GM}{O}$

I.12. In the differential equations (6.4) we must replace GM by $\pm \frac{eH}{m}$, where the upper sign (attraction) corresponds to the case of the positive ion, the lower sign (repulsion) to that of the negative ion. Note that here $\dot{x}=0$, $\dot{y}=-v_0$, and the meaning of ϕ is the same as in Fig. 6, so that Eqs. (6.5) give for $\phi = \frac{\pi}{2}$,

$$A = \pm \frac{eH}{m} C, \quad B = -v_0.$$

Eq. (6.6) then becomes

$$(1) \quad \frac{1}{r} = \pm \frac{eE}{m_0 C^2} (1 - \sin \phi) - \frac{v_0}{C} \cos \phi.$$

C changes from trajectory to trajectory with the distance of the firing direction from the y -axis. It follows that (1) represents a family of curves. To obtain the envelope of this family, differentiate Eq. (1) with respect to C , then eliminate C from this and the original equation to obtain

$$(2) \quad x^2 = p^2 - 2py, \quad p = \pm \frac{4eE}{m_0 v_0^2}.$$

Note that any electron path consists of only one branch of a hyperbola, whereas (1) represents both branches; verify—most simply by a sketch of the corresponding families of curves—that Eq. (2) is the envelope of the actual electron paths only in the case of repulsion.

I.13. It will be easiest to use the method of harmonic oscillations of § 3, (4). It is, however, instructive to check that the methods of § 6 also lead to the desired end.

I.14. The nuclear reaction treated here is not an elastic collision; nor is it an inelastic one. It is, so to speak, a “superelastic” one, in that the nuclear binding energy E is to be added to the primary energy E_p . The kinetic energy of the α -particles can be calculated in the classical form $E_\alpha = \frac{1}{2} m_\alpha v_\alpha^2$.

Elimination of v_α from the equations of energy and momentum then yields Kirchner's result for the symmetrical case,

$$\cos \phi = \left(\frac{m_p}{2m_\alpha} \frac{E_p}{E + E_p} \right)^{\frac{1}{2}}$$

1 ev is that energy which a potential drop of 1 volt ($= 10^9$ electromagnetic units of potential) imparts to the electronic charge e ($= 1.6 \cdot 10^{-20}$ electromagnetic units of charge), so that $1 \text{ ev} = 1.6 \cdot 10^{-12}$ erg.

The mass of the proton is $m_p = 1.65 \cdot 10^{-24}$ g, that of the α -particle, is hence $m_\alpha = 6.6 \cdot 10^{-24}$ g. The latter is needed in order to pass from E_α , at first expressed in ev and then converted to erg, to the velocity v_α . The value of v_α thus found shows that the classical form for E_α was justified and that the relativity correction of Eq. (4.11) is negligible.

I.15. In the second Eq. (3.27) we put $V_0 = 0$ and, say, $v_0 = 1$, so that one can immediately calculate the kinetic energy $\frac{1}{2} M V^2$ of the struck particle after the collision as function of $x = \frac{M}{m}$; in particular one finds it to be a maximum for $x = 1$ and to be small—only 1.9 % of the maximum value—for $x = 206$.

Proceeding from such considerations, Fermi in 1935 worked out his method for the production of "thermal" neutrons, i.e., slow neutrons of uniform velocity, which by frequent collisions have reached equilibrium with the protons of thermal energy contained in the paraffin.

I.16. The coordinates of E are

$$(1a) \quad \begin{aligned} x &= ML = a \cos u \\ &= SL - SM = r \cos \phi - \epsilon a \end{aligned}$$

$$(1b) \quad y = EL = r \sin \phi = b \sin u.$$

Write the polar equation of the ellipse in r, ϕ in the form

$$(1) \quad r = \epsilon r \cos \phi + p, \quad p = a(1 - \epsilon^2).$$

Substitute the value of $r \cos \phi$ from (1a) to obtain

$$(2) \quad r = \epsilon(a \cos u + \epsilon a) + a(1 - \epsilon^2) = a(1 + \epsilon \cos u).$$

A differentiation of (2) gives

$$(3) \quad dr = -\epsilon a \sin u du.$$

A differentiation of (1) gives

$$\epsilon \sin \phi d\phi = -p \frac{dr}{r^2}.$$

From this

$$(4) \quad \frac{-p}{\epsilon \sin \phi} \dot{r} = r^2 \dot{\phi} = C \quad (C = \text{areal velocity constant}).$$

Eq. (4) is transformed by (1b) and (3) into

$$\frac{pa}{b} r \dot{u} = C.$$

Finally replace r from (2), to arrive at the differential equation

$$(5) \quad (1 + \epsilon \cos u) du = n dt \qquad (6) \quad n = \frac{Cb}{pa^2}.$$

Integration of (5) yields

$$u - \epsilon \sin u = nt.$$

The integration constant vanishes because we agreed to measure time in such a way that for $u=0$ we have $t=0$. nt is called the *mean anomaly* and, like the other anomalies, is measured from perihelion in astronomy. The name comes from the fact that by means of Eq. (6.9) the right member of (6) can be transformed to $\frac{2\pi}{T}$.

II.1. Reduce

$$\delta f = \frac{\partial f}{\partial x} \delta x + \frac{\partial f}{\partial y} \delta y + \frac{\partial f}{\partial \phi} \delta \phi + \frac{\partial f}{\partial \psi} \delta \psi$$

by means of condition (1) of the problem, to obtain for the right member

$$\left(\frac{\partial f}{\partial x} a \cos \psi + \frac{\partial f}{\partial y} a \sin \psi + \frac{\partial f}{\partial \phi} \right) \delta \phi + \frac{\partial f}{\partial \psi} \delta \psi.$$

Now $\delta \phi$ and $\delta \psi$ can individually be put $=0$, so that

$$(2) \quad \frac{\partial f}{\partial \psi} = 0 \quad \text{and} \quad (3) \quad a \frac{\partial f}{\partial x} \cos \psi + a \frac{\partial f}{\partial y} \sin \psi + \frac{\partial f}{\partial \phi} = 0.$$

The latter equation is valid for all ψ and can therefore be differentiated with respect to ψ . With the help of (2) this gives

$$(4) \quad -a \frac{\partial f}{\partial x} \sin \psi + a \frac{\partial f}{\partial y} \cos \psi = 0$$

and, after a second differentiation with respect to ψ ,

$$(5) \quad a \frac{\partial f}{\partial x} \cos \psi + a \frac{\partial f}{\partial y} \sin \psi = 0.$$

From (4) and (5) it follows that

$$(6) \quad \frac{\partial f}{\partial x} = \frac{\partial f}{\partial y} = 0.$$

According to (3) we must then also have

$$(7) \quad \frac{\partial f}{\partial \phi} = 0.$$

(2), (6) and (7) show that there does not exist a condition $f=0$ dependent on x, y, ϕ, ψ , i.e., that our system is non-holonomic. Proof of G. Hamel, "Elementare Mechanik," 2nd Ed., Leipzig 1922.

II.2. Draw the work diagram of the engine, that is, the L -curve and the W -line with the crank angle from 0 to π as abscissa. Note that the areas enclosed between the L -curve and the abscissa and the W -line and the abscissa must be equal. This yields a relation between L and W . The angles ϕ_2 and ϕ_1 belonging to ω_{\max} and ω_{\min} are the points of intersection of the L - and W -curves in the diagram, $\sin \phi_1 = \sin \phi_2 = \frac{2}{\pi}$, $\phi_2 = \pi - \phi_1$, $\phi_1 = 39^\circ 33' = 0.69$ radians. Determine the difference in the kinetic energy of the flywheel between angles ϕ_2 and ϕ_1 and express it in terms of

I , ω_m and δ . The equation of energy written for the same interval yields the magnitude of the required I in the form

$$I = \frac{W}{\delta \omega_m^2} (\pi \cos \phi_1 - \pi + 2\phi_1) = \frac{0.86}{\delta \omega_m^2} W.$$

With

$$N = \frac{W\omega}{75} HP \quad \text{and} \quad n = \frac{60}{2\pi} \omega \text{ r.p.m.}$$

one obtains

$$I \cong 43,400 \frac{N}{\delta m^2} kg \cdot m \cdot sec^2$$

in the practical system of units.

II.3. For the magnitude of the earth's radius see Problem I.9. For the numerical calculation of the length of the day put $(8\pi)^{\frac{1}{2}} = 5$.

II.4. (a). If one thinks of the beam as held fixed in position, one need only consider the equilibrium of gravity and inertial forces at the pulley in a virtual rotation $\delta\phi$ of the pulley (torque equation). From this one obtains the acceleration \ddot{z} of the weights as a small fraction of g .

(b). Add a virtual rotation of the beam to the foregoing. Here the moments of the inertial forces about the fulcrum of the balance beam enter. One finds that equilibrium does not prevail. The beam is deflected downward on the side of the pan as long as the weight p is falling. In estimating the excess weight the diameter of the pulley may be neglected in comparison with the length of the balance beam. Another procedure using the same approximation is to compare the load on the pan with the load due to weights and inertial forces on the other side of the beam.

II.5. Let the equation of the inclined plane be

$$(1) \quad F(z, x, t) = z - ax - \phi(t) = 0.$$

$a = \tan \alpha$ determines the constant inclination α of the plane to the horizontal; $\phi(t)$ is its intersection with the z -axis which varies with time. Lagrange's equations of the first kind (12.9a) give

$$(2) \quad \ddot{x} = -\lambda a, \quad \ddot{z} = \lambda - g.$$

In order to determine λ , differentiate (1) twice with respect to t ,

$$(3) \quad \ddot{z} - a\ddot{x} = \ddot{\phi}(t).$$

Substitution of (2) in (3) yields λ ; the integration of (2) can now easily be carried out. With initial conditions $\dot{x}=\dot{z}=0$, $x=x_0$, $z=z_0$ at $t=0$ one obtains

$$x = x_0 - \frac{\alpha}{1+\alpha^2} \left(\phi(t) - \phi(0) - \dot{\phi}(0)t + g \frac{t^2}{2} \right),$$

$$z = z_0 + \frac{1}{1+\alpha^2} \left(\phi(t) - \phi(0) - \dot{\phi}(0)t - g\alpha^2 \frac{t^2}{2} \right).$$

From this we have for $\ddot{\phi} = +g$

$$x = x_0 - g \frac{t^2}{2} \sin 2\alpha, \quad z = z_0 + g \frac{t^2}{2} \cos 2\alpha$$

and for $\ddot{\phi} = -g$,

$$x = x_0, \quad z = z_0 - g \frac{t^2}{2},$$

as for a free fall. $\lambda=0$ only under the last assumption; otherwise λ acts as a pressure against the sliding body and hence does work.

The problem can be solved by means of d'Alembert's principle without introducing λ . Since the time is not to be varied (cf. p. 68), we have, from (1), $\delta z = \alpha \delta x$ for the virtual displacements. From d'Alembert's principle it follows that

$$\ddot{x} + (g + \ddot{z})\alpha = 0,$$

which, together with (3), allows one to calculate \ddot{x} and \ddot{z} directly. This example illustrates that d'Alembert's method leads to a solution more directly and simply than do Lagrange's equations; the latter, on the other hand, have the advantage that the forces of constraint are quantitatively determined.

II.6. In § 11, (1), d'Alembert's principle was used to derive the equation of acceleration of a system rotating under the influence of an external torque. We introduced a virtual rotation $\delta\phi$ about the axis of rotation, which we shall here take as our x -axis. Only the tangential inertial forces were relevant, since the normal ones, the centrifugal forces, did no work in the rotation $\delta\phi$.

Here we ask for the forces exerted on bearings A and B in a uniform rotation, or, instead, for their reactions A and B . It is precisely the centrifugal forces which are relevant, whereas the tangential inertial forces drop out in a uniform rotation. If we introduce the virtual translations δy , δz , the virtual work becomes equal to the product of δy and δz by the sum of

the y - and z -components of the centrifugal forces acting on the single mass elements, these forces being

$$dm y \omega^2, \quad dm z \omega^2.$$

An integration yields the inertial components Y and Z of the ordinary swinging motion of the total mass m , which are to be thought of as applied at the center of mass.

Next we introduce virtual rotations $\delta\phi_y$ and $\delta\phi_z$ about the y - and z -axis respectively. The virtual work done in these is given by

$$-\delta\phi_y \int dm x z \omega^2 \quad \text{and} \quad \delta\phi_z \int dm x y \omega^2.$$

They correspond to the torques

$$L_y = -I_{xz} \omega^2 \quad \text{and} \quad L_z = I_{xy} \omega^2.$$

To determine the bearing reactions A and B , fix the origin of coordinate system xyz , say, at the bearing A , designate by l the distance between the two bearings and by η and ζ the coordinates of the mass center along the y - and z -directions. We then obtain the two component equations

$$(1) \quad \begin{aligned} A_y + B_y &= -m\eta\omega^2, \\ A_z + B_z &= -m\zeta\omega^2 \end{aligned}$$

and the two moment equations

$$(2) \quad \begin{aligned} lB_z &= -I_{xz}\omega^2, \\ lB_y &= -I_{xy}\omega^2 \end{aligned}$$

for the determination of the four unknowns A_y , A_z and B_y , B_z .

Clearly these periodically varying reactions in the bearings are undesirable from the engineering standpoint. To avoid them it is not only necessary that the center of mass lie on the axis of rotation $\eta = \zeta = 0$, Eq. (1), but also that the axis of rotation be a principal axis of the mass distribution, $I_{xz} = I_{xy} = 0$, Eq. (2); see, in this connection, Ch. IV, § 22, near Eq. (15a). The fulfillment of this second condition is just as important as that of the first. The fulfillment of both conditions is called the "balancing" of the rotating body.

II.7. Let S be the tension of the string, z the portion of its length that is unwound at any given instant. We have during (a):

$$I\dot{\omega} = Sr, \quad S = m(g - \ddot{z}).$$

\dot{z} and \ddot{z} are positive; because of $\dot{z} = r\omega$,

$$(1) \quad \ddot{z} = r\dot{\omega} = \frac{Sr^2}{I},$$

$$(2) \quad S = \frac{mg}{1 + \frac{mr^2}{I}};$$

during (b):

The rotation ω retains its sense. The torque of the string tension acts against ω . \dot{z} becomes negative and we have

$$(3) \quad \dot{z} = -r\omega, \quad \ddot{z} = -r\dot{\omega} = +\frac{Sr^2}{I},$$

$$(4) \quad S = \frac{mg}{1 + \frac{mr^2}{I}}.$$

In both cases (a) and (b) the string tension is the same, and constant in time; it is smaller than the weight of the rotating body.

In the transition stage between (a) and (b) one perceives a very noticeable pull in the hand which corresponds to the transition from positive momentum $m\dot{z}$ to negative. During this interval S becomes greater than that given by Eq. (2).

II.8. The condition that the particle jump off is, according to (18.7),

$$\lambda = 0 \quad \text{or} \quad R_n = 0$$

so that, from (18.6),

$$(1) \quad mg\frac{z}{l} = -\frac{m}{l}(x\ddot{x} + y\ddot{y} + z\ddot{z}).$$

Now for every path on the sphere

$$x\dot{x} + y\dot{y} + z\dot{z} = 0, \quad \text{i.e.,} \quad x\ddot{x} + y\ddot{y} + z\ddot{z} = -(\dot{x}^2 + \dot{y}^2 + \dot{z}^2) = -v^2,$$

so that, instead of (1), we can write

$$(2) \quad \frac{mgz}{l} = \frac{mv^2}{l}.$$

The right side does not equal the centrifugal force along the path, since the path is not a geodesic in our case. In agreement with Meusnier's theorem of § 40 it is equal to the projection of this centrifugal force on the normal to the spherical surface.

From the equation of energy

$$(3) \quad v^2 = v_0^2 - 2g(z - z_0).$$

Eq. (2) can therefore be rewritten in terms of the initial values v_0, z_0 :

$$(4) \quad 3z = 2z_0 + \frac{v_0^2}{g} = 2(z_0 + h_0),$$

where $h_0 = \frac{1}{2} \frac{v_0^2}{g}$ is the height of free fall corresponding to velocity v_0 .

III.1. For a pendulum hanging almost vertically coordinates x and y are small quantities of the first order; z equals $-l$ to quantities of the second order. For this reason the third Eq. (18.2) gives, to quantities of the second order,

$$(1) \quad \lambda = -\frac{mg}{l}$$

and the first two Eqs. (18.2) define, as in Problem I.13, a harmonic elliptical motion of circular frequency

$$(2) \quad \frac{2\pi}{T} = \left(\frac{g}{l}\right)^{\frac{1}{2}}.$$

For the areal velocity constant of the elliptical motion we have

$$(3) \quad C = \frac{2\pi ab}{T} = \left(\frac{g}{l}\right)^{\frac{1}{2}} ab \rightarrow 0,$$

and for the energy constant (initial state $\theta_0 = \epsilon, \dot{\theta}_0 = 0$)

$$(4) \quad E = T + V = mgl \left(-1 + \frac{\epsilon^2}{2}\right).$$

With $u = \eta - 1$ one has, from (18.11),

$$U = -\frac{4g}{l} \left(\eta - \frac{\epsilon^2}{2}\right) \eta - \frac{C^2}{l^2} = \frac{4g}{l} (\eta_1 - \eta) (\eta - \eta_2),$$

$$\eta_{1,2} = \frac{\epsilon^2}{4} \pm \left(\frac{\epsilon^4}{16} - \frac{C^2}{4gl^2}\right)^{\frac{1}{2}}.$$

From (18.15) we then have

$$(5) \quad 2\pi + \Delta\phi = \frac{C}{4(lg)^{\frac{1}{2}}} \int_{\eta_2}^{\eta_1} \frac{d\eta}{\eta[(\eta_1 - \eta)(\eta - \eta_2)]^{\frac{1}{2}}}.$$

A substitution modelled after Eq. (46.11) transforms the integral of (5) into the known integral

$$\int_0^\pi \frac{dv}{A + B \cos v} = \frac{\pi}{(A^2 - B^2)^{\frac{1}{2}}}, \quad A = \frac{\epsilon^2}{4}, \quad B = \left(\frac{\epsilon^4}{16} - \frac{C^2}{4gl^2}\right)^{\frac{1}{2}}.$$

Thereupon (5) yields $\Delta\phi = 0$, which was to be proved.

III.2. The first assertion of the problem is proved immediately by differentiation of Eq. (19.10) for $|C|$ with respect to ω ; the second assertion is similarly proved by differentiation of $|C|\omega$ with respect to ω .

III.3. Let us designate the proportionality factors of the damping torque and the restoring torque by $2\rho I$ and $\omega_0^2 I$ respectively. One then obtains Eq. (19.9) as the equation of motion of the galvanometer, with the difference that the right member is now a constant C and α replaces x in the notation. Fit the constants a and b of the general solution

$$\alpha = C + e^{-\rho t} (a \cos [(\omega_0^2 - \rho^2)^{1/2} t] + b \sin [(\omega_0^2 - \rho^2)^{1/2} t])$$

to the conditions $\alpha = \dot{\alpha} = 0$ at $t = 0$, and the constant C to the condition $\alpha \rightarrow \alpha_\infty$ as $t \rightarrow \infty$.

In the case (a) one obtains a transient motion with decreasing oscillations, in the case (c), a monotonic transient motion towards the final position. Case (b) should be treated as limiting case of either (a) or (c); in it we arrive at a secular term containing t as a factor.

III.4. In part (a) of the problem d'Alembert's principle (x, y = coordinates of the oscillating mass point, y positive upward) demands

$$(1) \quad \ddot{x} \delta x + (\ddot{y} + g) \delta y = 0.$$

The equation of constraint is

$$(2) \quad (x - \xi)^2 + y^2 = l^2.$$

Its variation (t , and hence also ξ , being held fixed) gives

$$(3) \quad (x - \xi) \delta x + y \delta y = 0.$$

Combination of (1) and (3) results in

$$(4) \quad y \ddot{x} - (x - \xi) (\ddot{y} + g) = 0.$$

Differentiating (2) twice with respect to t yields a second equation for \ddot{x} and \ddot{y} which, together with (4), furnishes the exact differential equation of the problem.

When passing to small vibrations, one must remember that $x - \xi$ is a small quantity of first order so that, according to (2), $y \approx \pm l$ to small quantities of second order. \dot{y} and \ddot{y} are then also small quantities of second order, so that (4) becomes

$$(5) \quad l \ddot{x} + (x - \xi) g = 0.$$

With $x - \xi = u$ one obtains the inhomogeneous pendulum equation

$$(6) \quad \ddot{u} + \frac{g}{l} u = -\ddot{\xi},$$

showing that $-m\ddot{\xi}$ acts as driving force. The integration is performed as on p. 101. The phase relation between the motion of the point of suspension and that of the mass point emphasized in the text of the problem corresponds to Fig. 31. It will be instructive to make an experiment with a string whose lower end carries a weight, and whose upper end is moved horizontally to and fro by the hand. For fast motion of the hand (case above resonance) the out-of-phase motion of the two points can be very clearly observed.

Using the method of Lagrange's equations of the first kind, from Lagrange's equation for y one finds $\lambda = -\frac{g}{l}$ up to small quantities of second order, and from the x -equation one obtains Eq. (5).

In part (b) of the problem Eq. (1) remains valid. Condition (2) becomes

$$(7) \quad x^2 + (y - \eta)^2 = l^2.$$

Its variation yields, instead of (4),

$$(8) \quad (y - \eta)\ddot{x} - x(\ddot{y} + g) = 0.$$

If x is treated as a small quantity of first order, (7) gives to quantities of second order

$$(9) \quad y - \eta = -l, \quad \ddot{y} = \ddot{\eta}.$$

By this, (8) becomes

$$(10) \quad \ddot{x} + \frac{\ddot{\eta} + g}{l} x = 0.$$

The same follows from Lagrange's equations of the first kind, since the y -equation yields the value

$$(11) \quad \lambda = -\frac{\ddot{\eta} + g}{l}$$

if approximation (9) is used, so that the x -equation becomes identical to (10).

If the point of suspension is moved upward with constant acceleration $+g$ it follows that the force of gravity seems doubled; if the point is moved downward with $-g$, it seems to be annulled. This points to an equivalence between gravity and acceleration, which, together with the equality of the gravitational and inertial mass (p. 19), formed the foundation of Einstein's theory of gravitation.

III.5. Equilibrium of the tensions at points C and D (necessary because the wire is weightless!) demands that

$$(3) \quad S_1 \frac{x_1 - x_3}{l_1} = S \frac{x_3}{a} + S \frac{x_3 - x_4}{a}, \quad S_2 \frac{x_3 - x_4}{l_2} = S \frac{x_4}{a} + S \frac{x_4 - x_3}{a},$$

so that, from Eq. (1) of the problem, with $\sigma_1 = \frac{m_1 g}{S} \frac{a}{l_1}$, $\sigma_2 = \frac{m_2 g}{S} \frac{a}{l_2}$,

$$(4) \quad \begin{aligned} \sigma_1 x_1 &= (2 + \sigma_1)x_3 - x_4 \\ \sigma_2 x_2 &= (2 + \sigma_2)x_4 - x_3. \end{aligned}$$

We have presupposed weak coupling, so that σ_1 and σ_2 are small numbers; they can be cancelled in the right members of (4). Solving for x_3 , x_4 then yields

$$(5) \quad \begin{aligned} x_3 &= \frac{2}{3} \sigma_1 x_1 + \frac{1}{3} \sigma_2 x_2 \\ x_4 &= \frac{2}{3} \sigma_2 x_2 + \frac{1}{3} \sigma_1 x_1 \end{aligned}$$

and substitution in (2) gives

$$(6) \quad \begin{aligned} \ddot{x}_1 + \frac{g}{l_1} (1 - \sigma_1) x_1 &= \frac{1}{3} \frac{g}{l_1} (\sigma_2 x_2 - \sigma_1 x_1) \\ \ddot{x}_2 + \frac{g}{l_2} (1 - \sigma_2) x_2 &= \frac{1}{3} \frac{g}{l_2} (\sigma_1 x_1 - \sigma_2 x_2). \end{aligned}$$

These simultaneous differential equations are to be treated just like (20.10). The meaning, for our problem, of the quantities ω_1 , ω_2 , k_1 , k_2 introduced there can be found by comparison with Eq. (6) above.

III.6. The effect of m on M is represented by $k(X - x)$, that of M on m by $k(x - X)$. In the two resulting simultaneous differential equations for X and x put $X = 0$. It will be found that the condition required—that only m take part in the oscillation—is given by the resonance requirement that the circular frequency of the proper oscillation of system (m, k) be equal to the circular frequency ω of the external force.

Such an arrangement is used in engineering practice as an “oscillation quencher.” It may thus be used on a crank shaft with a flywheel rotating with constant angular velocity ω ; there the quencher is a device capable of variable rotation; its purpose is to absorb the oscillations of the crank with which it is coupled. In such a case the angle rotated through takes the place of coordinate x of our problem.

IV.1. Moments of inertia of plane mass distributions are important for the torsion and bending of beams in elasticity theory (Vol. II). Because of $r^2 = x^2 + y^2$ we have

$$I_p = \int r^2 dm = \int x^2 dm + \int y^2 dm = I_x + I_y$$

In problems of elasticity the mass is to be thought of as uniformly distributed with density 1 over the cross section of the beam, so that $dm = dS =$ element of area. For a circular disk of radius a and area $S = \pi a^2$ one then obtains

$$I_p = \int r^2 dS = 2\pi \int_0^a r^3 dr = \frac{1}{2} S a^2 \text{ and hence, } I_x = I_y = \frac{1}{4} S a^2.$$

IV.2. We leave the ratio of the magnitudes of the three principal moments of inertia arbitrary to the very last; we thus embrace, in one and the same calculation, the three cases in which A is the greatest, smallest, and intermediate principal moment of inertia.

IV.3. The impulse Z imparts to the ball (radius a) both a translational and a rotational momentum,

$$(1) \quad Mv = Z \quad \text{and} \quad (2) \quad I\omega = Zh,$$

where h is the height above the center at which the horizontally held cue strikes the ball. The axis of ω is perpendicular to the median plane. The peripheral velocity u at the lowest point lies in the median plane and equals $a\omega$. This is true not only at $t=0$ (time of the impact), but also for $t>0$.

According to (11.12a), $I = \frac{2}{5} Ma^2$, so that, for $t=0$, by Eqs. (2) and (1),

$$(3) \quad \frac{2}{5} Mau = Zh = Mvh.$$

$v=u$ means pure rolling, and from (3) requires $h = \frac{2}{5} a$. Notice that we have counted u positive in the direction opposite to v . For high shots $h > \frac{2}{5} a$ the sliding velocity $u-v$ of the point of contact between ball and cloth is >0 and opposed to v ; friction is therefore directed along v and of magnitude μMg . Its moment about the center, μMga , acts against the rotation ω .

For low shots the friction is directed in the opposite way. In general, we can associate the upper sign with a high shot, the lower sign with a low shot, and write for $t>0$,

$$(4) \quad \dot{v} = \pm \mu g,$$

$$(5) \quad \dot{u} = \mp \frac{5}{2} \mu g.$$

Discussion by means of graph: draw v and u as ordinates against t as abscissa; both are represented by straight lines which intersect in the case of high shots as well as that of low shots. At the point of intersection

$u=v$ pure rolling takes place. From then on the graphs of u and v run on in coincidence along a horizontal straight line. The abscissa of the intersection is

$$(6) \quad \tau = \pm \frac{5h-2a}{7a} \frac{Z}{\mu g M}.$$

Note that for a low shot the first numerator is negative since h lies between $-a$ and $\frac{2}{5}a$; the negative sign of the right member of (6) is therefore only a formal one. The increase or decrease of velocity for high and low shots respectively is given by $\Delta v = \pm \mu g \tau$. The final velocity of pure rolling becomes

$$v + \Delta v = \frac{5}{7} \frac{h+a}{a} \frac{Z}{M}$$

i.e., proportional to the height $h+a$ of the point of impact above the cloth.

Theory of the follow shot. The ball struck high meets a second ball in a central collision during the time interval $t < \tau$ in which $u > v$. Let u_0 and v_0 be the values of u and v at the moment of impact. v_0 is transferred to the second ball. According to (4), the first ball is then accelerated from $v=0$. From (5), its u decreases from u_0 on down. A new graph shows that there is an intersection at which pure rolling begins to take place. Abscissa of the point of intersection and velocity of pure rolling are, respectively,

$$(7) \quad \tau_1 = \frac{2}{7} \frac{u_0}{\mu g}, \quad v_1 = \mu g \tau_1 = \frac{2}{7} u_0.$$

Theory of the draw shot. Again the driven ball meets a second one in the interval $t < \tau$, where now, however, $u < v$. For an extremely low shot, which we shall presuppose, u is, as a matter of fact, negative, that is, has the same direction as v . Let u_0 and v_0 be the values of u and v just before impact. v_0 is again transmitted to the second ball. From (4), the first ball is accelerated from $v=0$ in the negative sense: it runs backward. Eq. (5) tells us that u increases from its negative initial value u_0 toward positive values, i.e., its absolute value decreases. The two straight lines of v and u intersect (new diagram); the abscissa of the point of intersection and the final velocity of pure rolling now become

$$(8) \quad \tau_2 = \frac{2}{7} \frac{|u_0|}{\mu g}, \quad |v_2| = \frac{2}{7} |u_0|.$$

IV.4. The cue is no longer held horizontally as in IV.3, but forms an angle with the horizontal plane; evidently the cue must hit the ball at a point of the upper hemisphere, as in our earlier "high shots." Put

the x -axis along the horizontal component of the impulse and the z -axis along the vertical. The components of the impulse Z become $(Z_x, 0, Z_z)$ and the components of the impulsive torque N referred to the center of the ball (which is also the origin of the xyz -system),

$$N_x = yZ_z, \quad N_y = zZ_x - xZ_z, \quad N_z = -yZ_x.$$

Here x, y and z are the coordinates of the point of impact of cue and ball. From the N_x, N_y we obtain the angular velocities

$$\omega_x = \frac{5}{2} \frac{N_x}{Ma^2}, \quad \omega_y = \frac{5}{2} \frac{N_y}{Ma^2}.$$

The associated peripheral velocities at the lowest point P of the ball are

$$(1) \quad u_x = -a\omega_y, \quad u_y = +a\omega_x.$$

N_z and ω_z do not interest us; they do not generate any sliding at P , but merely a "boring" friction to be neglected. Let the sliding motion at the cloth have components

$$(2) \quad v_x - u_x = -\rho \cos \alpha, \quad v_y - u_y = -\rho \sin \alpha.$$

It creates a friction R making an angle $\pi + \alpha$ with the x -axis and having magnitude $\mu g M$. Its influence on the translation and rotation for $t > 0$ is determined by

$$\begin{aligned} M\dot{v}_x &= R_x, & M\dot{v}_y &= R_y, \\ I\dot{\omega}_x &= aR_y, & I\dot{\omega}_y &= -aR_x. \end{aligned}$$

It follows that

$$\dot{v}_x = -\mu g \cos \alpha, \quad \dot{v}_y = -\mu g \sin \alpha$$

and, by virtue of (1) and (2),

$$(4) \quad \dot{u}_y = -\frac{5}{2}\mu g \sin \alpha, \quad \dot{u}_x = -\frac{5}{2}\mu g \cos \alpha;$$

$$(5) \quad \dot{v}_x - \dot{u}_x = -\frac{d}{dt}(\rho \cos \alpha) = -\frac{7}{2}\mu g \cos \alpha,$$

$$\dot{v}_y - \dot{u}_y = -\frac{d}{dt}(\rho \sin \alpha) = -\frac{7}{2}\mu g \sin \alpha.$$

Solution for $\dot{\alpha}$ and $\dot{\rho}$ from the last two members of Eqs. (5) gives

1. $\dot{\alpha} = 0$. The friction has constant direction; since it also has constant magnitude, the path of point P in the horizontal plane becomes a parabola.

The axis of the parabola is parallel to the initial direction α of the sliding motion, which can be gathered from the components of Z and N .

2. $\dot{\rho} = -\frac{7}{2}\mu g$, $\rho = \rho_0 - \frac{7}{2}\mu g t$, $\rho = 0$ for $t = \tau = \frac{2}{7} \frac{\rho_0}{\mu g}$. ρ_0 is the initial magnitude of sliding velocity which can likewise be determined from Z and N . For $t > \tau$ the sliding and friction are permanently 0. The ball pursues a straight course tangent to the parabola.

V.1. Let ϕ be the instantaneous angle by which the rotating plane has turned with respect to the fixed plane. We put

$$(1) \quad x + iy = (\xi + i\eta)e^{i\phi}.$$

Two differentiations with respect to t give, with $\dot{\phi} = \omega$,

$$(2) \quad \ddot{x} + i\ddot{y} = \{\ddot{\xi} + i\ddot{\eta} + 2i\omega(\dot{\xi} + i\dot{\eta}) + i\dot{\omega}(\xi + i\eta) - \omega^2(\xi + i\eta)\}e^{i\phi}.$$

$\xi + i\eta$ is the (complex) vector \mathbf{r} as observed from the rotating plane, $\dot{\xi} + i\dot{\eta} = \dot{\mathbf{r}}$ its velocity observed from the same plane, etc. Since $i(\dot{\xi} + i\dot{\eta}) = (\dot{\xi} + i\dot{\eta})e^{i\frac{\pi}{2}}$ is a vector perpendicular to the latter, we can write,

$$(3) \quad 2i\omega(\dot{\xi} + i\dot{\eta}) = 2\omega \mathbf{X} \dot{\mathbf{r}}, \quad i\dot{\omega}(\xi + i\eta) = \dot{\omega} \mathbf{X} \mathbf{r},$$

where ω is of course directed along the normal to the complex plane. As on p. 165, let us call \mathbf{w} the velocity $\dot{x} + i\dot{y}$, as observed from the fixed plane; we shall, however, retain the designation of superscript dots for the time derivatives referred to the rotating plane, as written in Eq. (3) above. Eq. (2) then transforms to the following equation analogous to (29.4):

$$(4) \quad \dot{\mathbf{w}} = \{\ddot{\mathbf{r}} + 2\omega \mathbf{X} \dot{\mathbf{r}} + \dot{\omega} \mathbf{X} \mathbf{r} - \omega^2 \mathbf{r}\} e^{i\phi}.$$

If $\mathbf{F} = F_x + iF_y$ is the force referred to the fixed plane, $\Phi = F_\xi + iF_\eta$ that referred to the rotating one, we have, from (1), $\mathbf{F} = \Phi e^{i\phi}$, so that

$$(5) \quad \Phi = \mathbf{F} e^{-i\phi}.$$

In the light of (4) and (5) we then have from $m\dot{\mathbf{w}} = \mathbf{F}$ that

$$(6) \quad m \{\ddot{\mathbf{r}} + 2\omega \mathbf{X} \dot{\mathbf{r}} + \dot{\omega} \mathbf{X} \mathbf{r} - \omega^2 \mathbf{r}\} = \Phi.$$

With this we have determined the additional forces required in the problem. In particular, one identifies the second term on the left with the Coriolis force.

We have intentionally treated this problem in complex notation in order to emphasize that two-dimensional vectors are best represented by complex variables.

V.2. Let us choose the plane in which the straight line rotates as the xy -plane; x -axis horizontal, y -axis vertically upward. Let $\phi = \omega t$ be the angle of the straight line with the x -axis. One can reduce the problem to the foregoing one by associating with the rotating straight line a vertical $\xi\eta$ -plane in which the line is fixed. This $\xi\eta$ -plane must then rotate in the xy -plane with constant angular velocity ω . It is convenient to put the ξ -axis along the rotating straight line. In order to keep the mass point on the ξ -axis one must exert on it a force of constraint in the η -direction. Our external force Φ is therefore the sum of the force of constraint, which we shall call mb , and the force of gravity mg . From Eq. (5) of the foregoing problem the contribution of the latter to Φ is $-img e^{-i\phi}$. Summing, we then have

$$\Phi = \Phi_{\xi} + i\Phi_{\eta} = -mg \sin \omega t - img \cos \omega t + imb.$$

In Eq. (6) of the previous problem one can put $r = \xi$ and, by virtue of (3) *ibid.*, $2\omega \times \dot{r} = 2i\omega \dot{\xi}$; further one must put $\dot{\omega} = 0$. One obtains

$$(1) \quad \ddot{\xi} + 2i\omega \dot{\xi} - \omega^2 \xi = -mg \sin \omega t + i(b - g \cos \omega t).$$

Its real part gives

$$(2) \quad \ddot{\xi} - \omega^2 \xi = -g \sin \omega t,$$

a differential equation with solution

$$(3) \quad r = A \cosh \omega t + B \sinh \omega t + \frac{g}{2\omega^2} \sin \omega t.$$

If one puts the imaginary part of (1) equal to zero, one obtains the relation between force of constraint, gravity and Coriolis force given in the problem, *viz.*,

$$(4) \quad b = g \cos \omega t + 2\omega \dot{\xi}.$$

V.3. (a) Let $x_0 + iy_0$ determine the position of O in the xy -plane. We then have

$$(1) \quad \begin{aligned} \dot{x}_0 + i\dot{y}_0 &= (u + iv)e^{i\phi} \\ \ddot{x}_0 + i\ddot{y}_0 &= \{u + iv + i\omega(u + iv)\}e^{i\phi}. \end{aligned}$$

Let $x + iy$ determine the position of G in the xy -plane. We have

$$(1) \quad \begin{aligned} x + iy &= x_0 + iy_0 + ae^{i\phi} \\ \dot{x} + i\dot{y} &= (u + iv + i\omega a)e^{i\phi} \end{aligned}$$

$$(2) \quad \ddot{x} + i\ddot{y} = [u + iv + i\omega a + i\omega(u + iv) - \omega^2 a] e^{i\phi}.$$

In the xy -plane there corresponds to the external force R the complex quantity

$$(2') \quad F = R i e^{i\phi}.$$

From (2) and (2') the Second Law, $\ddot{x} + i\ddot{y} = \frac{F}{M}$ leads to

$$\ddot{u} + i\ddot{v} + i\dot{\omega}a + i\omega(u + iv) - \omega^2a = i\frac{R}{M}$$

or, resolved into components,

$$(3) \quad \ddot{u} - \omega v - \omega^2a = 0,$$

$$(4) \quad \ddot{v} + \dot{\omega}a + \omega u = \frac{R}{M}.$$

In addition we have, from the law of angular momentum,

$$(5) \quad I\dot{\omega} = -Ra.$$

(b) Conditions $v=0$, $\dot{v}=0$ simplify (3) and (4) to

$$(3') \quad \ddot{u} - \omega^2a = 0, \quad (4') \quad \dot{\omega}a + \omega u = \frac{R}{M}.$$

Elimination of R from (4') and (5) gives

$$(6) \quad \dot{\omega}a \left(1 + \frac{I}{Ma^2}\right) + \omega u = 0.$$

Now put $I = Mb^2$ (b =radius of gyration) and

$$(7) \quad k^2 = 1 + \frac{b^2}{a^2} > 1,$$

which transforms (6) into

$$(6') \quad k^2 \dot{\omega}a + \omega u = 0.$$

After integration of the simultaneous Eqs. (3') and (6') R is determined by (4') or (5).

(c) Elimination of u from (3') and (6') yields

$$(8) \quad k^2 \frac{d}{dt} \frac{\dot{\omega}}{\omega} = -\omega^2.$$

After multiplication by $\frac{\dot{\omega}}{\omega}$ this equation becomes integrable and furnishes

$$(9) \quad k^2 \left(\frac{\dot{\omega}}{\omega}\right)^2 = k^2 c^2 - \omega^2, \quad (9') \quad k\dot{\omega} = \omega(k^2 c^2 - \omega^2)^{\frac{1}{2}},$$

where c is a constant of integration. One gets rid of the square root by putting

$$(10) \quad \omega = kc \cos \psi.$$

With suitable choice of the sign of the square root, (9') becomes

$$(10') \quad \dot{\psi} = c \cos \psi$$

or

$$c dt = \frac{d\psi}{\cos \psi}, \quad (11) \quad ct = \frac{1}{2} \ln \frac{1 + \sin \psi}{1 - \sin \psi}.$$

We have thus determined ψ as a function of t . We can now express all quantities in terms of ψ ; ω from (10), u and R from (6') and (4'):

$$(12) \quad u = ak^2 c \sin \psi, \quad (12') \quad R = \frac{M}{2} ak(k^2 - 1)c^2 \sin 2\psi.$$

This completes the integration.

Because of $\omega = \dot{\phi}$, comparison of (10) and (10') finally yields the relation $\dot{\psi} = \frac{\dot{\phi}}{k}$. Our auxiliary angle ψ is hence proportional to the angle of rotation ϕ ,

$$(13) \quad \psi = \frac{\phi}{k},$$

since the constant of integration can be made zero by suitable choice of the arbitrary direction of the x -axis.

(d) From (1'), for $v=0$,

$$(14) \quad \begin{aligned} |\dot{x} + i\dot{y}|^2 &= \dot{x}^2 + \dot{y}^2 = u^2 + \omega^2 a^2, \\ T &= \frac{M}{2}(\dot{x}^2 + \dot{y}^2) + \frac{I}{2}\omega^2 = \frac{M}{2}(u^2 + \omega^2 a^2) + \frac{M}{2}(k^2 - 1)a^2 \omega^2 \\ &= \frac{M}{2}(u^2 + k^2 a^2 \omega^2). \end{aligned}$$

From (10) and (12) this equals

$$(15) \quad T = \frac{M}{2} a^2 k^4 c^2 (\sin^2 \psi + \cos^2 \psi) = \text{Const.}$$

(e) From (1) and (12)

$$\dot{x}_0 = ak^2 c \sin \psi \cos \phi, \quad \dot{y}_0 = ak^2 c \sin \psi \sin \phi,$$

so that, by virtue of (10') and (13),

$$(16) \quad \frac{dx_0}{d\phi} = ak \tan \psi \cos \phi, \quad \frac{dy_0}{d\phi} = ak \tan \psi \sin \phi.$$

Eq. (11) tells us that

$$\text{for } \psi = 0, \quad t = 0$$

$$\text{for } \psi = \pm \frac{\pi}{2}, \quad t = \pm \infty.$$

The whole trajectory takes place between $-\frac{\pi}{2} < \psi < +\frac{\pi}{2}$, $-k\frac{\pi}{2} < \phi < +k\frac{\pi}{2}$.

At $t=0$ a cusp occurs; for, according to (16) with $\psi=0$, $\phi=0$,

$$\frac{dx_0}{d\phi} = \frac{dy_0}{d\phi} = \frac{d^2y_0}{d\phi^2} = 0; \text{ on the other hand, } \frac{d^2x_0}{d\phi^2} \text{ and } \frac{d^3y_0}{d\phi^3} \neq 0;$$

the cusp has tangents parallel to the x -axis on both of its branches.

For $t=\pm\infty$ the path becomes asymptotic, for ϕ becomes stationary: from (16), quite generally,

$$\frac{dx_0}{d\phi} = \frac{dy_0}{d\phi} = \pm\infty.$$

In addition (16) yields

$$\frac{dy_0}{dx_0} = \tan \phi = \pm \tan k\frac{\pi}{2},$$

so that the asymptotes are situated symmetrically with respect to the x -axis, with angles $\pm k\frac{\pi}{2}$ as shown by Fig. 57 of p. 252 for $k=1, \frac{3}{2}, 2, 3$.

VI.1. With z taken positive in the sense of fall, i.e. downward, $V = -mgz$. Initial position $z=0$ for $t=0$ lies above the final position $z=z_1$ at $t=t_1$.

(a) For $z=\frac{1}{2}gt^2$ we obtain

$$\int L dt = \int_0^{t_1} \left[\frac{m}{2} (gt)^2 + mg \cdot \frac{g}{2} t^2 \right] dt = \frac{1}{8} mg^2 t_1^3.$$

(b) For $z=ct$ we must choose c in such a way that for $t=t_1$

$$z=z_1 = g\frac{t_1^2}{2}; \text{ we therefore have } c = \frac{gt_1}{2}.$$

With this value we find

$$\int L dt = \int_0^{t_1} \left[\frac{m}{2} \left(\frac{gt_1}{2} \right)^2 + mg \frac{gt_1}{2} t \right] dt = \frac{3}{8} mg^2 t_1^3.$$

For $z=at^3$, $a=\frac{1}{2}\frac{g}{t_1}$, on the other hand,

$$\int L dt = \int_0^{t_1} \left[\frac{m}{2} \left(\frac{3g}{2t_1} \right)^2 t^4 + mg \frac{g}{2t_1} t^3 \right] dt = \frac{7}{20} mg^2 t_1^3.$$

Whereas in Hamilton's principle we compare paths differing only by infinitesimal amounts, here the trajectories of (b) in the phase space of the q, \dot{q} (here z, \dot{z}) differ by finite amounts from the real motion (a). Nevertheless even now the value of Hamilton's integral is smaller for (a) than for (b), as

$$\frac{1}{8} < \frac{3}{8} \quad \text{and} \quad \frac{1}{8} < \frac{7}{20}.$$

This is true here even for arbitrary lengths of path, which need not be the case as a general rule (cf. p. 208).

VI.2. As in Problem V.1, let ξ and η be the coordinates fixed in the rotating plane; let $\mathbf{u}=(\dot{\xi}, \dot{\eta})$ be the velocity measured with respect to this plane. The velocity relative to the fixed plane is then

$$\mathbf{w}=\mathbf{u}+\mathbf{v}, \quad \mathbf{v}=\boldsymbol{\omega} \times \mathbf{r}$$

[cf., for instance, the first line of the table of p. 139]. Resolution into components gives

$$w_{\xi}=\dot{\xi}-\omega\eta, \quad w_{\eta}=\dot{\eta}+\omega\xi,$$

$$|\mathbf{w}|^2=\dot{\xi}^2+\dot{\eta}^2+2\omega(\xi\dot{\eta}-\eta\dot{\xi})+\omega^2(\xi^2+\eta^2).$$

From this it follows, with $T=\frac{1}{2}m|\mathbf{w}|^2$, that

$$\frac{d}{dt}\frac{\partial T}{\partial \dot{\xi}}=m\frac{d}{dt}(\dot{\xi}-\omega\eta)=m(\ddot{\xi}-\omega\dot{\eta}-\dot{\omega}\eta)$$

$$\frac{d}{dt}\frac{\partial T}{\partial \dot{\eta}}=m\frac{d}{dt}(\dot{\eta}+\omega\xi)=m(\ddot{\eta}+\omega\dot{\xi}+\dot{\omega}\xi)$$

$$\frac{\partial T}{\partial \xi}=m(\omega\dot{\eta}+\omega^2\xi), \quad \frac{\partial T}{\partial \eta}=m(-\omega\dot{\xi}+\omega^2\eta).$$

Let Φ_{ξ} , Φ_{η} be the components of the external force \mathbf{F} with respect to the moving axes ξ , η ; we then obtain Lagrange's equations

$$m(\ddot{\xi}-2\omega\dot{\eta}-\dot{\omega}\eta-\omega^2\xi)=\Phi_{\xi},$$

$$m(\ddot{\eta}+2\omega\dot{\xi}+\dot{\omega}\xi-\omega^2\eta)=\Phi_{\eta}.$$

This is in exact agreement with Eq. (6) of Problem V.1, provided we resolve the latter into its components.

In the guiding on a rotating straight rod treated in Problem V.2 we have

$$v^2=\frac{dr^2+r^2d\phi^2}{dt^2}=\dot{r}^2+r^2\omega^2, \quad L=\frac{m}{2}(\dot{r}^2+r^2\omega^2)-mgr\sin\omega t;$$

$$\frac{d}{dt}\frac{\partial L}{\partial \dot{r}}=m\dot{r}, \quad \frac{\partial L}{\partial r}=mr\omega^2-mg\sin\omega t.$$

The Lagrange equation resulting from this is identical to Eq. (2) of V.2. It immediately leads to the solution (3) of that problem. With the present method we need not speak of Coriolis and similar forces, though, on the other hand, we do not learn anything about the force of constraint.

VI.3. The terms left out in Eq. (4) of the problem and indicated by . . . are

$$\left(1 + \frac{\xi}{R}\right) \dot{\eta} \quad \text{and} \quad -\frac{\eta}{R} \left(1 + \frac{\xi}{R}\right) \frac{\cos \theta}{\sin \theta} \dot{\xi}.$$

After multiplication by the factor of $\{\}$ they would give, on differentiation with respect to t , terms of second or higher order in the ξ , η , ζ or their derivatives. In connection with the differentiated equations (5) and (6) we should remark that terms of second order such as $\zeta \ddot{\xi}$, $\dot{\zeta} \dot{\xi}$, etc., have, of course, been omitted. It is worth noting that through this omission the radius R of the earth disappears from the results. In the complete Eq. (6) we would actually obtain, in addition to the term written down, a term in ω^2 , viz.,

$$R \sin \theta \cos \theta \omega^2,$$

which evidently represents the ξ -component of the ordinary centrifugal force; the corresponding ζ -component would occur in $\frac{\partial T}{\partial \zeta}$. These terms must, however, be omitted because they have already been included in the effective gravitational acceleration g , Eq. (30.1).

In the case of Foucault's pendulum one should evidently use not the ordinary form (34.6) of Lagrange's equations, but the mixed type (34.11), coupled with the equation of constraint (31.1).

Incidentally, note that due to the definition of η and ψ_0 in (1) and (2) our problem belongs to the class of problems dependent on the time discussed on p. 217.

VI.4. The center of mass describes a "curtate" cycloid in a plane normal to the axis of the cylinder. Its parametric equations in terms of the angle of rotation ϕ are obtained from Eq. (17.1) for a "common" cycloid by replacing a of Eq. (17.1) in part by s ,

$$\begin{aligned} \xi &= a\phi - s \sin \phi, & \dot{\xi} &= (a - s \cos \phi) \dot{\phi}, \\ \eta &= a - s \cos \phi, & \dot{\eta} &= s \sin \phi \dot{\phi}. \end{aligned}$$

(a) If we take the mass center as reference point O , we have

$$\begin{aligned} T_{\text{transl}} &= \frac{m}{2} (\dot{\xi}^2 + \dot{\eta}^2) = \frac{m}{2} (a^2 + s^2 - 2as \cos \phi) \dot{\phi}^2, \\ T_{\text{rot}} &= \frac{I}{2} \dot{\phi}^2, \quad T_m = 0, \quad V = mg\eta = mg(a - s \cos \phi). \end{aligned}$$

Notice that $\omega = \dot{\phi}$ is originally the angular velocity of the cylinder about its axis of symmetry, but that, according to (23.8), it is also the angular

velocity about a parallel axis through the mass center. Putting $I = mb^2$ (b = radius of gyration) and $c^2 = a^2 + s^2 + b^2$, we have

$$(1) \quad L = T_{\text{transl}} + T_{\text{rot}} - V = \frac{m}{2}(c^2 - 2as\cos\phi)\dot{\phi}^2 - mg(a - s\cos\phi)$$

$$\frac{1}{m} \frac{d}{dt} \frac{\partial L}{\partial \dot{\phi}} = (c^2 - 2as\cos\phi)\ddot{\phi} + 2as\sin\phi\dot{\phi}$$

$$\frac{1}{m} \frac{\partial L}{\partial \phi} = as\sin\phi\dot{\phi}^2 - gs\sin\phi.$$

Hence the equation of motion is

$$(2) \quad (c^2 - 2as\cos\phi)\ddot{\phi} + as\sin\phi\dot{\phi}^2 + gs\sin\phi = 0.$$

(b) If we choose the center of the cross section through the mass center as reference point O , the latter moves horizontally with velocity $a\dot{\phi}$; with $I' = I + ms^2$ [cf. (16.8)] we have

$$T_{\text{transl}} = \frac{m}{2}a^2\dot{\phi}^2, \quad T_{\text{rot}} = \frac{I'}{2}\dot{\phi}^2, \quad V \text{ as above,}$$

but now T_m is not 0; from Eq. (22.11) it is given by

$$T_m = -ma\dot{\phi}^2s\cos\phi.$$

As a result

$$(3) \quad L = T_{\text{transl}} + T_{\text{rot}} + T_m - V = \frac{m}{2}(c^2 - 2as\cos\phi)\dot{\phi}^2 - mg(a - s\cos\phi),$$

which is in agreement with (1), so that we obtain, once more, the equation of motion (2). For small oscillations about $\phi = 0$ it yields

$$\ddot{\phi} + \frac{g}{l_1}\phi = 0, \quad l_1 = \frac{c^2 - 2as}{g} = \frac{(a-s)^2 + b^2}{g} \dots : \text{stability;}$$

for small oscillations about $\phi = \pi$, on the other hand, with $\psi = \pi + \phi$,

$$\ddot{\psi} - \frac{g}{l_2}\psi = 0, \quad l_2 = \frac{c^2 + 2as}{g} = \frac{(a+s)^2 + b^2}{g} \dots : \text{instability.}$$

VI.5. 1. *Relations between the angular velocities.* The derivation of these relations is simplest if one remembers that at the points at which the bevel gears (ω) are in mesh with gear (ω_1) on the one hand and gear (ω_2) on the other, the peripheral velocities must, at any instant, be equal. Gears (ω) rotate about axle A with angular velocity ω ; in addition, this axle rotates together with (ω) about the common geometric axis of (Ω), (ω_1) and (ω_2) with angular velocity Ω . If r , r_1 and r_2 are the mean radii of bevel gears (ω), (ω_1), (ω_2), we must have at point of contact (ω , ω_1)

$$r\omega + r_1\Omega = r_1\omega_1$$

and at point of contact (ω , ω_2)

$$-r\omega + r_2\Omega = r_2\omega_2.$$

With $r_1=r_2$ we obtain from this the relations

$$(1) \quad \begin{aligned} 2\Omega &= \omega_1 + \omega_2 \\ 2\omega &= \frac{r_1}{r}(\omega_1 - \omega_2). \end{aligned}$$

Of course these relations can also be derived by introducing virtual rotations.

2. *Relations between the torques.* The virtual work of L must always equal the sum of the virtual work of L_1 and L_2 , i.e.,

$$L\Omega\delta t = L_1\omega_1\delta t + L_2\omega_2\delta t.$$

We now replace Ω in terms of ω_1 and ω_2 by means of (1) to arrive at

$$\left(\frac{L}{2} - L_1\right)\omega_1 + \left(\frac{L}{2} - L_2\right)\omega_2 = 0.$$

This is possible for arbitrary ω_1 , ω_2 only if

$$(2) \quad \frac{1}{2}L = L_1 = L_2.$$

It is seen that the driving torque of the engine is transferred in equal amounts to each rear wheel at all times, no matter what the values of angular velocities ω_1 and ω_2 .

3. *Equation of motion of the system.* Here it will be found simplest to use Lagrange's equations of the second kind. We have

$$T = \frac{1}{2}(I_1\omega_1^2 + I_2\omega_2^2 + I\omega^2 + I'\Omega^2).$$

We replace ω and Ω by their expressions in terms of ω_1 and ω_2 and introduce abbreviations

$$\begin{aligned} L_{11} &= I_1 + \frac{I'}{4} + \frac{I r_1^2}{4r^2}, \\ L_{22} &= I_2 + \frac{I'}{4} + \frac{I r_2^2}{4r^2}, \\ L_{12} &= L_{21} = \frac{I'}{4} - \frac{I r_1^2}{4r^2}. \end{aligned}$$

Lagrangian's equations then become

$$(3) \quad \begin{aligned} \frac{d}{dt}(L_{11}\omega_1 + L_{12}\omega_2) &= \frac{L}{2} - W_1, \\ \frac{d}{dt}(L_{21}\omega_1 + L_{22}\omega_2) &= \frac{L}{2} - W_2. \end{aligned}$$

W_1 and W_2 are two resisting torques acting at the two rear wheels; they have their origin in the static friction at the ground and may, if one wishes, include the other resistances (air, etc.).

If L , W_1 and W_2 are given as functions of the time, one can calculate the parentheses in the left members of (3) as time integrals of the right members, so that ω_1 and ω_2 become known functions of the time.

Averaged over the time, the right members of (3) are equal to zero, so that ω_1 and ω_2 are constant. If, however, the resistance acting on one wheel is decreased, which happens, for instance, if the wheel jumps off a bump in the road and momentarily turns in the air ($W=0$), this wheel is accelerated, whereas the other is decelerated.

4. *Analogy to electrodynamics.* Eqs. (3) are so written that they remind one of the interaction of two inductively coupled currents (see the remarks on p. 225 concerning Boltzmann). If we identify the L_{ij} with the coefficients of induction of the two circuits, ω_1 and ω_2 with the currents flowing in them, the left members of (3) are the electrodynamic induction effects. $\frac{1}{2}L$ corresponds to the "impressed EMF" acting in the circuits, and

$$T = \frac{1}{2} L_{11} \omega_1^2 + L_{12} \omega_1 \omega_2 + \frac{1}{2} L_{22} \omega_2^2$$

is the total magnetic field energy. According to p. 197, one calls cyclic systems those whose Lagrangian contains only the derivatives of the coordinates with respect to time (here $\omega_1 = \dot{\phi}_1$, $\omega_2 = \dot{\phi}_2$). They therefore constitute the mechanical analogue of stationary electric currents. Both the differential mechanism and the symmetrical top are doubly cyclic systems.

PREFACE*

It is due in part to the encouragement of former students of mine that I have decided to publish my general course of lectures on theoretical physics which I gave regularly during thirty-two years at the University of Munich.

They were of an introductory nature, attended not only by the physics majors of the University and the Polytechnic Institute, but also by the many candidates for degrees in the teaching of mathematics and physics—usually in their fourth to eighth semesters—as well as by astronomers and some physical chemists. Classes were held four times a week and supplemented by a two-hour problem period. Special courses in modern physics which were given concurrently have not been included in this series of books; their subject matter has found its way into my papers and treatises. While it is true that quantum mechanics always hovers in the background, reference being made to it now and then, the actual substance of these lectures is classical physics.

The order of subjects, which is retained in their publication, was

1. Mechanics
2. Mechanics of Deformable Media
3. Electrodynamics
4. Optics
5. Thermodynamics and Statistical Mechanics
6. Partial Differential Equations in Physics

The lectures on mechanics were given in alternate semesters by myself and by my colleagues in mathematics. Concurrent courses in hydrodynamics, electrodynamics and thermodynamics were taught by younger members of the faculty. Vector analysis was given in a separate course so that its systematic development could be omitted from my lectures.

Here, as in my classes, I shall not detain myself with the mathematical

* From the forewords to Vol. I and Vol. II, first and second edition.

foundations, but proceed as rapidly as possible to the physical problems themselves. My aim is to give the reader a vivid picture of the vast and varied material that comes within the scope of theory when a reasonably elevated vantage-point is chosen. With this purpose in mind I shall not be too concerned if I have left some gaps in the systematic justification and axiomatic structure of the work. At any rate, I have avoided frightening the student with drawn-out investigations of a mathematical or logical nature and distracting his attention from that which is physically interesting. I think that this attitude has proved its worth in my lectures; it has therefore been retained in the printed text. And when Planck's lectures are impeccable in their systematic organization, then I may perhaps claim for my own lectures a greater variety of subject matter and a more flexible handling of the mathematical apparatus. However, I gladly refer the reader to the more complete and often more thorough treatment of Planck, especially for thermodynamics and statistical mechanics.

The problems collected at the end of each volume should be considered as supplements to the text. They were presented by the students during the problem periods after they had worked them out and handed them in in writing. Elementary numerical calculations, such as are found in great number in textbooks and collections of exercises, have, in general, not been included. The problems are numbered by chapter. Sections are numbered through in each volume, and equations in each section. Within each volume references to earlier equations can thus be made by merely giving the numbers of section and equation.

In this second volume a fairly complete development of certain mathematical methods had to be given. These methods are often taken up in a separate introductory course on theoretical physics; their incorporation in Vol. II accounts for its larger size. But the actual subject of this volume is the mechanics of systems with an infinite number of degrees of freedom. The place of ordinary differential equations (governing the mechanics of systems with a finite number of degrees of freedom) is here taken by partial differential equations, the place of vector algebra by vector analysis, which is briefly summarized in Chap. 1. Besides, it was necessary to develop the fundamentals of tensor analysis, being an indispensable tool in the theory of elastic solids and viscous fluids. This has been done for Cartesian coordinates and to some extent also for orthogonal curvilinear coordinates.

Some points may be mentioned here in which this presentation seems to be more complete than the one generally found in textbooks on the same level: In Chap. I.2 it is proved that the curl is an axial vector (or antisymmetric tensor). Following O. Reynolds we consider in II.10 *two* laws of similitude and *two* corresponding invariants, viz. a dimensionless

number S characterizing the pressure dependence in addition to the usual Reynolds number. In III.15 we discuss the quasi-elastic body (gyroscopic ether); its logical place is among the continuous media that are compatible with the fundamental theorem of kinematics in I.1. Rather than explain Maxwell's equations by a mechanical model, we want to show in this discussion the fundamental difference between electrodynamics and mechanics. In Chap. V, Sections 27 and 28 deal with the somewhat involved problems of circular waves and ship waves. Complete calculations are supplied using the method of stationary phase which is a simplified version of the method of steepest descent. In the plate and jet problems of Chap. VI the dimensions of plate and of orifice etc. are carried as parameters throughout the entire calculation. This form of analysis has perhaps a stronger physical appeal than the usual one which employs dimensionless quantities. Kármán's vortex street (32) is extended according to Maue to include the unsymmetrical case in which the flow is not parallel to the street. The hydrodynamic theory of journal bearings is briefly dealt with in VII.36. Riemann's theory of shock waves is discussed in 37 with a particular view to the results that Bechert obtained in certain elementary integrable cases. Sec. 38 is a report on the history and present situation of the difficult turbulence problem and includes also Burger's mathematical model of turbulence. In VIII.43 one finds, in the problem of the helical spring, an example of combined bending and torsion. In 44 the boundary conditions for an oscillating parallelepiped are discussed, and the foundations laid for the quantum-theoretical thermodynamics of the solid body.

It is obvious that not all the topics found in this volume could have been touched upon in the brief period of one term; several of the subjects mentioned before have in fact been added for the print.

The *second edition* of Vol. II has been supplemented by a representation of general tensor calculus limited to three dimensions and orthogonal line elements. Tensor calculus does not hold an advantage over the simpler vector analytic formulas for the cases considered here (cf. App. IV), but, because of its importance in the general theory of relativity, it cannot be entirely omitted if a fairly complete exposition of the mathematical methods of theoretical physics is the goal.

The discussion of the turbulence problem, which already presented great difficulties in the first edition, had to be revised on the basis of so-far unpublished work by C. F. von Weizsäcker and W. Heisenberg. My opinion of long standing that turbulence would finally be accounted for by integration of the Navier-Stokes equations in their complete, non-linear, form, proved wrong in the special case of "isotropic turbulence" investigated by the two authors; here, as in the kinetic theory of gases, statistical methods have shown their superiority. It was, of course, impossible to

review the new results in detail, but the previous representation had to be corrected in many places in accordance with the new point of view.---

Munich, July 1946

Arnold Sommerfeld

In this translation of the second volume of Professor Sommerfeld's "Vorlesungen über theoretische Physik", the text of the second edition (1947, D. V. B., Wiesbaden) has been followed. Disregarding a few non-technical remarks that hold interest only for German readers, nothing has been omitted, and no changes have been made apart from necessary adaptations of the notation. Several brief footnotes have been inserted, however, to bridge over certain differences, mostly of a terminological nature. Topical references to the first volume have been supplemented by corresponding references to well-known American and British texts with the aim of making this volume independent from the preceding one, and a new index has been prepared.

G.K.

CHAPTER I

KINEMATICS OF DEFORMABLE BODIES

1. A Fundamental Theorem of Kinematics

Helmholtz establishes the following theorem at the beginning of his paper on vortex motions:¹ The most general motion of a sufficiently small element of a deformable (i.e., not rigid) body can be represented as the sum of

1. a translation,
2. a rotation,
3. an extension (contraction) in three mutually orthogonal directions.

The proof is based on the Taylor expansion of the relative displacement of two neighboring points P and O in terms of their original coordinate differences.

Let P be a point of the volume element under consideration and x, y, z its coordinates in a rectangular system the origin of which, O , lies within the element. In a general motion of the body the points P and O will both experience changes of position, which we denote by ξ, η, ζ and ξ_0, η_0, ζ_0 respectively, referring to the chosen space-fixed coordinate system. Taylor's formula then gives for the displacement of P

$$\begin{aligned} \xi &= \xi_0 + \frac{\partial \xi}{\partial x} x + \frac{\partial \xi}{\partial y} y + \frac{\partial \xi}{\partial z} z + \dots \\ \eta &= \eta_0 + \frac{\partial \eta}{\partial x} x + \frac{\partial \eta}{\partial y} y + \frac{\partial \eta}{\partial z} z + \dots \\ \zeta &= \zeta_0 + \frac{\partial \zeta}{\partial x} x + \frac{\partial \zeta}{\partial y} y + \frac{\partial \zeta}{\partial z} z + \dots \end{aligned}$$

Introducing for brevity

$$(2) \quad \frac{\partial \xi}{\partial x} = a_{11}, \quad \frac{\partial \xi}{\partial y} = a_{12}, \quad \frac{\partial \eta}{\partial x} = a_{21}, \quad \frac{\partial \eta}{\partial y} = a_{22}, \quad \dots,$$

¹Über Integrale der hydrodynamischen Gleichungen, welche den Wirbelbewegungen entsprechen. Crelles J. 55, 25 (1858).

we write each of the quantities a_{ik} as a sum of an "odd" and an "even" term

$$a_{ik} = \frac{a_{ik} - a_{ki}}{2} + \frac{a_{ik} + a_{ki}}{2};$$

"odd" and "even" refer, of course, to the commutation of the subscripts.

Now, (1) may be rewritten in the following form

$$\begin{aligned} \xi &= \xi_0 + \left| 0 + \frac{a_{12} - a_{21}}{2} y + \frac{a_{13} - a_{31}}{2} z \right| \\ &\quad + \left\| a_{11}x + \frac{a_{12} + a_{21}}{2} y + \frac{a_{13} + a_{31}}{2} z \right\| \\ \eta &= \eta_0 + \left| \frac{a_{21} - a_{12}}{2} x + 0 + \frac{a_{23} - a_{32}}{2} z \right| \\ (3) \quad &\quad + \left\| \frac{a_{21} + a_{12}}{2} x + a_{22}y + \frac{a_{23} + a_{32}}{2} z \right\| \\ \zeta &= \zeta_0 + \left| \frac{a_{31} - a_{13}}{2} x + \frac{a_{32} - a_{23}}{2} y + 0 \right| \\ &\quad + \left\| \frac{a_{31} + a_{13}}{2} x + \frac{a_{32} + a_{23}}{2} y + a_{33}z \right\|, \end{aligned}$$

where terms higher than first order in x, y, z have been omitted. Let us introduce the symbol \mathbf{s} for the total change of position of P ; the vertical separation lines in (3) indicate that the displacement \mathbf{s} is compounded of three partial motions $\mathbf{s}_0, \mathbf{s}_1, \mathbf{s}_2$, or

$$(4) \quad \mathbf{s} = \mathbf{s}_0 + \mathbf{s}_1 + \mathbf{s}_2.$$

The displacement \mathbf{s}_0 , with the components ξ_0, η_0, ζ_0 , is the same for all points P of a volume element and is therefore a *translation*.

The central portion of the set (3), \mathbf{s}_1 , is a *rotation*. Upon introducing the vector $\mathbf{\hat{\phi}}$, with the components

$$(5) \quad \varphi_x = \frac{a_{32} - a_{23}}{2}, \quad \varphi_y = \frac{a_{13} - a_{31}}{2}, \quad \varphi_z = \frac{a_{21} - a_{12}}{2},$$

and the position vector $OP = \mathbf{r}$, we obtain simply

$$(6) \quad \mathbf{s}_1 = \mathbf{\hat{\phi}} \times \mathbf{r}.$$

This displacement is well known from rigid body kinematics (Vol. I², Eq. 22.3) and corresponds to the infinitesimal rotation ϕ (the appropriate notation would be $\delta\phi$) whose axis and magnitude are given by the components ϕ_x, ϕ_y, ϕ_z .³

The infinitesimal rotation is not a vector in the proper sense, such as a polar vector that characterizes a translatory displacement. One may, nevertheless, denote it by the usual vectorial symbolism, associating with it a polar vector ϕ that points in the direction of the axis of rotation and has a length equal to the (infinitesimal) angle of rotation. More about axial vectors is found in 2.

There is, of course, *no change in the length of the vector* OP due to the displacement s_1 . This is self-evident if we consider s_1 from the point of view of rigid body kinematics, but will be shown here independently. The square of the distance \overline{OP} is

$$\overline{OP}^2 = |r + s_1|^2 = |r|^2 + 2r \cdot s_1 + |s_1|^2,$$

but according to (6)

$$r \cdot s_1 = r \cdot (\phi \times r) = \phi \cdot (r \times r) = 0.$$

Disregarding second order terms as in (3), we find

$$|r + s_1|^2 = |r|^2 = r^2$$

(It will be noticed that here and in all subsequent arguments of a similar nature, "no change" means "no change in first approximation.")

In order to pass from infinitesimal to finite quantities the displacements must be considered in their time dependence, which amounts to introducing velocities instead of displacements, viz.

$$(7) \quad s = v\Delta t, \quad \phi = \omega\Delta t,$$

or in components

$$(8) \quad \begin{aligned} \xi &= u\Delta t, & \eta &= v\Delta t, & \zeta &= w\Delta t, \\ \varphi_x &= \omega_x\Delta t, & \varphi_y &= \omega_y\Delta t, & \varphi_z &= \omega_z\Delta t. \end{aligned}$$

Here v is the velocity of the particle or volume element considered, and ω its vortex vector; the physical importance of the latter quantity was first recognized by Helmholtz.

²A. Sommerfeld, *Vorlesungen über Theoretische Physik*, Akademische Verlagsgesellschaft, Leipzig, 1944, Bd. I, quoted henceforth as Vol. I. English translation in press (Academic Press Inc., New York).

³See, e.g., J. L. Synge and B. A. Griffith, *Principles of Mechanics*, McGraw-Hill, New York, 1942 Sec. 10.5.

The components of the vortex vector in the system x, y, z are according to (8), (5), and (2)

$$(9) \quad \omega_x = \frac{1}{2} \left(\frac{\partial w}{\partial y} - \frac{\partial v}{\partial z} \right), \quad \omega_y = \frac{1}{2} \left(\frac{\partial u}{\partial z} - \frac{\partial w}{\partial x} \right), \quad \omega_z = \frac{1}{2} \left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} \right).$$

A more complete analysis of this fundamental definition belongs also to the review of vector analysis in the following article.

We turn now to the third partial motion s_2 indicated in the right hand part of our scheme (3). Here the deformability becomes significant, the two other partial motions having been recognized as the elements of the general motion of a rigid body.

The displacement s_2 is a *linear vector function* of the position vector \mathbf{r} , in the sense of Vol. I, 22.⁴ We denote the components of s_2 by ξ_2, η_2, ζ_2 , and introduce the notation

$$(10) \quad \begin{aligned} \xi_2 &= \epsilon_{xx}x + \epsilon_{xy}y + \epsilon_{xz}z, \\ \eta_2 &= \epsilon_{yx}x + \epsilon_{yy}y + \epsilon_{yz}z, \\ \zeta_2 &= \epsilon_{zx}x + \epsilon_{zy}y + \epsilon_{zz}z. \end{aligned}$$

The meaning of the coefficients ϵ_{ik} follows from (2) and (3):

$$(11) \quad \begin{aligned} \epsilon_{xx} &= \frac{\partial \xi}{\partial x}, & \epsilon_{xy} &= \epsilon_{yx} = \frac{1}{2} \left(\frac{\partial \xi}{\partial y} + \frac{\partial \eta}{\partial x} \right), \\ \epsilon_{yy} &= \frac{\partial \eta}{\partial y}, & \epsilon_{yz} &= \epsilon_{zy} = \frac{1}{2} \left(\frac{\partial \eta}{\partial z} + \frac{\partial \zeta}{\partial y} \right), \\ \epsilon_{zz} &= \frac{\partial \zeta}{\partial z}, & \epsilon_{zx} &= \epsilon_{xz} = \frac{1}{2} \left(\frac{\partial \zeta}{\partial x} + \frac{\partial \xi}{\partial z} \right). \end{aligned}$$

The quantities ϵ are the components of the *strain tensor*. The tensor itself may be symbolized in a similar way as the moment of inertia in Vol. I, 22.13b⁵ by the quadratic array

$$(12) \quad \epsilon = \begin{pmatrix} \epsilon_{xx} & \epsilon_{xy} & \epsilon_{xz} \\ \epsilon_{yx} & \epsilon_{yy} & \epsilon_{yz} \\ \epsilon_{zx} & \epsilon_{zy} & \epsilon_{zz} \end{pmatrix}$$

⁴See, e.g., L. Brand, *Vector and Tensor Analysis*, Wiley, New York, 1947, §§60 and 62.

⁵See, e.g., Synge and Griffith, *op. cit.*, Sec. 11.3.

In the present case the tensor is *symmetric* (i.e., the components are symmetric to the main diagonal that connects the upper left and lower right corners), a fact which is an immediate consequence of the definition of the third partial motion s_3 in (3). On the other hand, the scheme of coefficients of the partial motion s_1 represents an *antisymmetric tensor*. Its definition, given by Eq. (6) or Eq. (3) (the part between the vertical lines), yields the array

$$(12a) \quad \mathfrak{L} = \begin{pmatrix} 0 & \varphi_{xy} & \varphi_{xz} \\ \varphi_{yx} & 0 & \varphi_{yz} \\ \varphi_{zx} & \varphi_{zy} & 0 \end{pmatrix}, \quad \varphi_{ih} = -\varphi_{hi},$$

and our change of notation $\varphi_x = \varphi_{xx} = -\varphi_{xx}$ etc. establishes accordance with the double subscript notation introduced in (10). Note here that the antisymmetric tensor can always be represented by a vector, which is, of course, not true for a symmetric tensor, as will be proved in 2.

In the analysis of the strain tensor we make use of the concept of the *tensor quadric* as in Vol. I, 22.15 in the analysis of the moment of inertia. Consider for this purpose the scalar product

$$(13) \quad s_2 \cdot r = \epsilon_{xx}x^2 + 2\epsilon_{xy}xy + \epsilon_{yy}y^2 + \dots = f(x, y, z).$$

By putting $f(x, y, z) = \text{const}$, we obtain a surface of second order, the *strain* (or *deformation*) *quadric*, also called the *ellipsoid of strain* or of *dilatation*; this terminology, of course, does not exclude contraction, nor does it imply that the quadric is necessarily an ellipsoid as in the case of the inertia tensor. It may be any one of the surfaces of second order, e.g., a hyperboloid of one or two sheets or a degenerate surface such as a pair of planes.

In order to decide this, we refer the strain quadric to its principal axes. Upon introducing the corresponding rectangular coordinates X_1, X_2, X_3 , Eq. (13) takes the form

$$(14) \quad F(X_1, X_2, X_3) = \epsilon_1 X_1^2 + \epsilon_2 X_2^2 + \epsilon_3 X_3^2 = \text{const.}$$

The coefficients $\epsilon_1, \epsilon_2, \epsilon_3$ are called the *principal extensions* (or *contractions*, if negative).

If (13) is used, the linear vector function (10) may be rewritten in the form

$$(15) \quad \xi_1 = \frac{1}{2} \frac{\partial f}{\partial x}, \quad \eta_2 = \frac{1}{2} \frac{\partial f}{\partial y}, \quad \zeta_3 = \frac{1}{2} \frac{\partial f}{\partial z},$$

and in terms of the principal coordinates we have the correspondingly simplified linear vector function

$$(16) \quad \begin{aligned} \Xi_1 &= \frac{1}{2} \frac{\partial F}{\partial X_1} = \epsilon_1 X_1, & \Xi_2 &= \frac{1}{2} \frac{\partial F}{\partial X_2} = \epsilon_2 X_2, \\ \Xi_3 &= \frac{1}{2} \frac{\partial F}{\partial X_3} = \epsilon_3 X_3. \end{aligned}$$

The principal components of displacement Ξ_i introduced here are the projections of the vector \mathbf{s}_2 upon the principal axes X_i .

The proof of Helmholtz's theorem has been completed by the establishment of relations (16), which indicate that the third partial motion is composed of three extensions (contractions) in the mutually orthogonal directions of the principal axes of the deformation quadric. In fact, any point P of our volume element with coordinates X_i in the principal system is carried over, according to (16), into a point P' with coordinates

$$(17) \quad X_i + \Xi_i = X_i(1 + \epsilon_i).$$

The tensor quadric has been introduced here by formal definition, but a direct physical interpretation is possible when coordinate differentials or the equivalent direction cosines are introduced in place of the coordinates x, y, z [see Eq. (4.21)].

We now proceed from the linear extensions ϵ_i to the *cubical* extension or *dilatation* Θ which is defined as the specific change of volume (i.e. the volume change per unit of original volume)

$$(18) \quad \Theta = \frac{\Delta V' - \Delta V}{\Delta V}.$$

Here ΔV is the original and $\Delta V'$ the expanded (or compressed) volume of the element. The calculation is easy for a volume element that has the shape of a rectangular cell with sides parallel to the principal axes. Let one corner coincide with the point 0 and denote the sides before and after dilatation by a_i and a'_i . Then $\Delta V = a_1 a_2 a_3$, $\Delta V' = a'_1 a'_2 a'_3$. According to (17), $a'_i = a_i(1 + \epsilon_i)$, therefore $\Delta V' = \Delta V(1 + \epsilon_1)(1 + \epsilon_2)(1 + \epsilon_3)$ and, according to (18),

$$(19) \quad \Theta = (1 + \epsilon_1)(1 + \epsilon_2)(1 + \epsilon_3) - 1 = \epsilon_1 + \epsilon_2 + \epsilon_3.$$

(The product terms have again been omitted.)

The representation of Θ by (19) is valid in any Cartesian system: take for example the original system x, y, z . We assert that there is always

$$(20) \quad \Theta = \epsilon_{xx} + \epsilon_{yy} + \epsilon_{zz}.$$

For the proof we have to use certain properties of the transformation by which the surface $f = \text{const}$ of Eq. (13) is transformed into $F = \text{const}$ of Eq. (14). Writing the transformation in the schematic form

$$(21) \quad \begin{array}{c|ccc} & x & y & z \\ \hline X_1 & \alpha_1 & \beta_1 & \gamma_1 \\ X_2 & \alpha_2 & \beta_2 & \gamma_2 \\ X_3 & \alpha_3 & \beta_3 & \gamma_3 \end{array} \quad \begin{array}{l} \sum \alpha_i^2 = 1, \quad \sum \alpha_i \beta_i = 0, \dots \\ (21a) \quad \alpha_1^2 + \beta_1^2 + \gamma_1^2 = 1, \dots \\ \alpha_1 \alpha_2 + \beta_1 \beta_2 + \gamma_1 \gamma_2 = 0, \dots \end{array}$$

and reading the scheme (21) from left to right (i.e., solving for the X_i), we obtain by substituting in (14)

$$\begin{aligned} F &= \sum \epsilon_i X_i^2 = \sum \epsilon_i (\alpha_i x + \beta_i y + \gamma_i z)^2 \\ &= x^2 \sum \epsilon_i \alpha_i^2 + 2xy \sum \epsilon_i \alpha_i \beta_i + y^2 \sum \epsilon_i \beta_i^2 + \dots \end{aligned}$$

This expression must be identical with (13), therefore

$$(22) \quad \begin{aligned} \epsilon_{xx} &= \alpha_1^2 \epsilon_1 + \alpha_2^2 \epsilon_2 + \alpha_3^2 \epsilon_3, \\ \epsilon_{yy} &= \beta_1^2 \epsilon_1 + \beta_2^2 \epsilon_2 + \beta_3^2 \epsilon_3, \\ \epsilon_{zz} &= \gamma_1^2 \epsilon_1 + \gamma_2^2 \epsilon_2 + \gamma_3^2 \epsilon_3. \\ \epsilon_{xy} &= \alpha_1 \beta_1 \epsilon_1 + \alpha_2 \beta_2 \epsilon_2 + \alpha_3 \beta_3 \epsilon_3, \\ (22a) \quad \epsilon_{yz} &= \beta_1 \gamma_1 \epsilon_1 + \beta_2 \gamma_2 \epsilon_2 + \beta_3 \gamma_3 \epsilon_3, \\ \epsilon_{xz} &= \gamma_1 \alpha_1 \epsilon_1 + \gamma_2 \alpha_2 \epsilon_2 + \gamma_3 \alpha_3 \epsilon_3. \end{aligned}$$

On adding Eqs. (22) and taking into account the orthogonality relations (21a), we finally obtain

$$(23) \quad \epsilon_{xx} + \epsilon_{yy} + \epsilon_{zz} = \epsilon_1 + \epsilon_2 + \epsilon_3.$$

The result is: The sum of the elements in the principal diagonal of the strain tensor is independent of the choice of the system of coordinates; it is an *invariant of the tensor*. In 4 this result will be supplemented by a search for all invariants of a tensor. Also the relations (22a) not fully exploited so far will reappear there.

By (19), (20), and (11) the dilatation Θ can be put in the simple form

$$(24) \quad \Theta = \frac{\partial \xi}{\partial x} + \frac{\partial \eta}{\partial y} + \frac{\partial \zeta}{\partial z}.$$

Having established the geometrical significance of the *principal* extensions ϵ_i , our next task is the geometrical interpretation of the *general* strain components ϵ_{xx} and ϵ_{xy} . For the diagonal components ϵ_{xx} , \dots the case is not different from that of the quantities ϵ_1 , \dots : ϵ_{xx} is the increment in length of an x -fiber per unit of original length. If such a fiber is cut from the body between the points $x = 0$ and $x = \Delta l$, its length after straining $\Delta l' = \Delta l + \xi - \xi_0$, whence the specific change of length is

$$\frac{\Delta l' - \Delta l}{\Delta l} = \frac{\xi - \xi_0}{\Delta l}.$$

But the last expression is seen to be equal to

$$\frac{\partial \xi}{\partial x} = \epsilon_{xx},$$

when we substitute the special values $x = \Delta l$, $y = z = 0$ in Eq. (1).

For the purpose of interpreting the components ϵ_{xy} , we consider an " x,y -lamina" instead of an " x -fiber". Let 0123 denote an infinitesimal rectangular part of the lamina with sides a and b (Fig. 1). In the process

FIG. 1. Geometric interpretation of the strain component ϵ_{xy} as angular change in an originally orthogonal volume element. The diagram gives the projection in the x,y -plane.

of straining, the points 0, 1, 2 are displaced to $0'$, $1'$, $2'$, and the rectangle is deformed into a parallelogram. (Note that displacements in z -direction are disregarded; think of the strained figure as projected on the x,y -plane: the projection $3'$ of the strained point 3 will then coincide with the fourth corner of the parallelogram subtended by $0'1'$ and $0'2'$, if higher order terms are omitted. Note the analogous omission also in the case of the ϵ_{xx} .) The angles γ_1 and γ_2 indicated in Fig. 1 can now be calculated, again omitting higher order terms:

$$\begin{aligned} \gamma_1 &= \operatorname{tg} \gamma_1 = \frac{\eta_1 - \eta_0}{a + \xi_1 - \xi_0} = \frac{\eta_1 - \eta_0}{a} = \frac{\partial \eta}{\partial x} \\ (25) \quad \gamma_2 &= \operatorname{tg} \gamma_2 = \frac{\xi_2 - \xi_0}{b + \eta_2 - \eta_0} = \frac{\xi_2 - \xi_0}{b} = \frac{\partial \xi}{\partial y} \\ \gamma_1 + \gamma_2 &= \frac{\partial \eta}{\partial x} + \frac{\partial \xi}{\partial y} = 2\epsilon_{xy}. \end{aligned}$$

In this equation, subscripts on ξ , η refer to the displaced points. The angle $\gamma = \gamma_1 + \gamma_2$ is equal to the change of the originally right angle at O due to the distortion of the rectangle $O123$; ϵ_{xy} , which is half of that angle, is the *shearing strain* or, simply the *shear*. The quantities ϵ_y , and ϵ_{xz} have the same significance relative to the y,z - and z,x -laminae.

A short compilation of the more common notations of the strain tensor follows.

This book	ϵ_{xx}	ϵ_{yy}	ϵ_{zz}	$\epsilon_{xy} = \epsilon_{yx}$	$\epsilon_{yz} = \epsilon_{zy}$	$\epsilon_{zx} = \epsilon_{xz}$
Love and some American authors . .	e_{xx}	e_{yy}	e_{zz}	$e_{xy} = e_{yx}$	$e_{yz} = e_{zy}$	$e_{zx} = e_{xz}$
Kirchhoff and Planck	x_x	y_y	z_z	$\frac{1}{2} x_y = \frac{1}{2} y_x$	$\frac{1}{2} y_z = \frac{1}{2} z_y$	$\frac{1}{2} z_x = \frac{1}{2} x_z$
Some English authors	e	f	g	$\frac{1}{2} a$	$\frac{1}{2} b$	$\frac{1}{2} c$
Engineering usage . .	ϵ_x	ϵ_y	ϵ_z	$\frac{1}{2} \gamma_{xy} = \frac{1}{2} \gamma_{yx}$	$\frac{1}{2} \gamma_{yz} = \frac{1}{2} \gamma_{zy}$	$\frac{1}{2} \gamma_{zx} = \frac{1}{2} \gamma_{xz}$

The inclusion of the factor $\frac{1}{2}$ in our definition of the ϵ_{xy} , . . . is suggested by the system of notation of general tensor analysis, but we shall see in 40 that Kirchhoff's choice of the x_x , . . . which sets this factor in evidence has a certain advantage when simple expressions for energetic quantities are desired.

2. Review of Vector Analysis

Throughout this volume we shall make continual use of *vector analysis*, that is, calculus applied to vector quantities. Thus, while familiarity with *vector algebra* and with the basic concepts of *vector analysis* is assumed on the part of the reader, a clarification of some of the fundamental points seems appropriate.

First, we repeat here the definition of vector and scalar given in Vol. I, following 22.6. A quantity is a vector if, in an orthogonal transformation of the coordinate system, it follows the same transformation rules as the position vector $\mathbf{r} = x, y, z$; it is a scalar if it is invariant in such transformations.⁶

Let us put this definition to use in the proof that the quantity Θ , derived from the vector $\mathbf{s} = x, y, z$ in (1.24), is a scalar. We replace \mathbf{s} by

⁶For this definition compare H. and B. S. Jeffreys, *Methods of Mathematical Physics*, Cambridge University Press, Cambridge, 1946, Chap. 2.023.

an arbitrary vector $\mathbf{A} = A_x, A_y, A_z$,⁷ and consider instead of Θ more generally the quantity

$$(1) \quad \operatorname{div} \mathbf{A} = \frac{\partial A_x}{\partial x} + \frac{\partial A_y}{\partial y} + \frac{\partial A_z}{\partial z},$$

called the divergence of the vector field \mathbf{A} .

The invariance of $\operatorname{div} \mathbf{A}$, which we now prove, amounts to the following equality:

$$\operatorname{div}' \mathbf{A} = \frac{\partial A_{x'}}{\partial x'} + \frac{\partial A_{y'}}{\partial y'} + \frac{\partial A_{z'}}{\partial z'} = \operatorname{div} \mathbf{A}$$

For the sake of brevity, the coordinates, primed or unprimed, will be numbered rather than lettered. Transformation (1.21) reads in the simplified notation

$$(2) \quad \begin{array}{c|ccc} & x_1 & x_2 & x_3 \\ \hline x'_1 & \alpha_{11} & \alpha_{12} & \alpha_{13} \\ x'_2 & \alpha_{21} & \alpha_{22} & \alpha_{23} \\ x'_3 & \alpha_{31} & \alpha_{32} & \alpha_{33} \end{array} \quad (2a) \quad \begin{aligned} \sum_k \alpha_{ik} \alpha_{jk} &= \delta_{ij}, \\ \sum_i \alpha_{ik} \alpha_{il} &= \delta_{kl}. \end{aligned}$$

The meaning of the symbol δ_{ij} (and correspondingly δ_{kl}) is the usual one:

$$\delta_{ij} = \begin{cases} 1 & \text{for } i = j \\ 0 & \text{for } i \neq j \end{cases}.$$

For an arbitrary function $U(x_1, x_2, x_3)$, which may at the same time be considered as a function of x'_1, x'_2, x'_3 because of (2), one has

$$(3) \quad \frac{\partial U}{\partial x'_i} = \sum_k \frac{\partial U}{\partial x_k} \frac{\partial x_k}{\partial x'_i}.$$

This can be rewritten as

$$(3a) \quad \frac{\partial U}{\partial x'_i} = \sum_k \alpha_{ik} \frac{\partial U}{\partial x_k}$$

if the scheme of coefficients (2) is read vertically downward. According to our vector definition we may apply the transformation rule for \mathbf{r} , that is

⁷In the original German text, vectors and their components are printed in the same Gothic types. The more usual way of making a typographical distinction between the two has been adopted for this translation.

the scheme (2), to the vector **A**. Thus, on reading (2) from left to right, it follows

$$(4) \quad A'_i = \sum_j \alpha_{ji} A_j .$$

We now identify the arbitrary function U in (3a) with the vector component A_i . Doing this for $i = 1, 2, 3$ and adding leads us to

$$\sum_i \frac{\partial A'_i}{\partial x'_i} = \sum_i \sum_k \sum_l \alpha_{ik} \alpha_{li} \frac{\partial A_l}{\partial x_k} = \sum_k \sum_l \delta_{kl} \frac{\partial A_l}{\partial x_k} .$$

Here the first member is $\text{div}' \mathbf{A}$ and the last member $\text{div} \mathbf{A}$ if proper account is taken of the δ -symbol, hence the invariance of the divergence has been proved. The cubical dilatation (1.24) can now be written as $\Theta = \text{div} \mathbf{s}$.

The divergence operator derives a scalar from a vector. The gradient operator, on the other hand, is the simplest differential operator that derives a vector from a scalar. Denoting the scalar by U (a scalar point function as before), we construct the vector

$$(5) \quad \text{grad } U = \frac{\partial U}{\partial x_1}, \frac{\partial U}{\partial x_2}, \frac{\partial U}{\partial x_3} .$$

Its vector character follows at once from (3a) which can be written by means of the symbol "grad"

$$(5a) \quad \text{grad}'_i U = \sum_k \alpha_{ik} \text{grad}_k U .$$

Thus the gradient transforms in the same way as the position vector.

We now turn to the differential operation introduced in (1.9) for which the symbol "curl" is used. Writing (1.9) with this symbol, we have

$$(6) \quad \mathbf{B} = \text{curl } \mathbf{A}, \quad \text{curl}_x \mathbf{A} = \frac{\partial A_z}{\partial y} - \frac{\partial A_y}{\partial z}, \quad \text{etc.},$$

where \mathbf{B} stands for $2\omega^s$ and \mathbf{A} for $\mathbf{v} = u, v, w$. Eq. (1.6) already contains a definition of the vector ω . On setting as in (1.7)

$$\mathbf{s}_1 = \mathbf{v}_1 \Delta t, \quad \phi = \omega \Delta t,$$

(1.6) is carried over into

$$(7) \quad \mathbf{v}_1 = \omega \times \mathbf{r} .$$

^sWe shall later come back to this factor $\frac{1}{2}$ that is now included in the definition of \mathbf{B} .

The developments in 1 make it evident that the definition of ω by (6) [or (1.9)] agrees with that by (7) [or (1.6)]; this will be checked by direct calculation in problem I.1.

Let us now write (7) with the same lettering as (6); we can again use \mathbf{B} instead of 2ω , but we may use \mathbf{A} also for \mathbf{v}_1 , since in what follows we are only concerned with the vector character of this quantity and $\text{curl } \mathbf{v}_1$ is identical with $\text{curl } \mathbf{v}$. In this way (7) becomes

$$(7a) \quad 2\mathbf{A} = \mathbf{B} \times \mathbf{r}.$$

Our aim is to show that the quantity \mathbf{B} has, at least in a certain sense, vector character. Such a proof, which furnishes a better understanding of the concept "curl", is by no means superfluous although it is omitted in most textbooks.

The formal proof can be based directly on the definition (6), in which case it amounts to a rather cumbersome calculation (problem I, 2), but a clarification of the issue can also be obtained if one starts from Eq. (7a).⁹ There the components of \mathbf{B} appear as coefficients of a linear *vector function*, like the quantities ϵ_{ik} in (1.10). Introducing double subscripts and numbering the vector components (instead of lettering), we write

$$(8) \quad \begin{aligned} B_x &= B_1 = B_{32} = -B_{23}, & A_x &= A_1, \\ B_y &= B_2 = B_{13} = -B_{31}, & A_y &= A_2, \\ B_z &= B_3 = B_{21} = -B_{12}, & A_z &= A_3. \end{aligned}$$

This notation for the components of \mathbf{B} corresponds to the representation of Φ by (1.12a); in both cases the diagonal terms (B_{ii} , φ_{ii}) vanish and the "vector" \mathbf{B} is really an *antisymmetric tensor* like φ .

Eq. (7a) now takes the simple form

$$(9) \quad 2A_i = \sum_k B_{ik}x_k$$

which we can check, say, for $i = 1$; we find

$$2A_1 = 2A_x = B_{11}x_1 + B_{12}x_2 + B_{13}x_3 = -B_y y + B_z z = (\mathbf{B} \times \mathbf{r})_x$$

in agreement with (7a).

In order to define the quantities B for the rotated coordinate system x' , we write Eqs. (9) in this system

$$(10) \quad 2A'_i = \sum_k B'_{ik}x'_k$$

⁹Note, however, that Eq. (6) by no means implies Eq. (7a) in the case of a general vector field \mathbf{A} . Observe the careful formulation of problem I.1.

and reintroduce x and A by

$$x'_k = \sum_i \alpha_{ki} x_i, \quad A'_i = \sum_k \alpha_{ik} A_k$$

according to (2). This transforms (10) into

$$(11) \quad 2 \sum_k \alpha_{ik} A_k = \sum_k \sum_l B'_{ik} \alpha_{kl} x_l.$$

On substituting for the components A in the first member of this equation according to (9) which, obviously, can be written as $2A_k = \sum_l B_{kl} x_l$ by a mere relettering of the subscripts, Eq. (11) becomes

$$\sum_k \sum_l B_{kl} \alpha_{ik} x_l = \sum_k \sum_l B'_{ik} \alpha_{kl} x_l,$$

which is an identity in the three independent variables x_1, x_2, x_3 . By comparing the coefficients, the following three equations between the B and B' are obtained

$$(12) \quad \sum_k B_{kl} \alpha_{ik} = \sum_k B'_{ik} \alpha_{kl}, \quad l = 1, 2, 3,$$

from which the B' must be determined. This is done by multiplying Eqs. (12) with α_{jl} and summing over l . The second members of (12) add up to

$$(12a) \quad \sum_l \sum_k B'_{ik} \alpha_{kl} \alpha_{jl} = \sum_k B'_{ik} \sum_l \alpha_{kl} \alpha_{jl} = \sum_k B'_{ik} \delta_{kj} = B'_{ij}.$$

Thus the new components B' have been found, viz.

$$(13) \quad \sum_l \sum_k B_{kl} \alpha_{ik} \alpha_{jl} = B'_{ij}.$$

As it stands, each B' is a linear function of all nine components B , but, with $B_{ki} = -B_{ik}$ and $B_{kk} = 0$, the number of terms reduces to three. Written more completely, the expressions for B' are

$$(14) \quad \begin{aligned} B'_{ij} = & B_{32}(\alpha_{i3}\alpha_{j2} - \alpha_{i2}\alpha_{j3}) + B_{13}(\alpha_{i1}\alpha_{j3} - \alpha_{i3}\alpha_{j1}) \\ & + B_{21}(\alpha_{i2}\alpha_{j1} - \alpha_{i1}\alpha_{j2}). \end{aligned}$$

Let us write out one of them, say, for $i = 3, j = 2$:

$$(15) \quad \begin{aligned} B'_{32} = & B_{32}(\alpha_{33}\alpha_{22} - \alpha_{32}\alpha_{23}) + B_{13}(\alpha_{31}\alpha_{23} - \alpha_{33}\alpha_{21}) \\ & + B_{21}(\alpha_{32}\alpha_{21} - \alpha_{31}\alpha_{22}). \end{aligned}$$

The coefficients of the quantities B in (15) are nothing else but the cofactors of the elements in the first row of the determinant of the transformation (2). Depending on whether this determinant is $+1$ or -1 , the cofactors are *equal* or *opposite* to the elements to which they belong¹⁰ (see, e.g., Vol. I, problem I.10.). Eq. (15) may therefore be rewritten as

$$\pm B'_1 = \alpha_{11}B_1 + \alpha_{12}B_2 + \alpha_{13}B_3$$

where the single subscript notation has been reintroduced for the B . In the same way B'_2 and B'_3 are obtained. The result can be written in the form

$$(16) \quad \pm B'_i = \sum_j \alpha_{ij}B_j,$$

which is exactly the vector transformation rule of Eq. (4) except for the ambiguity of the sign.

Two things can be learned from this result:

1. *The quantity $\mathbf{B} = \text{curl } \mathbf{A}$ behaves like an ordinary (polar) vector in a rotation, that is, in an orthogonal coordinate transformation with determinant $+1$, hence the general use of the simple terminology "curl vector" which we shall also adopt.*
2. *The curl is, strictly speaking, not a polar, but an axial vector for the following reason: In a transition from a dextral to a sinistral system or, more generally, in a rotation with a subsequent change of orientation (determinant -1) the new components of the curl are the negatives of the new components of the (polar) vector that represents the curl in the original system.*

We can now easily see why the use of double subscripts is an advantage in the foregoing proof: An axial vector is not appropriately represented by an arrow in the direction¹¹ of the axis; the correct symbol should be a circular arrow about the axis. In this way the plane of the circular arrow, say the y, z -plane, takes over the function of the x -axis, and a better way to write the left member of Eq. (6) would be

$$(17) \quad \text{curl}_{yz} \mathbf{A} = \frac{\partial A_z}{\partial y} - \frac{\partial A_y}{\partial z}.$$

The notation $\text{curl}_x \mathbf{A}$ represents the axial vector by a polar vector. This is possible in pure rotation according to 1. and is indeed quite often an aid to the imagination.

In this connection a well-known and often applied rule may be men-

¹⁰Cf., e.g., Brand, *op. cit.*, §149.

¹¹In fact, two orientations are possible and only one is chosen in accordance with the orientation of the coordinate system.

tioned that helps to keep in mind the structure of the expressions (6) or (17) and in particular the sequence of signs in those formulas. It reads:

$$(18) \quad \text{curl } \mathbf{A} = \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ \frac{\partial}{\partial x} & \frac{\partial}{\partial y} & \frac{\partial}{\partial z} \\ A_x & A_y & A_z \end{vmatrix}.$$

The letters \mathbf{i} , \mathbf{j} , \mathbf{k} denote here unit vectors¹² in the directions of the x -, y -, z -axes. Multiplication with $\partial/\partial x$, $\partial/\partial y$, $\partial/\partial z$ means differentiation with respect to the corresponding variable. The expansion of the determinant (18) yields

$$(18a) \quad \text{curl } \mathbf{A} = \mathbf{i} \left(\frac{\partial A_z}{\partial y} - \frac{\partial A_y}{\partial z} \right) + \mathbf{j} \left(\frac{\partial A_x}{\partial z} - \frac{\partial A_z}{\partial x} \right) + \mathbf{k} \left(\frac{\partial A_y}{\partial x} - \frac{\partial A_x}{\partial y} \right),$$

which represents the correct way to form the curl components.

It should be noted, however, that the mapping of an axial upon a polar vector is possible only in *three-dimensional space*. This can be inferred from the number of components ν which is, of course, equal to the number of dimensions n in the case of the polar vector, while for an axial vector in general

$$\nu = \frac{n(n-1)}{2}, \quad \text{or} \begin{cases} \text{for } n = 1, 2, 3, 4, \dots \\ \nu = 0, 1, 3, 6, \dots \end{cases}$$

The number ν is correlated with the double subscript notation of the axial vector: it is the number of combinations of the n directions in space in groups of two. That ν coincides with n for $n = 3$ is, one might say, a coincidence. The number of components $\nu = 6$ in four-dimensional space plays a decisive part in electrodynamics, where it coincides with the *number of components of the electromagnetic field* (3 electric + 3 magnetic components).

We return to our starting point, Eq. (19), which we write in vector form

$$(19) \quad \boldsymbol{\omega} = \frac{1}{2} \text{curl } \mathbf{v}.$$

¹²The \mathbf{i} , \mathbf{j} , \mathbf{k} in the original German text have not been printed as vectors. The symbolic notation $\mathbf{V} = iV_x + jV_y + kV_z$ has then the character of a "higher complex number" and indicates more strongly the conceptual relationship between vectors, ordinary complex numbers, and Hamilton's quaternions.

It cannot be denied that the factor $\frac{1}{2}$ in this formula is a flaw. The meaning of ω is, as we know now, the whirl or rotation associated with the velocity distribution \mathbf{v} . Our formal introduction of the symbol curl in (6) implies that the "physical rotation" is only half of the "mathematical rotation". It is not feasible to remove this paradox by absorbing the factor $\frac{1}{2}$ in the definition of the curl symbol; that would have the most uncomfortable consequences for general vector analysis, in particular for electrodynamics. Nothing can be done but to point out the flaw and apologize.

The three operators grad, div, and curl have so far been defined by *differential* operations. There exists, however, a very convenient way of introducing div and curl by means of *integral* operations. Let us start with the *divergence*.

Visualize the vector field \mathbf{A} as a field of flow, that is, let magnitude and direction of the flow be given everywhere by the magnitude and direction of \mathbf{A} . Let the field point P be surrounded by a closed surface and $\Delta\tau$ be the enclosed volume. If \mathbf{n} is the outward normal associated with the surface element $d\sigma$, A_n represents the outflow per unit of surface, normal to the surface. On forming $(1/\Delta\tau) \int A_n d\sigma$, the limit for vanishing $\Delta\tau$ (or σ) becomes

$$(20) \quad \operatorname{div} \mathbf{A} = \lim_{\Delta\tau \rightarrow 0} \frac{1}{\Delta\tau} \int A_n d\sigma.$$

The agreement between this definition and (1) is evident in the special case that $\Delta\tau$ is chosen as a rectangular cell with center P and sides Δx , Δy , Δz (Fig. 2). If A_x at the point $x + \Delta x$ is expanded after Taylor and

FIG. 2. Calculation of $\operatorname{div} \mathbf{A}$ by an integral over the surface of an infinitesimal parallelepiped.

higher powers of Δx are neglected as before, one finds for the two x -surfaces (that is, the surfaces normal to the x -axis)

$$\int A_n d\sigma = \int (A_x(x + \Delta x) - A_x(x)) dy dz = \int \frac{\partial A_x}{\partial x} \Delta x dy dz = \frac{\partial A_x}{\partial x} \Delta\tau$$

and two corresponding terms for the two pairs of y - and z -surfaces; altogether one obtains the expression for $\operatorname{div} \mathbf{A}$. In writing (20) mathematicians would add the proviso that the limit indicated therein actually

exists. This we have omitted, since the restrictions as to continuity imposed on the vector field by such a proviso certainly would not be more severe than those which are inherent in definition (1). Thus, as a definition, (20) is certainly equivalent to (1); it should be preferred, however, as it is of a less formalistic nature.

The curl can be defined by the following construction in our field of flow. Let an arbitrarily chosen, oriented line a pass through the point P ; in the plane that contains P and is normal to a , draw a closed curve s surrounding P , and denote the enclosed area by $\Delta\sigma$. Let A_s be the component of \mathbf{A} in direction of the arc element ds , taken in that sense of direction which forms a right hand screw with the axis a . Consider now the line integral $\oint A_s ds$, for which Lord Kelvin introduced the appropriate name *circulation*. The limit of the ratio of the circulation to the area $\Delta\sigma$ is

$$(21) \quad \text{curl}_a \mathbf{A} = \lim_{\Delta\sigma \rightarrow 0} \frac{1}{\Delta\sigma} \oint A_s ds.$$

The agreement of this definition with the previous one, (17), can again be seen quite easily if the curve s is appropriately chosen. Suppose one wants to verify (21) for the y, z -component of the curl. The line a then coincides with the $+x$ -direction, and s may be chosen as a rectangle with center P and sides $\Delta y, \Delta z$ (see Fig. 3). On expanding the contributions

FIG. 3. Calculation of curl \mathbf{A} by a line integral over an orthogonal circuit.

of each pair of sides as before, the first pair (which is parallel to the y -axis) yields

$$\int A_s ds = \int (-A_y(z + \Delta z) + A_y(z)) dy = -\frac{\partial A_y}{\partial z} \Delta y \Delta z,$$

and the second pair

$$\int A_s ds = \frac{\partial A_z}{\partial y} \Delta y \Delta z.$$

Altogether one obtains according to (21)

$$\text{curl}_x \mathbf{A} = \text{curl}_{xx} \mathbf{A} = \frac{\partial A_z}{\partial y} - \frac{\partial A_y}{\partial z}.$$

The other components come out if the line α is made to coincide with the other coordinate axes, and the results are found by cyclic permutation ("rotation") of the letters.

The "integral" definitions put geometrical meaning into the operators div and curl previously introduced by formal analytic means, but a visualization of the operation $\text{grad } U$ is still lacking. Imagine for this purpose the level surfaces (that is, the surfaces $U = \text{const}$) and their orthogonal trajectories marked in space. The direction of the gradient is everywhere tangential to the trajectory; its magnitude, $\partial U / \partial n$, expresses itself in the concentration of the level surfaces as they follow each other: for constant δU , $\partial U / \partial n$ is the larger, the smaller δn .

Compared with the original definitions (1), (5), and (17), the advantage of the geometrical definitions is not only their less formalistic nature, but also their validity in *general* coordinates, which permits in particular an easy transition to any required system of curvilinear *orthogonal* coordinates.

We show this for the general case of a system of three mutually orthogonal families of surfaces, while the more elementary special cases such as polar coordinates will be treated in prob. I.3. Let p_1, p_2, p_3 be the parameters of the three families of surfaces. As a consequence of the mutual orthogonality, the analytic expression for the square of the distance of two neighbored points contains no mixed terms of the type $dp_i dp_j$. Following the notation g_{ik} of the general theory of relativity, we denote the coefficients of the quadratic terms by g_i^2 , so that the square of the element of length is

$$(22) \quad ds^2 = g_1^2 dp_1^2 + g_2^2 dp_2^2 + g_3^2 dp_3^2,$$

which implies in particular the following expressions for the differentials in the three coordinate directions:

$$(23) \quad ds_1 = g_1 dp_1, \quad ds_2 = g_2 dp_2, \quad ds_3 = g_3 dp_3.$$

These expressions replace dx, dy, dz , if orthogonal curvilinear coordinates are used instead of the usual Cartesian coordinates. The components of the gradient, heretofore

$$\text{grad } U = \frac{\partial U}{\partial x}, \frac{\partial U}{\partial y}, \frac{\partial U}{\partial z},$$

now become

$$(24) \quad \text{grad } U = \frac{1}{g_1} \frac{\partial U}{\partial p_1}, \frac{1}{g_2} \frac{\partial U}{\partial p_2}, \frac{1}{g_3} \frac{\partial U}{\partial p_3}.$$

The expression for the divergence in the new coordinates is obtained from (20) if the volume $\Delta\tau$ is chosen as an infinitesimal cell with (curvilinear) sides $\Delta s_1, \Delta s_2, \Delta s_3$:

$$(25) \quad \operatorname{div} \mathbf{A} = \frac{1}{g_1 g_2 g_3} \left\{ \frac{\partial}{\partial p_1} (g_2 g_3 A_1) + \frac{\partial}{\partial p_2} (g_3 g_1 A_2) + \frac{\partial}{\partial p_3} (g_1 g_2 A_3) \right\}.$$

The expression for the 1-component of the curl is obtained by choosing the surface that contains the "rectangular" circuit orthogonal to the coordinate direction p_1 :

$$(26) \quad \operatorname{curl}_1 \mathbf{A} = \frac{1}{g_2 g_3} \left(\frac{\partial (g_3 A_2)}{\partial p_1} - \frac{\partial (g_2 A_3)}{\partial p_1} \right),$$

The 2- and 3-components follow by "rotating" the numbers 1, 2, 3.

3. The Theorems of Gauss, Stokes, and Green

It is not difficult to proceed from the integral definitions of divergence and curl in (2.20) and (2.21) to the integral theorems of Gauss and Stokes.

Let the vector field \mathbf{A} be differentiable inside the closed surface σ so as to establish the value of $\operatorname{div} \mathbf{A}$ everywhere in the interior. The following integral relation then constitutes *Gauss's theorem*:

$$(1) \quad \int \operatorname{div} \mathbf{A} \, d\tau = \int A_n \, d\sigma.$$

Here n is the outward¹³ normal associated with the surface element $d\sigma$.

To prove this relation we divide the volume τ in a number of small cells $\Delta\tau_m$; in accordance with the mathematical definition of the definite integral, a set of such divisions with decreasing cell size may be used to write the first member of (1) as the limit

$$(1a) \quad \lim_{M \rightarrow \infty} \sum_{m=0}^M \operatorname{div} \mathbf{A} \, \Delta\tau_m,$$

where the value of $\operatorname{div} \mathbf{A}$ may be taken at an arbitrary point of the cell $\Delta\tau_m$. If the integral definition (2.20) is substituted for $\operatorname{div} \mathbf{A}$ the sum in (1a) becomes

$$(1b) \quad \sum_m \Delta\tau_m \lim_{\Delta\tau \rightarrow 0} \frac{1}{\Delta\tau} \int A_n \, d\sigma.$$

There is no objection against writing the factor $\Delta\tau_m$, which is still finite, to the right of the limit sign; also the summation, which so far refers only

¹³This convention may cause some inconvenience, as in the case $\mathbf{A} = \operatorname{grad} U$, where $\partial U / \partial n$ is then in general not defined outside of σ ; we may, however, replace $\partial U / \partial n$ by $-\partial U / \partial n'$ where n' is now the inward normal.

to a finite number of terms, may be interchanged with the limit sign. The expression (1b) then takes the form

$$(1c) \quad \lim_{\Delta\tau \rightarrow 0} \sum_m \frac{\Delta\tau_m}{\Delta\tau} \int A_n d\sigma.$$

Let it now be agreed upon that the cell $\Delta\tau$ which serves to define the divergence be *identical* with the cell $\Delta\tau_m$ that belongs to the definite integral.¹⁴ At the same time let us write $d\sigma_m$ instead of $d\sigma$, to indicate that $d\sigma_m$ is now an element of the surface of $\Delta\tau_m$. After these changes (1c) becomes

$$(1d) \quad \lim_{\Delta\tau_m \rightarrow 0} \sum_m \int A_n d\sigma_m.$$

In carrying out the summation over m the parts of the σ_m -surfaces that lie *inside* σ cancel each other in pairs because of the opposite signs of the normals n . Only the contributions of the surface elements that are adjacent to the σ -surface are left over; hence the sum in (1d) may simply be written

$$(1e) \quad \int A_n d\sigma,$$

where the integral refers to the *surface of the originally given region in space* as in the integral (1). Since this integral is independent of the division into cells $\Delta\tau_m$, the limiting process required in (1d) does not change anything, neither does the summation required in (1a). Expression (1e), as it stands, is therefore the value of the expression (1a) which, in turn, was only another way of writing the volume integral on the left side of (1). Since (1e) is identical with the right member of (1), everything is proved.

The formal proof of Gauss's theorem usually found in textbooks is based on a partial integration in rectangular coordinates; it can be replaced, as we have seen, by an argument that uses only the general principles of integral calculus and vector analysis. The same is true for Stokes's theorem, for which we shall outline only the general idea of the proof, referring to the foregoing for the formal details.

In terms of fluid flow, the second member of (1) means the outflow through the boundary surface (inflow, if negative). The first member of (1) represents the algebraic sum of the strengths of all sources or sinks, continuously distributed throughout the interior. The equality of the two members is thus intuitively evident.

¹⁴To be sure, this means that the limiting processes $\Delta\tau \rightarrow 0$ and $\Delta\tau_m \rightarrow 0$ (or $m \rightarrow \infty$) are carried out simultaneously, whereas the two processes should be carried out independently according to (1b).

In *Stokes's theorem* we consider an arbitrary, in general curved, surface σ bounded by a closed, oriented curve s (circuit). At each surface element $d\sigma$ construct the normal n and let it point in the direction that forms a right hand screw with the orientation of s . The content of Stokes's theorem is then: For any vector field A , continuous in the neighborhood of σ ,

$$(2) \quad \int \text{curl}_n A \, d\sigma = \oint A_s \, ds.$$

For a proof divide σ into small surface elements that can be considered as parts of the associated tangential planes, and let their boundaries s_m be oriented in accordance with the orientation of s . Write down equation (2.21) for each of the elements $\Delta\sigma_m$, multiply with $\Delta\sigma_m$ and sum over m . This leads to

$$(3) \quad \lim_{m \rightarrow \infty} \sum_m \text{curl}_n A \, \Delta\sigma_m = \lim_{m \rightarrow \infty} \sum_m \oint \lim_{\Delta\sigma \rightarrow 0} \frac{\Delta\sigma_m}{\Delta\sigma} A_s \, ds_m.$$

On making $\Delta\sigma = \Delta\sigma_m$ and proceeding as in Eqs. (1a)-(1d), the contributions of all internal boundaries cancel each other, since each segment belongs to two adjacent surface elements and is therefore traversed twice in opposite directions. Only the contributions of the external boundaries remain and sum up to the line integral on the right hand side of (2). In terms of fluid flow, Eq. (2) states: the circulation around the boundary curve s equals the flux of the vortex vector through an *arbitrary* surface σ subtended by s .

The integral taken over the boundary curve vanishes if the surface integral in Stokes's theorem refers to a *closed* surface. We indicate this as follows:

$$(4) \quad \oint \text{curl}_n A \, d\sigma = 0$$

where we assume, of course, the continuity of $\text{curl } A$, a point which has been emphasized before.

If the vector A is, in particular, chosen as a gradient, $A = \text{grad } U$, say, then the differential expression

$$(5) \quad A_s \, ds = A_x \, dx + A_y \, dy + A_z \, dz$$

becomes a total differential dU . In this case

$$(6) \quad \oint A_s \, ds = 0$$

for any boundary curve. The first member of (2) must then vanish for any surface σ and any normal direction n . This implies that quite generally

$$(7) \quad \text{curl grad } U = 0,$$

a formula which can also be read from the differential definition of the curl, Eq. (2.6).

The equation $\text{curl } \mathbf{A} = 0$, written in rectangular coordinates, is equivalent to the three conditions for the differential expression $A_x dx + A_y dy + A_z dz$ to be a total differential [see Eq. (5)]. These same conditions already appeared in Vol. I, Eq. (18.17) for the existence of a potential in a force field; they can now be written in the comprehensive form $\text{curl } \mathbf{A} = 0$.

Note, by the way, that the operation curl grad has a well defined meaning, but grad curl has not, since the gradient, by its definition, cannot be applied to a vector.

When Gauss's theorem is applied to a curl vector, that is, when $\text{curl } \mathbf{B}$ is substituted for \mathbf{A} in (1), the right member of (1) becomes an integral of the form (4), hence it vanishes. Consequently the expression on the left side of (1) is zero for any closed surface σ in τ . This means that generally

$$(8) \quad \text{div curl } \mathbf{B} = 0,$$

an identity which can also be read directly from the differential definition (2.1) and (2.6). Again the converse symbol $\text{curl div } \mathbf{B}$ carries no meaning since the operation curl cannot be applied to a scalar.

Let us also have a look at the symbols div grad and grad div . The first applies to a scalar, say U . We write

$$(9) \quad \text{div grad } U = \nabla^2 U.$$

In Cartesian coordinates the operator ∇^2 is

$$(9a) \quad \nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}.$$

In orthogonal curvilinear coordinates p_1, p_2, p_3 the relations (2.24) and (2.25) yield

$$(9b) \quad \nabla^2 U = \frac{1}{g_1 g_2 g_3} \left\{ \frac{\partial}{\partial p_1} \left(\frac{g_2 g_3}{g_1} \frac{\partial U}{\partial p_1} \right) + \frac{\partial}{\partial p_2} \left(\frac{g_3 g_1}{g_2} \frac{\partial U}{\partial p_2} \right) + \frac{\partial}{\partial p_3} \left(\frac{g_1 g_2}{g_3} \frac{\partial U}{\partial p_3} \right) \right\}.$$

The symbol ∇^2 is called the *Laplace Operator* or *Laplacian*, also the *second differential parameter*. The *first differential parameter* is defined by

$$(9c) \quad \begin{aligned} DU = (\nabla U)^2 &= \left(\frac{\partial U}{\partial x} \right)^2 + \left(\frac{\partial U}{\partial y} \right)^2 + \left(\frac{\partial U}{\partial z} \right)^2 \\ &= \frac{1}{g_1^2} \left(\frac{\partial U}{\partial p_1} \right)^2 + \frac{1}{g_2^2} \left(\frac{\partial U}{\partial p_2} \right)^2 + \frac{1}{g_3^2} \left(\frac{\partial U}{\partial p_3} \right)^2. \end{aligned}$$

Both symbols operate on scalar point functions. Other notations for the

Laplacian are Δ^2 and Δ , the latter mainly in French and German literature.¹⁵

The converse symbol, grad div, applies to vectors. Let it here be sufficient to mention that it appears in the useful formula

$$(10) \quad \text{curl curl } \mathbf{A} = \text{grad div } \mathbf{A} - \nabla^2 \mathbf{A}.$$

Caution is necessary in the application of (10) since in this formula the symbol $\nabla^2 = \text{div grad}$ operates on a vector, contrary to its definition. Actually, the formula refers to the *Cartesian components* of the vector \mathbf{A} , and ∇^2 operates on the individual component of \mathbf{A} , considered as a scalar. Accordingly, the proof of (10) must be carried out in Cartesian coordinates and consists in checking the equality of the two members by an easy calculation; the operator ∇ can also be used.

Formula (10), conversely, serves to transform into general coordinates the quantity $\nabla^2 \mathbf{A}$, which so far is only known for Cartesian components. We define

$$(10a) \quad \nabla^2 \mathbf{A} = \text{grad div } \mathbf{A} - \text{curl curl } \mathbf{A}.$$

The right member is known in arbitrary orthogonal coordinates according to (2.24)-(2.26) so as to give a definite meaning to the left member. We shall see this procedure applied in 9, after Eq. (18). In problem I.4 we discuss and interpret the difference between the correctly and incorrectly calculated components of $\nabla^2 \mathbf{A}$ in cylindrical coordinates.

We turn now to *Green's theorem*¹⁶ which occupies a *unique place* among

¹⁵The sign ∇ (read "del" or "nabla", the latter being the name of a Hebrew musical instrument of inverted triangular shape) is symbolically defined by

$$\nabla = \mathbf{i} \frac{\partial}{\partial x} + \mathbf{j} \frac{\partial}{\partial y} + \mathbf{k} \frac{\partial}{\partial z}.$$

∇^2 is meant as a scalar product:

$$\nabla^2 = \nabla \cdot \nabla = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}.$$

The product of ∇ with a scalar φ is the gradient of φ : The scalar product $\nabla \cdot \mathbf{A}$, if evaluated according to the formal rules of vector algebra, gives the divergence of \mathbf{A} :

$$\nabla \cdot \mathbf{A} = \frac{\partial A_x}{\partial x} + \frac{\partial A_y}{\partial y} + \frac{\partial A_z}{\partial z} = \text{div } \mathbf{A}.$$

The vector product $\nabla \times \mathbf{A}$ means, accordingly, the curl of \mathbf{A} ; one obtains, with $\mathbf{i} \times \mathbf{j} = -\mathbf{j} \times \mathbf{i} = \mathbf{k}$, $\mathbf{i} \cdot \mathbf{i} = 0$, etc., as in (2.18b),

$$\nabla \times \mathbf{A} = \mathbf{i} \left(\frac{\partial A_z}{\partial y} - \frac{\partial A_y}{\partial z} \right) + \mathbf{j} \left(\frac{\partial A_x}{\partial z} - \frac{\partial A_z}{\partial x} \right) + \mathbf{k} \left(\frac{\partial A_y}{\partial x} - \frac{\partial A_x}{\partial y} \right) = \text{curl } \mathbf{A}.$$

¹⁶George Green, *An Essay on the Application of Mathematical Analysis to the Theories of Electricity and Magnetism*, published in Nottingham, 1828. The theorem is announced and established in full generality in art. 3 of this paper, the calculations are, of course, carried out in (Cartesian) coordinates, not in vectors. The notations U , V , used in (11), are Green's.

the vector-analytic integral theorems. Its applications in mathematical physics are very numerous. It is of fundamental importance in potential theory for which Green first devised it; indispensable in hydrodynamics, electrodynamics, and optics, it is also highly useful in pure mathematics. Riemann based his theory of complex functions upon the two-dimensional form of Green's theorem; it is likely to turn up at any time in the calculus of variations and in the theory of eigenfunctions and integral equations. Green proved his theorem by partial integrations as it is often done at present. We shall derive it more simply from Gauss's theorem which, apparently, was not known to Green. Let U and V be two scalar point functions satisfying the necessary continuity requirements (existence of the second and continuity of the first partial derivatives) and substitute for A in (1)

$$(11) \quad A = U \operatorname{grad} V - V \operatorname{grad} U,$$

and, consequently, for A_n

$$(12) \quad A_n = U \frac{\partial V}{\partial n} - V \frac{\partial U}{\partial n}.$$

We calculate¹⁷

$$(13a) \quad \operatorname{div} (U \operatorname{grad} V) = \operatorname{grad} U \cdot \operatorname{grad} V + U \operatorname{div} \operatorname{grad} V,$$

$$(13b) \quad \operatorname{div} (V \operatorname{grad} U) = \operatorname{grad} V \cdot \operatorname{grad} U + V \operatorname{div} \operatorname{grad} U$$

and find for $\operatorname{div} A$ from (11)

$$(14) \quad \operatorname{div} A = U \operatorname{div} \operatorname{grad} V - V \operatorname{div} \operatorname{grad} U = U \nabla^2 V - V \nabla^2 U.$$

On using (14) and (12), Gauss's theorem (1) becomes

$$(15) \quad \int (U \nabla^2 V - V \nabla^2 U) d\tau = \int \left(U \frac{\partial V}{\partial n} - V \frac{\partial U}{\partial n} \right) d\sigma,$$

which constitutes *Green's theorem in its first form*. (Unfortunately, the nomenclature is not uniform. Many authors refer to (15) as *Green's second formula* which seems to be the preferred usage in current American literature.)

Green's theorem is correct for any two functions U and V and any boundary σ of the volume τ . Note that the positive direction of n points outward.

It was assumed so far that the volume τ has only *one* exterior boundary surface. If an inner boundary exists also as in the case of a body with

¹⁷For an arbitrary scalar ψ and an arbitrary vector A one easily verifies the formula $\operatorname{div} \psi A = \psi \operatorname{div} A + A \cdot \operatorname{grad} \psi$.

one or more cavities, the integration on the right side of (15) must include the inner boundary. This happens in particular if the interior contains points where one of the functions U or V becomes infinite or otherwise singular, so that these points must be excluded from the integration by inner boundaries σ_i . The corresponding integrals then appear in addition on the right side of (15).

If one substitutes $A = U \text{ grad } V$, that is, $A_n = U \partial V / \partial n$ in Gauss's theorem, (1) becomes on account of (13a)

$$(16) \quad \int \text{grad } U \cdot \text{grad } V \, d\tau + \int U \nabla^2 V \, d\tau = \int U \frac{\partial V}{\partial n} \, d\sigma$$

which constitutes the *second form of Green's theorem* (or *Green's first formula* if the other terminology is used). On identifying U and V one obtains the form

$$(16a) \quad \int (\nabla U)^2 \, d\tau + \int U \nabla^2 U \, d\tau = \int U \frac{\partial U}{\partial n} \, d\sigma,$$

which contains both differential parameters (9b, c).

The last identity leads directly to conclusions of fundamental importance in potential theory, which is, mathematically speaking, nothing else but the theory of the differential equation

$$(17) \quad \nabla^2 U = 0$$

the solutions of which are known as *harmonic* or *potential functions*. From formula (16a) one derives at once the following lemma: *A potential function that vanishes on a closed surface σ and is regular inside, vanishes everywhere in the interior of σ . In fact, Eq. (16a) implies*

$$(17a) \quad \int (\nabla U)^2 \, d\tau = 0 \quad \text{inside } \sigma$$

because of (17) and the boundary condition $U = 0$; but (17a) requires $\nabla U = 0$, the integrand being non-negative. This means $U = \text{const}$, and since U vanishes on σ , $U = 0$.

The *uniqueness of solution of the boundary value problem* of potential theory can also be proved by means of (16a). We formulate this problem as follows: required an integral U of (17) that assumes given values on a given boundary surface and is regular everywhere inside. If there were two solutions U_1 and U_2 satisfying the conditions of the problem, the difference $U = U_1 - U_2$ would satisfy the conditions of the foregoing lemma; thus $U = 0$ inside σ as before, and $U_1 = U_2$.

The result holds, with a slight modification, also in the case that instead of U the normal derivative $\partial U / \partial n$ is prescribed on the boundary (see problem I.5).

These few remarks should give a general idea of the scope of Green's theorem; 20 will bring a characteristic example of how it is put to work.

4. Some Remarks on Tensor Analysis

One distinguishes between *symmetric*, *antisymmetric*, and general or *asymmetric* tensors. A general tensor can be considered as the sum of a symmetric and an antisymmetric tensor in exactly the same way as the coefficients a_{ik} in 1. The antisymmetric tensor, in turn, is representable by an (axial) vector as in (1.12a), hence we have only to deal with *symmetric* tensors in this article. As we shall limit our discussion to second order tensors (i.e. tensors whose components carry not more than two subscripts), the representation (1.12) of the strain tensor may be taken as a starting point. Our remarks will be formulated so as to refer to the strain tensor, but they are of course valid for any symmetric tensor of second order, in particular for the stress and friction tensors of Chapter II.

The behavior of a tensor in a transformation of coordinates, which is so closely connected with the general significance of the tensor concept, can be studied either by means of its representation through the scheme of coefficients of a linear vector function as in (1.10), or by means of its relation to the tensor quadric (1.13). In rewriting these two equations we replace x, y, z by x_1, x_2, x_3 ; $\epsilon_{xx}, \epsilon_{xy}, \dots$ by ϵ_{ik} ; the special vector ξ_1, η_2, ζ_3 by the general vector symbol A with components A_1, A_2, A_3 , and obtain:

$$(1) \quad A_i = \sum_k \epsilon_{ik} x_k, \quad (2) \quad \sum_i \sum_k \epsilon_{ik} x_i x_k = \text{const.}$$

We compare these with the transformed equations

$$(1') \quad A'_i = \sum_k \epsilon'_{ik} x'_k, \quad (2') \quad \sum_i \sum_m \epsilon'_{im} x'_i x'_m = \text{const.},$$

in order to find the relations that connect the tensor components ϵ and ϵ' . We shall again use the relations between the vector components x, A and x', A' known from (2.2), viz.

$$(3) \quad A'_i = \sum_k \alpha_{ik} A_k, \quad A_i = \sum_k \alpha_{ki} A'_k,$$

$$(4) \quad x_i = \sum_l \alpha_{il} x'_l, \quad x_k = \sum_m \alpha_{mk} x'_m.$$

The comparison of (1) with (1') need not be carried out here, since the procedure is formally identical with the transformation of the antisymmetric tensor, carried out in (2.9)-(2.13); one has only to write ϵ_{ik} instead of B_{ik} , A instead of $2A$, and to observe that the antisymmetry of

the B is not made use of until (2.14). Then the result (2.13) reads in the present notation

$$(5) \quad \epsilon'_{ij} = \sum_l \sum_k \alpha_{il} \alpha_{jl} \epsilon_{kl}.$$

This same result can also be obtained by comparison of (2) with (2'): Substitute, according to (4), x_i and x_k in (2) and reverse the order of summation. The expression $\sum_l \sum_m \sum_i \sum_k \epsilon_{ik} \alpha_{il} \alpha_{mk} x'_l x'_m = \text{const}$ must be identical with (2'), therefore

$$(6) \quad \epsilon'_{lm} = \sum_i \sum_k \epsilon_{ik} \alpha_{il} \alpha_{mk},$$

which is indeed the same as (5), except for the lettering of the subscripts.

The second method to establish the transformation rules is, of course, much simpler, but could not have been applied in the case of the anti-symmetric tensor of rotation. The attempt to associate a quadric with such a tensor fails as the quadric vanishes identically: the coefficients of the squares vanish ($\varphi_{ii} = 0$), the product terms cancel in pairs because of $\varphi_{ik} = -\varphi_{ki}$.

Our result (6) may be expressed in form of the following proposition: *The components of the symmetric tensor transform as the products and squares of the coordinates*, a statement which, conversely, can be considered as the definition of a tensor. The corresponding statement for a polar vector would be: *The components transform as the coordinates themselves*.

Eqs. (6) are generalizations of our previous relations (1.22) and (1.22a); they are sums of six terms, while (1.22) and (1.22a) are sums of three terms. The reason is evidently that the strain tensor was assumed in "diagonal form", that is, referred to its principal axes. But a rectangular cell cut parallel to the principal axes remains rectangular after straining; its angular changes and, therefore, its shears vanish. Thus three of the six tensor components in (6) are zero whenever the ϵ refer to principal axes.

We shall now discuss the *invariants of a tensor*, supplementing what was learned in Eq. (1.23) about the invariance of the diagonal sum, and prove first that the determinant of the coefficients of the quadric (2) is invariant in orthogonal coordinate transformations.

Denoting the determinant by D we have to show

$$(7) \quad D = \begin{vmatrix} \epsilon_{11} & \epsilon_{12} & \epsilon_{13} \\ \epsilon_{21} & \epsilon_{22} & \epsilon_{23} \\ \epsilon_{31} & \epsilon_{32} & \epsilon_{33} \end{vmatrix} = D',$$

where D' stands for the determinant of the ϵ' in Eq. (6). The proof is based on the multiplication theorem for determinants, which we apply here as follows: when the determinant of the ϵ is multiplied with the determinant of the transformation coefficients α , the result can again be written as a determinant whose elements β_{ik} are $\sum_i \epsilon_{ik} \alpha_{il}$. On multiplying the determinant of the β once more with the determinant of the α , the elements of the resulting determinant are

$$\sum_k \beta_{ki} \alpha_{mk} = \sum_k \sum_l \epsilon_{kl} \alpha_{li} \alpha_{mk}.$$

According to (6) this is identical with the transformed tensor component ϵ'_{ik} , the determinant of which was denoted by D' . Thus we have found

$$(7a) \quad D' = D \cdot |\alpha_{il}| |\alpha_{mk}|,$$

but this does not differ from assertion (7) as the determinant of the α equals unity.

When the surface $f = \sum \sum \epsilon_{ik} x_i x_k = \text{const}$ is orthogonally transformed into $f' = \sum \sum \epsilon'_{ik} x'_i x'_k = \text{const}$, the quadratic form $\varphi = \sum x_i^2$ is transformed into $\varphi' = \sum x_i'^2$. (The "circle at infinity" $\varphi = 0$ which is the gauge quadric of Euclidean metric, transforms into itself in orthogonal transformations.) Consequently a specified quadric of the family $f + \lambda\varphi = \text{const}$ transforms into $f' + \lambda\varphi' = \text{const}$ and the parameter λ has the same value in these two equations of the same surface of second order. But since the determinant of the coefficients of *this* surface is also invariant, it follows that

$$(8) \quad D_\lambda = \begin{vmatrix} \epsilon_{11} + \lambda & \epsilon_{12} & \epsilon_{13} \\ \epsilon_{21} & \epsilon_{22} + \lambda & \epsilon_{23} \\ \epsilon_{31} & \epsilon_{32} & \epsilon_{33} + \lambda \end{vmatrix} = D'_\lambda,$$

and this must hold for any choice of the arbitrary parameter λ . Thus a generalization of (7) has been proved.

The determinant D_λ may now be expanded in powers of λ ,

$$(8a) \quad D_\lambda = D + \lambda\Delta + \lambda^2\Theta + \lambda^3.$$

Here Θ is our previous diagonal sum of (1.23) and Δ the quadratic expression

$$(9) \quad \Delta = \epsilon_{11}\epsilon_{22} + \epsilon_{22}\epsilon_{33} + \epsilon_{33}\epsilon_{11} - \epsilon_{12}\epsilon_{21} - \epsilon_{23}\epsilon_{32} - \epsilon_{31}\epsilon_{13}.$$

On doing the same with D'_λ and denoting the coefficients by D' , Δ' , Θ' in analogy to (8a), we obtain because of (8)

$$D + \lambda\Delta + \lambda^2\Theta + \lambda^3 = D' + \lambda\Delta' + \lambda^2\Theta' + \lambda^3.$$

This must hold for any value of λ , therefore

$$(10) \quad D = D', \quad \Delta = \Delta', \quad \Theta = \Theta'.$$

The symmetrical tensor possesses three invariants, that is, three characteristic scalars that are independent of the incidental way in which the tensor is represented by its components. The geometrical relations between the invariants and the tensor quadric are the object of problem I.6. The invariant Θ is, in mechanical interpretation, equivalent to the cubical dilatation, as previously shown. In general, Θ is known as the *first scalar* or *spur* of the tensor.

The preceding argument relates to quadratic forms in a general way and must be valid for the antisymmetric as well as for the symmetric tensor. Hence, also the antisymmetric tensor ought to have three invariants, but the invariant Θ is identically zero (the diagonal terms vanish) and the determinant D vanishes (so does any antisymmetric determinant of odd order). There remains only the invariant Δ for which (9) supplies the special form

$$(11) \quad \Delta = \epsilon_{23}^2 + \epsilon_{31}^2 + \epsilon_{12}^2,$$

which is equal to the sum of squares of the components of the associated axial vector. Hence in the case of the axial vector only *one quantity exists that is independent of the choice of the coordinate system*, exactly as in the case of the polar vector. For the polar vector this is the length and for the axial vector the magnitude of the "twist", which equals the length of the polar vector by which the axial vector is represented.

As in the case of the moment of inertia¹⁸ (Vol. I, Fig. 40 a, b, c), we shall now discuss some particular cases of the tensor quadric. The significance of a *spherical* tensor quadric is evident. In terms of strain it means *uniform extension or contraction in all directions*: no shears occur since every axis may be considered as principal axis; all right angles are preserved.

Unidirectional extension, e.g., in x -direction with vanishing extensions in all directions normal to x is associated with the quadric $x^2 = \text{const}$, which is a *pair of planes*. Note, however, that this is not the state of strain caused by unidirectional stress in x -direction, since an additional contraction normal to x is produced in that case. The strain quadric is then a *hyperboloid of one sheet*, axisymmetric with respect to the x -axis.

A state of strain that presents some interest arises when the points of the body are displaced along concentric circles about an invariable axis in such a way that the displacements are inversely proportional to the

¹⁸ Cf. Synge and Griffith, *op. cit.*; Sec. 11.3 contains a table.

distance from the axis, r . It prompts itself to introduce cylindrical coordinates and to define the displacement vector by

$$(12) \quad s_r = 0, \quad s_\varphi = \frac{A}{r}, \quad s_z = 0.$$

The strain components in the same coordinates are determined on the basis of formulas (26) and (28) to be derived presently; they are correct for arbitrary orthogonal curvilinear coordinates and yield in the present case

$$(13) \quad e_{r\varphi} = -\frac{A}{r^2}, \quad e_{rr} = e_{\varphi\varphi} = e_{zz} = e_{\varphi z} = e_{zr} = 0.$$

We now write the tensor quadric for a point r, φ, z in (local) coordinates ξ, η, ζ oriented parallel to the increments $dr, d\varphi, dz$:

$$(14) \quad 2e_{r\varphi}\xi\eta = \text{const.}$$

The coefficient $e_{r\varphi}$ varies with the distance r , but has a fixed value in Eq. (14), which refers to a certain point of the body. We may then include the factor $2e_{r\varphi}$ in the constant, and have instead of (14)

$$(15) \quad \xi\eta = \text{const.},$$

an equilateral hyperbola. Hence the tensor quadric is quite generally an *equilateral hyperbolic cylinder*. The axes of the hyperbola (15) form an angle of 45° with the asymptotes $\xi = 0, \eta = 0$.

A volume element cut parallel to $dr, d\varphi, dz$ is after straining in a state

FIG. 4a. In the state of pure shear an originally rectangular volume element is transformed into a rhomboid.

FIG. 4b. The principal strains form an angle of 45° with the directions of the shear and are equal and opposite to each other.

of *pure shear*. The face that originally had four right angles is distorted into a rhomboid-like shape (see Fig. 4a). By setting

$$s(r) = s_0 + \delta s, \quad s(r + dr) = s_0 - \delta s, \quad (\varphi = \text{const})$$

it is seen that only δs contributes to the distortion, while the effect of s_0 is a mere translation (not indicated in the figure). On the other hand, the volume element drawn in Fig. 4b which is oriented parallel to the *principal*

axes of the tensor quadric is not only *free of shear strain* (as required by the definition of the principal axes) but also *free of dilatation*.¹⁹

This is a consequence of the "equilateral shape" of the tensor quadric: from (13) it is seen that the spur Θ vanishes; hence it must also vanish for the volume element cut parallel to the principal axes (invariance of the spur). Since $\Theta = \epsilon_1 + \epsilon_2 + \epsilon_3$ and $\epsilon_3 = \epsilon_{xx} = 0$, we have $\epsilon_2 = -\epsilon_1$. The state of *pure shear* is characterized by *opposite principal extensions*.

In conclusion we derive the formulas that express *the strain tensor in curvilinear coordinates* (we have already used them to obtain (13)). These formulas cannot be written down in such a direct way as those for grad, div, and curl in Eqs. (2.24)-(2.26), because there exists no definition of the tensor that is intuitively meaningful or carries self-evident geometrical invariance such as the definitions of grad, div, curl in 2. The following analysis²⁰ should make up for that and contribute to a deeper understanding of the tensor quadric. It is somewhat laborious, but will prove a great help later, e.g. in the torsion problem, 42.

Let ds be the distance of two neighboring points P and P' of the medium under consideration, let dx, dy, dz be the differences of their Cartesian and dp_1, dp_2, dp_3 the differences of their curvilinear coordinates. According to (2.22) one has

$$(16) \quad ds^2 = dx^2 + dy^2 + dz^2 = g_1^2 dp_1^2 + g_2^2 dp_2^2 + g_3^2 dp_3^2.$$

In the deformation of the medium all points suffer displacements given by (1.10), which we shall now denote by δq . By dq we denote, on the other

FIG. 5. To illustrate the transformation of the strain tensor in general orthogonal coordinates: a line element dq is shifted along the displacement vector δq .

hand, the relative position vector of two neighboring points before the deformation, so that $|dq| = ds$. The symbol $d\delta q$ denotes the change of the displacement δq caused by the transition d from one field point to a neighboring field point. With the notation of Fig. 5, this is the difference of the displacement vectors $P'Q'$ and PQ . The symbol δdq means, again in terms of Fig. 5, the change of the position vector PP' caused by the

¹⁹Note also that this state of strain is formally the same as in a bar of circular cross section subjected to torsion, but the generators of the tensor quadric are perpendicular to the bar axis in the latter case [compare (4.13) with (42.3)].

²⁰Cf. E. Beltrami, *Annali di Matematica* 10, 188 (1881). *Opere Matematiche*, III, 383.

displacement operation δ , which carries P into Q and P' into Q' ; $\delta d\mathbf{q}$ is thus the difference of the position vectors QQ' and PP' , after and before deformation. But the quadrilateral $PQQ'P'$ supplies the vector relation $PP' + P'Q' = PQ + QQ'$ or $P'Q' - PQ = QQ' - PP'$, which is equivalent to the commutative relation

$$(17) \quad d\delta\mathbf{q} = \delta d\mathbf{q}.$$

We return now to (1.10) and have in Cartesian coordinates

$$(18) \quad d\delta\mathbf{q} = \begin{cases} d\delta x = \epsilon_{xx} dx + \epsilon_{xy} dy + \epsilon_{xz} dz, \\ d\delta y = \epsilon_{yx} dx + \epsilon_{yy} dy + \epsilon_{yz} dz, \\ d\delta z = \epsilon_{zx} dx + \epsilon_{zy} dy + \epsilon_{zz} dz. \end{cases}$$

These relations give the change of the displacement $d\delta\mathbf{q}$ as a linear vector function of the Cartesian components of the vector $d\mathbf{q}$. If we decompose $d\mathbf{q}$ into its curvilinear components given by (2.23), viz.

$$(19) \quad ds_1 = g_1 dp_1, \quad ds_2 = g_2 dp_2, \quad ds_3 = g_3 dp_3$$

we obtain again a linear vector function for $d\delta\mathbf{q}$ the coefficients of which are the tensor components we look for:

$$(20) \quad d\delta\mathbf{q} = \begin{cases} d\delta s_1 = \epsilon_{11} ds_1 + \epsilon_{12} ds_2 + \epsilon_{13} ds_3, \\ d\delta s_2 = \epsilon_{21} ds_1 + \epsilon_{22} ds_2 + \epsilon_{23} ds_3, \\ d\delta s_3 = \epsilon_{31} ds_1 + \epsilon_{32} ds_2 + \epsilon_{33} ds_3. \end{cases}$$

Our task is to calculate the "curvilinear tensor components" ϵ_{ik} from the displacement components $\delta q_1, \delta q_2, \delta q_3$ in directions p_1, p_2, p_3 as in (1.11).

We first determine in Cartesian coordinates the change of the square of the element of length ds^2 produced by the displacement $\delta\mathbf{q}$. From (16), (17), and (18) we infer

$$\begin{aligned} \frac{1}{2} \delta ds^2 &= dx \delta dx + dy \delta dy + dz \delta dz \\ (21) \quad &= \epsilon_{xx} dx^2 + \epsilon_{yy} dy^2 + \epsilon_{zz} dz^2 \\ &\quad + 2\epsilon_{xy} dx dy + 2\epsilon_{yz} dy dz + 2\epsilon_{zx} dz dx. \end{aligned}$$

The last member is identical with the polynomial of the tensor quadric except for the notation of the variables dx, dy, dz that replace the former x, y, z . The first member of (21) may be written in the form $ds \delta ds$. (On dividing by ds^2 we obtain $\delta ds/ds$ which is the *extension of the ds -fiber per*

unit of length; the variables are now the quantities dx/ds , dy/ds , dz/ds . Hence the *tensor quadric* gives directly the *specific extension* of the ds -fiber in terms of the *direction cosines* dx/ds , dy/ds , dz/ds and thus lends intuitive physical meaning to the concept of the symmetrical tensor.

The procedure leading to Eq. (21) can just as well be carried out in curvilinear coordinates p_1, p_2, p_3 . Using (19) we write the length element in the form $ds^2 = ds_1^2 + ds_2^2 + ds_3^2$. Eqs. (20) and (17) then yield

$$\begin{aligned} \frac{1}{2} \delta ds^2 &= ds_1 \delta ds_1 + ds_2 \delta ds_2 + ds_3 \delta ds_3 \\ (22) \quad &= \epsilon_{11} ds_1^2 + \epsilon_{22} ds_2^2 + \epsilon_{33} ds_3^2 \\ &\quad + 2\epsilon_{12} ds_1 ds_2 + 2\epsilon_{23} ds_2 ds_3 + 2\epsilon_{31} ds_3 ds_1. \end{aligned}$$

On dividing this equation by ds^2 the extension of the ds -fiber is obtained as before.

The required relations between the ϵ_{ik} and the displacement components δq_i are now obtained by the direct calculation of $\frac{1}{2} \delta ds^2$ in terms of the ds_i and subsequent comparison with the right member of (22). Writing (16) in condensed form, we obtain first

$$(22a) \quad \frac{1}{2} \delta ds^2 = \sum_i g_i \delta q_i dp_i^2 + \sum_i g_i^2 dp_i \delta dp_i.$$

Here we have to express the variations, imposed on the coefficients g_i and on the coordinate differentials dp_i by the displacement δq_i in terms of the variations and differentials of the coordinates themselves; in other words, we have to substitute in (22a)

$$\delta g_i = \sum_k \frac{\partial g_i}{\partial p_k} \delta p_k, \quad \delta dp_i = d\delta p_i = \sum_k \frac{\partial \delta p_i}{\partial p_k} dp_k$$

and obtain

$$(23) \quad \frac{1}{2} \delta ds^2 = \sum_i \sum_k g_i \frac{\partial g_i}{\partial p_k} \delta p_k dp_i^2 + \sum_i \sum_k g_i^2 \frac{\partial \delta p_i}{\partial p_k} dp_i dp_k.$$

Now we are ready to introduce the ds_i . According to (19), we write ds_i/g_i for the dp_i . The "curvilinear" displacement components δp_i are obviously connected with the components δq_i by

$$\delta q_i = g_i \delta p_i, \quad \text{or} \quad \delta p_i = g_i^{-1} \delta q_i.$$

In this way the first of the two sums on the right side of (23) becomes

$$(23a) \quad \sum_i \sum_k \frac{\delta q_k}{g_k} \frac{\partial g_i}{\partial p_k} ds_i^2;$$

the second sum becomes

$$\sum_i \sum_k \frac{g_i}{g_k} \frac{\partial}{\partial p_k} \left(\frac{\delta q_i}{g_i} \right) ds_i ds_k$$

or, on carrying out the differentiations,

$$(23b) \quad \sum_i \sum_k \frac{1}{g_k} \frac{\partial \delta q_i}{\partial p_k} ds_i ds_k - \sum_i \sum_k \frac{\delta q_i}{g_i g_k} \frac{\partial g_i}{\partial p_k} ds_i ds_k.$$

Now we can compare the coefficients of $ds_i ds_k$ in (22) with those in the sum of (23a) and (23b). Let us do this first for the diagonal terms: the coefficient of a *specified* ds_i^2 in (23a) is

$$(24a) \quad \sum_k \frac{\delta q_k}{g_i g_k} \frac{\partial g_i}{\partial p_k};$$

in (23b), k must be identified with the given i . The coefficient is then simply

$$(24b) \quad \frac{1}{g_i} \frac{\partial \delta q_i}{\partial p_i} - \frac{\delta q_i}{g_i^2} \frac{\partial g_i}{\partial p_i}.$$

Upon adding (24a) and (24b), two terms cancel and one obtains

$$(25) \quad \frac{1}{g_i} \left(\frac{\partial \delta q_i}{\partial p_i} + \sum_{k \neq i} \frac{\delta q_k}{g_k} \frac{\partial g_i}{\partial p_k} \right).$$

This, then, is the value of ϵ_{ii} . Written in extenso, (25) means

$$(26) \quad \begin{aligned} \epsilon_{11} &= \frac{1}{g_1} \left(\frac{\partial \delta q_1}{\partial p_1} + \frac{\delta q_2}{g_2} \frac{\partial g_1}{\partial p_2} + \frac{\delta q_3}{g_3} \frac{\partial g_1}{\partial p_3} \right) \\ \epsilon_{22} &= \frac{1}{g_2} \left(\frac{\partial \delta q_2}{\partial p_2} + \frac{\delta q_3}{g_3} \frac{\partial g_2}{\partial p_3} + \frac{\delta q_1}{g_1} \frac{\partial g_2}{\partial p_1} \right) \\ \epsilon_{33} &= \frac{1}{g_3} \left(\frac{\partial \delta q_3}{\partial p_3} + \frac{\delta q_1}{g_1} \frac{\partial g_3}{\partial p_1} + \frac{\delta q_2}{g_2} \frac{\partial g_3}{\partial p_2} \right). \end{aligned}$$

In the determination of the shears ϵ_{ik} , we note first that (23a) gives no contribution. In (23b), either sum yields two terms if i and k are specified, viz. one term $\dots ds_i ds_k$ and another $\dots ds_k ds_i$. This amounts to the four term expression

$$(27) \quad \frac{1}{g_k} \frac{\partial \delta q_i}{\partial p_k} + \frac{1}{g_i} \frac{\partial \delta q_k}{\partial p_i} - \frac{1}{g_i g_k} \left(\delta q_i \frac{\partial g_i}{\partial p_k} + \delta q_k \frac{\partial g_k}{\partial p_i} \right)$$

which, on the other hand, equals $2\epsilon_{ik}$. If we write (27) in extenso, we obtain

$$\begin{aligned}
 \epsilon_{12} &= \frac{1}{2} \left(\frac{1}{g_2} \frac{\partial \delta q_1}{\partial p_2} + \frac{1}{g_1} \frac{\partial \delta q_2}{\partial p_1} \right) - \frac{1}{2g_1 g_2} \left(\delta q_1 \frac{\partial g_1}{\partial p_2} + \delta q_2 \frac{\partial g_2}{\partial p_1} \right) \\
 (28) \quad \epsilon_{23} &= \frac{1}{2} \left(\frac{1}{g_3} \frac{\partial \delta q_2}{\partial p_3} + \frac{1}{g_2} \frac{\partial \delta q_3}{\partial p_2} \right) - \frac{1}{2g_2 g_3} \left(\delta q_2 \frac{\partial g_2}{\partial p_3} + \delta q_3 \frac{\partial g_3}{\partial p_2} \right) \\
 \epsilon_{31} &= \frac{1}{2} \left(\frac{1}{g_1} \frac{\partial \delta q_3}{\partial p_1} + \frac{1}{g_3} \frac{\partial \delta q_1}{\partial p_3} \right) - \frac{1}{2g_3 g_1} \left(\delta q_3 \frac{\partial g_3}{\partial p_1} + \delta q_1 \frac{\partial g_1}{\partial p_3} \right).
 \end{aligned}$$

Formulas (26) and (28) can be cast in a much more comprehensive form if the notation of general tensor calculus is employed as in Appendix I.

For the present we apply these formulas only to verify our Eqs. (13). If we specify the p_i as cylindrical coordinates by setting $p_1 = r$, $p_2 = \varphi$, $p_3 = z$, it follows that $g_1 = g_3 = 1$, $g_2 = r$, and the displacement (12) reads

$$\delta q_1 = \delta q_3 = 0, \quad \delta q_2 = \frac{A}{r}.$$

As a consequence, only those terms in (26) and (28) contribute something that contain δq_2 or $\partial \delta q_2 / \partial p_1$ and do not have a vanishing coefficient $\partial g_i / \partial p_k$ (note that all these derivatives vanish except $\partial g_2 / \partial p_1$ which equals unity). Only ϵ_{12} contains such terms, viz.

$$\frac{1}{2g_1} \frac{\partial \delta q_2}{\partial p_1} = -\frac{1}{2} \frac{A}{r^2} \quad \text{and} \quad -\frac{1}{2g_1 g_2} \delta q_2 \frac{\partial g_2}{\partial p_1} = -\frac{1}{2} \frac{A}{r^2}.$$

Thus the system (26) and (28) reduces in our case to: $\epsilon_{12} = -A/r^2$, and all other ϵ vanish, in agreement with (13).

Let us finally interpret the displacement field (12) as a velocity field by setting

$$(29) \quad v_r = 0, \quad v_\varphi = \frac{A}{r}, \quad v_z = 0.$$

This motion is of fundamental importance in the theory of vortices. We shall see that it is *irrotational* wherever $r > 0$, that is, at all points outside the axis. This is true in spite of our inclination to "see" (29) as a whirl about the axis $r = 0$. The steady motion characterized by the velocity distribution (29) is known as a *circulating motion*, also as a (straight) *line vortex* or *simple vortex*. The latter terminology makes it evident that the points of the axis have a particular significance: they form a vortex line, that is, a concentrated vortex filament. This will be discussed more fully in 19, p. 140, where the irrotationality of the vortex motion will also be shown; the latter point, however, can be verified right now by means of

the tabulated answer to problem I.3. One has only to identify our vector (29) with the vector **A** in the formulas giving the curl components in cylindrical coordinates.

The tensor concept has been developed in this article by studying the behavior of a tensor in the transition from one Cartesian coordinate system to another. If more general transformations are to be considered, the methods of general tensor analysis must be employed of which a short account is found in Appendix I-IV.

CHAPTER II

STATICS OF DEFORMABLE BODIES

5. Concept of Stress; General Classification of Deformable Bodies

The term statics will be used throughout this book in the same sense as in the mechanics of a finite number of degrees of freedom, where it was applied according to the following definition: Statics treats of the forces to which matter is subjected regardless of the motion caused by them (cf. Vol. I, 5).

One distinguishes between external and internal forces. Once a mechanical system has been delimited, the *internal* forces of the system are those which obey Newton's third law (equality of action and reaction). Among the *external* forces, gravity and centrifugal force¹ are commonly encountered in mechanics of deformable bodies. Capillary forces occur also; they act between internal and surface molecules or between a solid boundary and the molecules of the surrounding fluid. Examples of internal forces are the reactions (tension and pressure forces, surface forces) that have their origin in the distribution of matter over a limited space. They play the most important part² in the mechanics of deformable bodies.

In solids the reactions measured per unit of area are known as *stresses*; in the case of fluids we usually speak of *pressures* (negative stresses); both have the dimension of a force per unit area, dyne/cm² in the CGS system.

To analyze the stress concept in the case of an elastic solid, we imagine a plane surface cutting through the body and consider the interaction between the two parts of the body across this surface. In Fig. 6 such a surface of separation has been drawn normal to the x -axis, and the two parts of the body have been disjoined for the sake of clarity in the drawing. On the part to the left a "positive x -surface" has been marked by cross hatching. (A surface with an outward normal pointing in the positive x -direction is called positive x -surface for brevity.) We assume the x -surface

¹The proper place for the centrifugal force, which is an inertia effect, is in dynamics (Chap. III), but it may be considered in statics since it is equivalent to an external force for an observer moving with the body.

²The distinction between external and internal forces in a specified system does not in general coincide with the distinction between forces of physical origin (impressed forces) and forces of geometrical origin (due to spatial constraints to which the system is subjected).

in this figure bounded in the shape of a rectangle with the sides Δy , Δz . The x -surface bounding the right part of the body, which in reality coincides with the positive x -surface, has also been cross hatched. It is a negative x -surface since its outward normal points in the negative x -direction.

Consider now the forces which the negative x -surface exerts upon the positive x -surface. When these forces are parallel to the positive x -direction we speak of a positive *normal stress* σ_{xx} ; its magnitude equals the sum of the forces divided by the area $\Delta y \Delta z$. In general, however, the total force will by no means be perpendicular to the x -surface. We then resolve the force and the associated stress into components in the positive x -, y -, and z -directions. The y and z components are known as *tangential* or *shear stresses* and denoted by σ_{xy} , σ_{xz} . This notation indicates the position of the surface by the first subscript and the direction of the stress by the second.

The principle of action and reaction requires us to draw for the right part in Fig. 6 the stress arrows that act across the negative x -surface in

FIG. 6. Normal and shear stresses acting on a volume element of an elastic body. Positive and negative x -surfaces.

opposite direction. A positive σ_{xx} means here a stress in the negative x -direction. The same is true for the negative x -surface of the body element in the left part of the figure which is obtained by a mere displacement (through $-\Delta x$) of the negative x -surface considered before. In speaking of the entirety of quantities σ_{ik} characteristic for a volume element, we use the term *stress tensor* although the proof of the tensor character will be given in 8 only, by showing the symmetry of the σ_{ik} and their transformation rules. The term stress tensor is, by the way, redundant since the word tensor in itself implies tension.

The forces exerted by the surrounding elements of the body may be directed either toward the exterior or the interior of the body element under consideration. In the latter case (compression) it is more appropriate to speak of pressures than of stresses. We shall, however, retain the uniform terminology "stress" in the case of an elastic *solid*, and consider pressures as negative stresses.

Not so in the case of *fluids*. The cohesive forces in a fluid are weak, its "ultimate strength" under ordinary circumstances is exceedingly small if compared with that of a solid. In other words, the resistance of fluids against tension is so small that positive stresses practically never occur; we then prefer to deal in our equations with *pressures* p rather than stresses σ . In a sketch such as Fig. 6, the positive p_{xx} would have to be drawn as an arrow directed inward.³

The totality of pressures p_{ik} acting upon a fluid element will again be called a *tensor*. There is, however, an essential difference between the normal pressures p_{ii} and the tangential pressures p_{ik} , at least in the state of rest or of slow motion. A fluid layer may be moved along the adjacent layer without expenditure of a noticeable amount of energy provided the motion is slow; this means that the tangential pressures p_{ik} are quite small if the two layers are slowly displaced parallel to each other. By extension, we must assume that the tangential pressures vanish altogether in the state of rest. In this way a fundamental simplification of the pressure tensor p is accomplished which will be applied in 6 (hydrostatics).

For larger relative velocities of the fluid particles the complete pressure tensor must be studied and its dependence on the velocity gradient investigated. This will be done in 10 (viscous flow).

The concept of the fluid state is meant to cover also *gases* and *vapors*, the latter two being characterized by larger compressibility. Fluids in the restricted sense, or *liquids*, are essentially incompressible. Of course, they yield to a certain extent if subjected to strong external forces, but their compressibility is very small in comparison with gases or vapors and can be neglected in a great number of problems; so is water often considered as *incompressible*.

The *condition for incompressibility* reads $\Theta = 0$ according to (1.24); on passing from the displacement vector s to the velocity vector v as in (1.7), we obtain the relation

$$(1) \quad \operatorname{div} v = 0,$$

expressing the fact that the balance of outflow and inflow for a given volume element $\Delta\tau$ is zero at any time. If Δm denotes the mass contained in $\Delta\tau$, we have

$$(2) \quad \Delta m = \rho \Delta\tau$$

where ρ stands for the *density*. For homogeneous incompressible fluids ρ is constant in time as well as in space.

³It is only consequent to invert the direction of the arrows also for p_{xy} , p_{yz} , etc. so that p_{xy} is counted *positive* if it points in the *negative* y -direction. This rule will be followed from now on.

What corresponds to Eq. (1) in the case of a *compressible fluid* where not the volume but the mass is preserved? The mass Δm cannot decrease unless part of it passes through the boundary of the volume element $\Delta \tau$. The mass flow at any point of its boundary is represented by the normal component of the vector $\rho \mathbf{v}$. The total outflow of mass during the time element Δt is therefore [cf. e.g. (2.20)]

$$(3) \quad \int \rho v_n d\sigma \Delta t = \operatorname{div} (\rho \mathbf{v}) \Delta \tau \Delta t.$$

On the other hand, the loss of mass during the same time is found from (2) as

$$- \frac{\partial \rho}{\partial t} \Delta t \Delta \tau.$$

Comparison with (3) yields the following *condition for the conservation of mass*

$$(4) \quad \frac{\partial \rho}{\partial t} + \operatorname{div} (\rho \mathbf{v}) = 0,$$

also known under the name of *equation of continuity*. It may be written in the form:

$$(4a) \quad \frac{d\rho}{dt} + \rho \operatorname{div} \mathbf{v} = 0$$

The first term in this equation is the *material differential quotient* which will be discussed more fully at the beginning of 11. Its definition is

$$(4b) \quad \frac{d\rho}{dt} = \frac{\partial \rho}{\partial t} + \mathbf{v} \cdot \operatorname{grad} \rho.$$

If ρ is constant in time *and* space, Eq. (4) takes again the form of the incompressibility condition (1). In an incompressible inhomogeneous fluid (ρ variable in space) we have by (4b)

$$(4c) \quad \frac{d\rho}{dt} = 0 \quad \text{that is} \quad \frac{\partial \rho}{\partial t} = -\mathbf{v} \cdot \operatorname{grad} \rho,$$

which describes the temporal fluctuations of ρ at a fixed point of observation, while the material rate of change of ρ vanishes.

We add here Eqs. (1), (4), and (4a) spelled out in Cartesian coordinates:

$$(1') \quad \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0,$$

$$(4') \quad \frac{\partial \rho}{\partial t} + \frac{\partial(\rho u)}{\partial x} + \frac{\partial(\rho v)}{\partial y} + \frac{\partial(\rho w)}{\partial z} = 0,$$

$$(4a') \quad \frac{d\rho}{dt} + \rho \left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} \right) = 0.$$

In problems involving capillary forces we are concerned with the fluid layers that are closest to the surface (surface film). The *surface of separation* introduced previously (see Fig. 6) is now to be replaced by a *linear cut* through the film. The object is again to study the reaction forces transferred from one bank of the cut to the other. Referring the forces to the unit length of the cut we speak of *surface tension*; its dimension is dyne/cm.

6. Equilibrium of Incompressible Fluids (Hydrostatics).

The subject of this section is, of course, not only water ("hydor" in Greek) but any liquid in equilibrium since differences in the rheological characteristics have no bearing on the *state of rest*: shear stresses, as already observed, are zero in equilibrium, or

$$(1) \quad p_{ik} = 0, \quad i \neq k.$$

This equation actually amounts to a *definition of the fluid* in the state of rest—in contrast to the state of solidification: glass which has no crystalline structure must be characterized physically as a *fluid in the solid state* for which Eq. (1) is, of course, incorrect.

A fundamental conclusion from (1) is that the hydrostatic pressure is associated with a *spherical* tensor quadric. Any diameter of the quadric may be taken as a principal axis, because (1) must be true in any coordinate system. The complete symmetry of the tensor of hydrostatic pressure can be expressed as follows. *At a given point the pressure acts on any surface element in the direction of its normal i , its magnitude being the same for all directions i ; $p_{11} = p_{22} = p_{33}$ for any three orthogonal directions.* Pascal⁴, it appears, was the first to perceive this law.

We can summarize this result in the statement that the hydrostatic pressure is a *scalar quantity*. It will be denoted by p , as is usually done with omission of the subscripts that are now abundant. Note that there is no preferential loading of the *horizontal* cross sections if a *vertical* force such as gravity acts on the fluid; the same pressure p is transferred

⁴Blaise Pascal (1624-1662), the great geometer (Pascal's theorem) and mathematician (Pascal's triangle, foundation of the calculus of probabilities), a great writer and theologian too; he studied the laws of air pressure and at his instigation the first barometrical determination of an altitude was carried out.

through any cross-section (also a vertical one). *The unidirectional character of the force does not interfere with the symmetry of the pressure.*

In order to calculate the pressure if magnitude and direction of the external force are given, let \mathbf{F} denote the external force per unit of fluid volume, so that the dimension of \mathbf{F} is dyne/cm³. Then the volume element $\Delta\tau$ is acted upon by the force $\mathbf{F}\Delta\tau$. On delimiting the volume element as rectangular cell ($\Delta\tau = \Delta x\Delta y\Delta z$) and marking the negative x -surface by the value x of the x -coordinate and, consequently, the positive x -surface by $x + \Delta x$, the forces in positive x -direction are:

	on the neg. x -surface	on the pos. x -surface	on the vol. element
(2)	$p(x)\Delta y\Delta z$	$-p(x + \Delta x)\Delta y\Delta z$	$F_x\Delta\tau$

The first and second contributions add up to

$$(3a) \quad -\frac{\partial p}{\partial x}\Delta x\Delta y\Delta z = -\frac{\partial p}{\partial x}\Delta\tau$$

and yield after division by $\Delta\tau$

$$(3b) \quad -\frac{\partial p}{\partial x} + F_x = 0;$$

this can be written in the form

$$(4) \quad \text{grad } p = \mathbf{F},$$

which is correct for any direction at any point of the liquid.

The relations (3b) or (4) for the force components obviously constitute a necessary condition for the equilibrium. From statics of rigid bodies a second condition is known requiring that the resultant moment be zero. This condition must also apply to non-rigid bodies, for, if we remove or relax the internal constraints of a rigid mechanical system, we obtain a non-rigid system with a vastly increased number of degrees of freedom. Hence, *quite generally, any equilibrium condition for a rigid body must be valid a fortiori for a deformable body.*

It is, however, easily seen that the second or moment equilibrium condition is automatically fulfilled in the case of a liquid. The normal pressure cannot produce a moment about any axis. Moments about the x -axis, for instance, could be produced only by the shearing stresses p_{xy} and p_{yx} , but they vanish. The external force \mathbf{F} cannot produce a moment either; this is certainly true when we assume a continuous distribution of lines of force; such a distribution can be always considered as parallel in any infinitesimal region (the field of gravity is a simple example for what is meant). If, on the other hand, the lines of the field \mathbf{F} have a singular

point at our volume element (a point where the field lines intersect), then \mathbf{F} must needs vanish there, and so does the moment of \mathbf{F} . Eq. (4) is in fact not only a *necessary* but also a *sufficient* condition of equilibrium.

Eq. (4) includes a very remarkable theorem: *equilibrium is only possible if the external force has a potential*, that is, if \mathbf{F} can be represented as the gradient of a scalar function. In this case we may write

$$(5) \quad \mathbf{F} = - \text{grad } U$$

where the minus sign is prompted by the relation to the potential energy, cf. Vol. I, appendix to 18.⁵ The *existence* of the potential function U is not sufficient, U must also be *single valued within the space occupied by the liquid*. Only under this assumption is it possible to calculate p from (4) as a single-valued scalar point function in the form

$$(6) \quad p + U = \text{const.}$$

The integration constant in (6) must be determined by special conventions concerning the normalization of the potential and the pressure.

Postponing the further discussion of this theorem to the end of this article, we deal for the present with the regular case in which the force \mathbf{F} has a single-valued potential and take gravity as an example. Let $z = 0$ be the surface of the liquid (call it "water" for simplicity) and orient the positive z -axis vertically downward. Then

$$(7a) \quad \mathbf{F} = F_z \mathbf{k}; F_z = \rho g = \gamma,$$

$$(7b) \quad U = -\rho g z = -\gamma z.$$

Here $\gamma (= \rho g)$ denotes the *specific weight* of the water as distinguished from the *specific mass* or density ρ . In writing (7b) the arbitrary constant in U has been adjusted so as to give zero potential at the surface. We obtain now from (6)

$$(8) \quad p = \gamma z + \text{const.},$$

where *const* is the pressure value at the surface $z = 0$, equal to the atmospheric pressure; however, p can also be given the meaning of the overpressure relative to the atmosphere (gauge pressure), which is more convenient for what follows. Let p have this meaning, then (8) becomes

$$(8a) \quad p = \gamma z.$$

This equation contains the well known elementary rules about communicating vessels, viz. equal pressure at equal depth in each of the

⁵See e.g., T. C. Slater and N. H. Frank, *Mechanics*, McGraw-Hill, New York, 1947, Sec. III,2.

interconnected vessels regardless of shape. The same equation may also be obtained directly from the differential formula (4). One follows the shape of the vessel along a broken line consisting of a series of vertical and horizontal segments inside the water and integrates. Along the horizontal segments $dp = 0$, along the vertical ones $dp = \gamma dz$. Summation of the vertical contributions gives immediately $p = \gamma z$ at the depth z .

Let us insert here a few basic numerical constants: normal atmospheric pressure = 76 cm Hg, density of Hg 13.596 gr/cm³; hence from (8a), $p_{atm} = 76 \times 13.596 \times g \text{ gr/cm}^2 = 1033 g \times \text{gr/cm}^2 = 1.033 \text{ kg-wt./cm}^2$. One cm² of a water surface carries a pressure load of about 1 kg-weight which makes 10 metric tons per m². The height of a water column corresponding to 76 cm Hg would be 10.33m, since for this height $p_{atm} = 1033 \times 1 \times g \text{ gr/cm}^2 = 1.033 \text{ kg-wt./cm}^2$ where $\rho = 1$ has been used.

We now consider an example that combines centrifugal force and gravity: a liquid in a drum (centrifuge) rotates with constant angular velocity ω about a vertical axis. The centrifugal force per unit of volume is

$$(9) \quad \mathbf{F} = F_r \mathbf{r}; F_r = \rho r \omega^2; \mathbf{r} \text{ is a unit vector } \perp \text{ to the axis.}$$

Its potential is given by

$$(9a) \quad U = -\frac{1}{2} \rho r^2 \omega^2.$$

The total potential of gravity and centrifugal force is (except for a constant) given by

$$U = -\rho g z - \frac{1}{2} \rho r^2 \omega^2 = -\gamma \left(z + \frac{r^2 \omega^2}{2g} \right).$$

From (6), the pressure in the rotating liquid is found as

$$(10) \quad p = \gamma \left(z + \frac{r^2 \omega^2}{2g} \right) + \text{const.}$$

To determine the constant in (10) let us first mark the water level in the axis of the drum, i.e., at $r = 0$, by z_0 . If p is again the overpressure, we have for $z = z_0$ and $r = 0$ from (10)

$$0 = \gamma z_0 + \text{const}, \quad \text{const} = -\gamma z_0$$

and in general

$$(11) \quad p = \gamma \left(z - z_0 + \frac{r^2 \omega^2}{2g} \right).$$

The free surface, characterized by $p = 0$, has the equation

$$(12) \quad z_0 - z = \frac{r^2 \omega^2}{2g}.$$

It is the well known paraboloid of rotation indicated in Fig. 7. Since z is positive downward, $z_0 - z$ is the ordinate of the parabolic meridian curve counted positive upward. On denoting by h the difference of the water

FIG. 7. The paraboloid surface of a fluid mass in rotation. The rise along the wall can be considered as velocity head.

FIG. 8. The equilibrium of a prismatic hull. The buoyancy is the resultant of all pressure forces acting on the surface.

levels at the circumference and the center, and by v the circumferential velocity, h appears in the well known form of the velocity head,

$$(13) \quad h = \frac{v^2}{2g}.$$

The surfaces of constant pressure are congruent paraboloids, obtained by displacing the free surface vertically downward.

Next we turn to the problem of the *equilibrium of a boat* where again gravity is the only external force present. Fig. 8 represents a cross section normal to the longitudinal axis of the boat (positive y -axis forward). Let us think of the hull as a cylindrical surface with generatrices parallel to the y -axis. S is the center of mass of the boat, C the center of mass of the displaced water or of the "displacement", when the boat is upright.

Defining the buoyancy of the boat as the resultant of all pressure forces acting upon the wetted surface, we can show that this resultant passes through C . The point C is thus called the center of buoyancy.

Let $d\sigma$ be a surface element of the hull. According to the simplified form of the hull, $d\sigma = ds dy$ where ds is the line element of the cross section. The pressure γz acts in line with the surface normal of $d\sigma$, thus the pressure force is $\gamma z d\sigma$ and its vertical component is $\gamma z d\sigma \cos(n, z)$, where n is the inward normal of $d\sigma$. With $d\sigma \cos(n, z)$ being numerically

equal to the projection of $d\sigma$ upon the horizontal, the vertical component of the force element can be written $\gamma z \, dx \, dy$. The buoyancy is then found as

$$(14) \quad B = \gamma \int z \, dx \, dy = \gamma V,$$

where V is the volume of the displacement; $B = \gamma V$ expresses, of course, the principle of Archimedes. The vector \mathbf{B} points vertically upward and its *line of action* is obtained in exactly the same way as if the elements $\gamma z \, dx \, dy$ were vertical vectors; \mathbf{B} can therefore be found as the resultant of the gravity forces that act upon the columns $z \, dx \, dy$ and thus passes through the center of gravity C of the displacement. In equilibrium, C and S lie on the same vertical and \mathbf{B} balances the weight of the boat \mathbf{W} as indicated in Fig. 8.

The condition $B = \gamma V = W$ determines the draught of the boat; naturally, the draught increases with the ship load. Note that also the horizontal components of the pressure forces acting on two opposite elements $d\sigma_1$ and $d\sigma_2$ at the same depth z balance each other. This remains true, even if the boat is unsymmetrically loaded, and follows immediately from the equality of the two projections upon the vertical plane $\cos(n_1, x) \, d\sigma_1 = \cos(n_2, x) \, d\sigma_2$.

We now want to learn something about the *oscillations of the boat* if the equilibrium position is disturbed. This is still a question well within the bounds of hydrostatics; for, in good approximation to reality, we may assume that the pressure distribution at any phase of the motion does not differ greatly from the hydrostatic pressure distribution that would prevail if this phase were a possible rest position.

Let us apply this idea to the rolling motion of the boat (rotation about the longitudinal or y -axis). The symmetry plane of the boat now subtends a variable angle with the vertical which will be denoted by ϑ . During the roll the shape of the displacement and the position of C will change. Assume a roll of small amplitude and let C' be the center of mass of the displacement at the end of the roll, C'' the corresponding point when the roll has gone in the opposite direction. Let \mathfrak{M} be the center of curvature of the curve $C'C''$ at the point C . (In Fig. 9, \mathfrak{M} has been constructed in an approximate way by intersecting the normals at the points C' and C'' .) This point \mathfrak{M} is known as the *metacenter*. Our figure illustrates the instant of the motion when the buoyancy \mathbf{B} passes through C' . As it is, \mathbf{B} is to the right of the weight vector \mathbf{W} which always passes through S . The moment \mathbf{M} of the couple formed by \mathbf{B} and \mathbf{W} is indicated in the figure by a circular arrow that acts so as to decrease the angle of roll ϑ . This is the necessary and sufficient condition for the *stability of*

the boat. It is fulfilled whenever the metacenter \mathfrak{M} is *above* the center of mass S , (so drawn in the figure). If \mathfrak{M} were below S , the moment M would tend to increase the disturbance and finally make the boat capsize.

FIG. 9. Metacenter and restoring moment for the tilted hull.

The distance between S and \mathfrak{M} is called the metacentric height h . According to the figure one has for small ϑ

$$|M| = M_r = hW \sin \vartheta \sim hW\vartheta.$$

The differential equation of the rolling motion is therefore the same as that of a compound pendulum (see e.g. Vol. I, 16).^o With Θ denoting the moment of inertia of the boat about its longitudinal axis,

$$(15) \quad \Theta \ddot{\vartheta} = M_r = -hW\vartheta,$$

and the circular frequency of the oscillations

$$(16) \quad \omega = \sqrt{\frac{hW}{\Theta}}.$$

Practical values of h are about 3 to 5 times the distance CS .

The validity of the foregoing is limited, strictly speaking, to infinitesimal amplitudes, where only one metacenter \mathfrak{M} has to be considered. \mathfrak{M} is actually the limiting position of the metacenter for $\vartheta \rightarrow 0$. In naval architecture one has to investigate the stability also for finite ϑ values, and takes into account that the point \mathfrak{M} moves in reference to the boat when ϑ changes.

We now turn to a discussion of what happens in a field of force that has *no single-valued potential*. Instead of an exposition in general terms

^oCf. Synge and Griffith, *op. cit.*, Sec. 7.2.

let us consider a simple example which can be easily shown in an actual experiment. A weakly conducting fluid such as a solution of CuSO_4 is placed in a shallow cylindrical container with insulating bottom and conducting side wall. A copper wire runs along the axis of the container. A potential difference of a few volts is put between center wire and side wall so as to maintain a current flowing from the axis through the fluid and spreading out toward the wall. Let I be the current and \mathbf{J} the vector of the current density, $|\mathbf{J}|$ being the current passing radially through the unit of area at the distance r from the axis. Obviously

$$(17) \quad |\mathbf{J}| = \frac{I}{2\pi r h}$$

where h is the height of the fluid layer. Now we impose a fairly homogeneous magnetic field \mathbf{H} whose lines of force pass perpendicularly through the fluid layer. The electromagnetic force acting upon a fluid element of unit volume is then given by

$$(18) \quad \mathbf{F} = \mathbf{J} \times \mathbf{H},$$

a vector that is normal to \mathbf{J} and \mathbf{H} and points therefore in the tangential direction. On introducing the polar angle φ and considering (17) and (18), we have

$$(19) \quad |\mathbf{F}| = F_\varphi = \frac{A}{r}, \quad A = \frac{I \cdot H}{2\pi h}.$$

This force has the potential

$$(20) \quad U = -A\varphi.$$

The negative gradient of U taken with respect to the cylindrical coordinates r, z is indeed zero and for the φ -direction

$$-\text{grad}_\varphi U = -\frac{1}{r} \frac{\partial U}{\partial \varphi} = \frac{A}{r} = F_\varphi.$$

Yet this potential is obviously not single-valued in the (doubly connected!) domain of the fluid, since it changes its value by the amount $2\pi A$ for each revolution of the variable φ about the axis $r = 0$.

Since the hydrostatic pressure must be a single-valued point function, a pressure distribution that balances this potential in the sense of Eq. (6) cannot exist. Hence the fluid yields to the force F_φ and begins to move. The velocity pattern of the motion is the single-vortex motion described in (4.29); the circumferential velocity is in our case

$$|\mathbf{v}| = v_\varphi = \frac{A}{r} \frac{t}{\rho}$$

where t is the time through which the magnetic field has been acting and ρ the density of the fluid. The velocity would grow continually if there were no friction.

The mathematician who studies a multi-valued function tries to arrange its set of values in a number of different branches. He leads an appropriate cut through the domain of definition of the function to restrict the possible types of curves along which the independent variable may be changed, and thereby establishes a single-valued branch of the function. We can do the analogous thing in our experiment by putting a separating wall (wood or cardboard) into the fluid between the axis and the side wall. The fluid builds up on one side and recedes from the other, and the potential is now a single-valued function in the domain of the fluid; a hydrostatic pressure $p = A\phi$ is built up so as to balance the potential U , and the motion stops. The pressure distribution can be inferred from the shape of the surface; on one side of the separating wall, the level is by the amount $2\pi A$ higher than on the other side. The level difference is thus equal to the modulus of periodicity of the potential.

7. Statics of Compressible Fluids

The density of compressible gases and vapors depends on the pressure. Let the relation between the two have the form $p = C\rho^n$ which can be set up in reference to a normal state p_0, ρ_0 as follows:

$$(1) \quad \frac{p}{p_0} = \left(\frac{\rho}{\rho_0}\right)^n.$$

The curve corresponding to this equation is known in technical and astrophysical applications as a *polytrope*; n is called the *polytropic exponent*.

In the isothermal state (constant temperature throughout the fluid), n equals 1. This is an immediate consequence of the equation of state

$$(2) \quad p = \rho \frac{R}{\mu} T,$$

where R = universal gas constant, μ = molar weight⁷ of the gas (e.g.,

⁷As is well known the number of grams in a *mole* equals the sum of the atomic weights of the gas. Instead of *molar* weight the term *molecular* weight is frequently used, but we wish to save this term in order to apply it to the actual weight (or more properly, the mass) of the single molecule. As R. W. Pohl has pointed out (Z.f.Phys., 121, 5-13, 1943) the definition of the mole depends on the definition of the unit of mass. If gr is replaced by kg, the mole changes into the "kilomole". The molar volume and Loschmidt's number per mole (Avogadro's number) change correspondingly (see later).

$\mu = 32$ gr for O_2), T = absolute temperature. In the *adiabatic* state (convective equilibrium such as results from a vigorous mixing process without heat exchange) $n = 1.4$ for diatomic gases.* In aeronautics a mean value of $n = 1.2$ is sometimes assumed (polytropic exponent of the atmosphere, see below).

It is known that the exponent $n = 1.4$ of the adiabatic state is equal to the ratio c_p/c_v of the specific heats at constant pressure and constant volume. This ratio follows from the first law of thermodynamics by means of an application of classical statistics (equipartition theorem of energy). The theoretical value is obtained as $c_p/c_v = 1 + 2/f$, where f is the number of degrees of freedom of the gas molecule. For a diatomic molecule such as N_2 or O_2 this number equals 5 (three degrees of freedom of translation and two of rotation; the rotation about the line connecting the two atoms cannot be excited for quantum-theoretical reasons), hence the value $n = 1 + 2/5 = 1.4$.

In the case of a compressible fluid, it is convenient to follow a different convention in measuring the external force. Previously referred to the *unit of volume* and denoted by F , we refer the external force now to the *unit of mass* and denote it by P . Thus

$$(3a) \quad F\Delta\tau = P\Delta m, \quad \text{hence } F = \rho P.$$

In the case of gravity where $|F| = \rho g$ we have simply

$$(3b) \quad \pm |P| = P_z = \pm g,$$

the sign depending on the choice of the orientation of the z -axis; in the case of the centrifugal force where $|F| = \rho r\omega^2$ as in (6.9) we have

$$(4) \quad |P| = r\omega^2.$$

The advantage of the new notation becomes apparent if we consider the

In CGS units the gas constant $R = 8.31 \times 10^7$ erg/centigrade; on the other hand, if one uses Meter-Kilogram-Second (MKS) units as Pohl does, the powers of ten drop out. In the same way as the unit of force in the MKS system is defined by 1 Dyne = 10^5 dyne, we can introduce as unit of energy in the MKS system

$$1 \text{ Erg} = 1 \text{ M}^2\text{KS}^{-2} = 1 \text{ M} \cdot 1 \text{ Dyn} = 10^7 \text{ erg} = 1 \text{ Joule}.$$

The gas constant is then $R = 8.31$ Erg/centigrade. Cf. the remarks about MKS-units in Vol. I, end of 1, also Slater and Frank, *op. cit.*, Sec. I.5.

*The pressure distribution within the gaseous mass is such that an arbitrary adiabatic displacement of a particle does not disturb its temperature equilibrium with the neighboring particles, cf. problem II, 1a.

equilibrium condition (6.4) which is correct for both compressible and incompressible fluids. It reads now

$$(5) \quad \frac{1}{\rho} \text{grad } p = \mathbf{P},$$

where the second member is a known quantity and the first member can be expressed in terms of either p or ρ , if a p, ρ -relation is known.

For the p, ρ -relation (1), Eq. 5 takes the form

$$(6) \quad \text{grad } \Phi = \mathbf{P}, \quad \text{where} \quad (6a) \quad \Phi = \frac{p_0^{1/n}}{\rho_0} \frac{p^{1-(1/n)}}{1 - (1/n)}.$$

The same Eq. (6) is correct for any non-polytropic p, ρ -relation provided we explain the quantity Φ by

$$(6b) \quad \Phi = \int_A^B \frac{dp}{\rho}.$$

Here A is a fixed point, B is the variable field point with coordinates x, y, z .

In the same way as (6.4), Eq. (6) implies that *in a compressible fluid, too, equilibrium is only possible when the external force, that is in the present case, the external force per unit of mass \mathbf{P} , has a potential*. On denoting the potential by V , we draw from (6)

$$(7) \quad \text{grad } (\Phi + V) = 0, \quad \Phi + V = \text{const.}$$

For the field of gravity $V = gz$, where z is counted positive upward. When the polytropic relation (1) is used, \mathbf{P} is given by (6), and the second relation (7) takes the form

$$(8) \quad \frac{p_0^{1/n}}{\rho_0} p^{1-(1/n)} = \frac{n-1}{n} (\text{const} - gz).$$

At $z = 0$, $p = p_0$ (reference pressure). The constant in (8) is found from $p_0/\rho_0 = \text{const } (n-1)/n$. Eq. (8) can then be written as

$$(9) \quad p = p_0 \left(1 - \frac{n-1}{n} \frac{\rho_0}{p_0} gz \right)^{n/(n-1)}.$$

On expressing p by ρ we obtain

$$(9a) \quad \rho = \rho_0 \left(1 - \frac{n-1}{n} \frac{\rho_0}{p_0} gz \right)^{1/(n-1)}.$$

Formulas (9) and (9a) represent the distribution of pressure and density in a polytropic atmosphere; its altitude h can be determined by setting $p = 0$ or $\rho = 0$:

$$(9b) \quad h = \frac{n}{n-1} \frac{p_0}{\rho_0 g}.$$

By reintroducing h in (9) and (9a) these equations can now be simplified and read

$$(10) \quad p = p_0 \left(1 - \frac{z}{h}\right)^{n/(n-1)}, \quad \rho = \rho_0 \left(1 - \frac{z}{h}\right)^{1/(n-1)}.$$

The distribution of the temperature can be found when the ratio p/ρ is calculated from (10) and the equation of state (2) is applied:

$$(11) \quad RT = \mu \frac{p_0}{\rho_0} \left(1 - \frac{z}{h}\right).$$

According to this, the temperature distribution in the polytropic atmosphere is a linear function of the altitude, dropping from $T_0 = \mu p_0 / \rho_0 R$ to $T = 0$ between $z = 0$ and $z = h$.

Numerical results for the altitude of the polytropic atmosphere are found from (9b): in the adiabatic case, $n = 1.4$, the altitude is only 28 km; in the polytropic case, when one chooses $n = 1.2$, one obtains 48 km; the altitude of the isothermal atmosphere is, of course, *infinite*.

The assumption $T = \text{const}$ is not permissible for the entire atmosphere. In the troposphere, the lowest part of the atmosphere, there is a very noticeable temperature lapse as one goes up; in the stratosphere, the temperature first remains constant over a considerable interval and increases later on. The boundary between troposphere and stratosphere is located at an average height of 12 km, at the poles it is lower than at the equator. For minor altitude differences the assumption of constant temperature may be maintained. The pressure and density distribution resulting in this case is well known under the name of the *barometric formula*. Since this formula is of general interest, it will be derived directly from the fundamental Eq. (5).

On setting $P_z = -g$ and writing (2) in the form

$$(12) \quad \rho = Cp, \quad C = \frac{\mu}{RT},$$

we obtain from (5)

$$\frac{1}{p} \frac{dp}{dz} = -Cg.$$

This gives on integration

$$(13) \quad \log p = -Cgz + \log p_0,$$

where p_0 is the pressure at the ground ($z = 0$); on solving for p , one has

$$(14) \quad p = p_0 e^{-Cgz} = p_0 e^{-\mu g z / RT}.$$

The same formula holds for the distribution of the density [comp. (12) or $\rho/\rho_0 = p/p_0$]:

$$(15) \quad \rho = \rho_0 e^{-\mu g z / RT}.$$

According to (13), the altitude may be read directly from a barometer if the instrument is furnished with an appropriate scale.*

One can interpret Eq. (15) in the sense of a sedimentation equilibrium of the air masses. It was Jean Perrin who successfully applied this idea to make a laboratory model of the atmosphere using a homogeneous emulsion of mastic droplets in water. His aim was to determine in this way a fundamental constant of atomic theory. That this can be done is evident as soon as μ in Eq. (15) is replaced by Lm , where L is Loschmidt's⁹ (or Avogadro's) number, i.e. the number of molecules per mole, and m is the mass of the single molecule; mg would therefore be the molecular weight in the proper sense of the word. Eq. (15) then becomes

$$(15a) \quad \rho = \rho_0 e^{-Lmgz/RT}.$$

While it is impossible to measure directly m of an actual molecule, Perrin's model gas permits of a direct determination of *its* m (e.g. by weighing a sufficiently large number of mastic droplets). Eq. (15a) can then be

*Eq. (14) or (15) can be derived from the general Eq. (9) or (9a) by making n approach the limit 1 and using

$$e^x = \lim_{n \rightarrow \infty} \left(1 + \frac{x}{n}\right)^n.$$

⁹Sometimes one uses the term "Loschmidt's number" in the sense of the number of molecules per cm³ and distinguishes it from "Avogadro's number" = number of molecules per mole, a definition of Loschmidt's number that was proposed by Boltzmann in a memorial address for Loschmidt (L. Boltzmann, *Populäre Schriften*, Leipzig 1905, p. 243). It is true that Loschmidt had focused his attention only on the first of the two numbers which he was able to estimate by several gas-kinetic methods, but he could have easily derived the second from the first number on the basis of Avogadro's law. Yet one must admit that not even the crudest estimate of the order of magnitude of either one of the numbers was within Avogadro's reach, if one considers the general state of knowledge of his time. Since the number of molecules *per mole* is a fundamental constant of all atomic physics, it appears reasonable to give a characteristic name to this number alone. Should it not be the name of the man who was the first to devise methods for its determination?

used for a determination of L if the densities ρ and ρ_0 have been observed. The value obtained by Perrin in this way is 68×10^{22} , which is remarkably close to the value $L = 60.2 \times 10^{22}$ accepted today.

When we introduce in (15a) instead of R the gas constant per molecule¹⁰

$$(15b) \quad k = \frac{R}{L},$$

the exponential in (15a) becomes

$$(15c) \quad e^{-mgs/kT} = e^{-V/kT}.$$

Note that V stands here for the potential energy of a mass point m that has been elevated to the altitude z in the field of gravity. The right member of (15c) is called the *Boltzmann factor*; it involves a specified energy V , but its physical meaning can be extended to the energy states of any physical system and represents, generally speaking, the relative probability of such a state in reference to a standard state of equal temperature.

The Boltzmann factor is fundamental in all statistical investigations; the purpose of this short digression into atomic theory has been to point to its connection with the elementary barometric formula.

Since the molar weight μ occurs in formula (15), a possibility arises to separate heavy from light molecules in a mixture of gases by sedimentation. Practically, this cannot be done in the field of gravity, but a centrifugal field may be effectively used for that purpose.

The potential of the centrifugal force (4) per unit of mass is

$$(16) \quad V = -\frac{1}{2}r^2\omega^2.$$

According to (7) we have for the quantity Φ

$$(16a) \quad \Phi = \text{const} + \frac{1}{2}r^2\omega^2.$$

Here we assume ω to be constant [as in (6.9a)] all over the inside of the centrifuge. On the other hand, the integral Φ for an isothermal gas or mixture of gases is found from (6b) and (12)

$$(17) \quad \Phi = \frac{RT}{\mu} \int \frac{dp}{p} = \frac{RT}{\mu} \log \frac{p}{p_0}.$$

Here p_0 is the pressure at the axis of the centrifuge ($r = 0$), and the con-

¹⁰Usually called Boltzmann's constant although Planck, following Boltzmann's ideas, was the first to introduce it definitely.

stant in (16a) vanishes. From (16a) and (17) the pressure distribution inside the centrifuge is obtained:

$$(18) \quad \log \frac{p}{p_0} = \frac{\mu}{RT} \cdot \frac{1}{2} r^2 \omega^2, \quad p = p_0 \exp \left(\frac{\mu}{2} \frac{r^2 \omega^2}{RT} \right).$$

The pressure is seen to increase exponentially with increasing r .

Consider now a mixture of two gases with molar weights μ_1 and μ_2 . Eq. (18) gives two different partial pressures p_1 and p_2 with two different constants p_{01} , p_{02} that depend on the mixing ratio. The total pressure is $p = p_1 + p_2$. According to Eq. (18), the partial pressure that belongs to the larger molar weight increases more rapidly than that belonging to the smaller μ , when r increases. Since for a given temperature the pressures and densities change proportionally, the heavier component of the mixture is concentrated in the proximity of the circumference of the centrifuge. The numerical magnitude—or rather minuteness—of this effect for air (21% O₂, 79% N₂) will be the object of problem II.2.

As in the incompressible case, we may consider gravity in addition to the centrifugal force; the *gravity potential* $-gz$ is then to be added in Eq. (16). Instead of (18) we have

$$(19) \quad p = p_0 \exp \left\{ \frac{\mu}{RT} \left(-gz + \frac{1}{2} r^2 \omega^2 \right) \right\}.$$

The surfaces of constant pressure (hence constant density) are again paraboloids, but p_0 is now the pressure at the particular paraboloid $gz = r^2 \omega^2 / 2$, from which the other isobaric surfaces are obtained by an upward or downward translation. Note that there does not exist a free surface toward vacuum ($p = 0$) since the exponential function does not become zero for finite values of the argument.

Design and construction of centrifuges of enormous efficiency have become possible through the researches of Th. Svedberg. The speed of these devices which now are commercially available under the name of ultracentrifuges goes up to 100,000 r.p.m., the strength of the centrifugal field reaches 750,000g. One of the purposes of these machines is to sort protein molecules (molar weight about 30,000). Their principal field of application is in colloidal chemistry and biology where the objects of investigation are approximately incompressible mixtures of liquids rather than compressible gases.

8. The State of Stress of an Elastic Solid

The mathematical characterization of the stresses in a solid body is complete when the stress is recognized as a symmetrical tensor of second

order. In other words, it must be shown that the array of stresses

$$\sigma = \begin{pmatrix} \sigma_{xx} & \sigma_{xy} & \sigma_{xz} \\ \sigma_{yx} & \sigma_{yy} & \sigma_{yz} \\ \sigma_{zx} & \sigma_{zy} & \sigma_{zz} \end{pmatrix}$$

is symmetric about the principal diagonal,

$$(1) \quad \sigma_{xy} = \sigma_{yx}, \text{ etc.,}$$

and that the components transform in the same way as the squares and products of the coordinates in passing to another Cartesian system [cf. Eq. (4.6)]

The symmetry can be easily inferred from the condition of moment equilibrium. Let us first set up the moment about the z -axis which acts on the volume element with the sides Δx , Δy , Δz , cf. Fig. 10. The normal

FIG. 10. The symmetry of the strain tensor. The resulting moment of the shear forces must vanish.

FIG. 11. Illustrating the equilibrium of forces acting on a tetrahedral volume element. F denotes the area.

stresses do not contribute anything to this moment since their vectors intersect with the z -axis. Consider now the tangential stresses σ_{xy} and σ_{yx} indicated in the figure. The corresponding forces transmitted to the volume element and the arms of these forces are

$$\sigma_{xy}\Delta y\Delta z, \quad \frac{1}{2}\Delta x \quad \text{and} \quad \sigma_{yx}\Delta z\Delta x, \quad \frac{1}{2}\Delta y.$$

For the signs of the resulting moments refer to Fig. 10, observing the convention that the direction of a stress component be indicated by its second index, when it acts on a "positive" surface element (cf. p. 38). The sum of the moments due to σ_{xy} and σ_{yx} then becomes

$$(2) \quad \frac{\Delta\tau}{2} (\sigma_{xy} - \sigma_{yx}).$$

This does not take care of the contributions of the shear stresses acting across the "negative" x - and y -surfaces of our volume element. Let σ'_{xy} and σ'_{yx} be these stresses; on expanding the first in terms of Δx , the second in terms of Δy , one sees immediately that $\sigma'_{xy} = -\sigma_{xy}$ and $\sigma'_{yx} = -\sigma_{yx}$ if terms of the order Δx and Δy are neglected. The contributions of these stresses to the moment about the z -axis is therefore once more the quantity (2) if only terms of the order of magnitude $\Delta\tau$ are retained. An additional external force \mathbf{F} (per unit of volume) will in general also be present; its moment is $|\mathbf{F}| \Delta\tau l$ where the arm l is of a smaller order of magnitude than the side length [see 6, after Eq. (4)]: it cannot possibly balance the reactive moments. Thus the equilibrium condition requires that the expression (2) vanishes by itself, but this is identical with the first symmetry condition in (1). The other two follow in the same way by considering moments about the x - and y -axes.

The proof of our second point, the *tensor character of the stress*, is more involved. It must be based on the *vector character* of the *reactive forces* that are transmitted across a surface element, just as the corresponding proof for the strain tensor was based on the vector character of the displacement.

We first set up the conditions for the equilibrium of forces acting on a tetrahedron, three faces of which coincide with the coordinate planes while the fourth is formed by a plane of arbitrary normal direction n (Fig. 11). Let the area of the oblique face be F_n , and F_x , F_y , F_z the areas of the faces lying in the planes $x = 0$, $y = 0$, $z = 0$ and consider these areas as projections of F_n :

$$(3) \quad F_x = F_n \cos(n, x), \quad F_y = F_n \cos(n, y), \quad F_z = F_n \cos(n, z).$$

The equilibrium condition for the x -direction is then¹¹

$$(4) \quad F_n \sigma_{nx} = F_x \sigma_{xx} + F_y \sigma_{yx} + F_z \sigma_{zx},$$

which because of (3) may be written

$$(5) \quad \sigma_{nx} = \alpha_1 \sigma_{xx} + \beta_1 \sigma_{yx} + \gamma_1 \sigma_{zx}.$$

¹¹One checks with the aid of Fig. 11 that F_x , F_y , F_z are *negative* x -, y -, z -surfaces; hence, in the total x -force, the terms with factors σ_{xx} , σ_{yx} , σ_{zx} are originally negative. In Eq. (4) they have been transferred to the right side with the *positive* sign.

Here α_1 , β_1 , γ_1 have been written for the direction cosines in (3) as indicated in the following scheme:

	n	t	t'
x	α_1	α_2	α_3
y	β_1	β_2	β_3
z	γ_1	γ_2	γ_3

Eq. (5) expresses the x -component of the stress acting across the n -surface. The y - and z -components can be determined analogously by setting up the equilibrium conditions for the y - and z -directions. One obtains

$$(6) \quad \sigma_{ny} = \alpha_1 \sigma_{xy} + \beta_1 \sigma_{yy} + \gamma_1 \sigma_{zy},$$

$$(7) \quad \sigma_{nz} = \alpha_1 \sigma_{xz} + \beta_1 \sigma_{yz} + \gamma_1 \sigma_{zz}.$$

The *normal stress* on the n -surface results now from (5), (6) and (7) by projecting the stress vector

$$(8a) \quad \sigma_{nx} \mathbf{i} + \sigma_{ny} \mathbf{j} + \sigma_{nz} \mathbf{k}$$

on the n -direction. The projection equals

$$(8) \quad \begin{aligned} \sigma_{nn} &= \alpha_1 \sigma_{nx} + \beta_1 \sigma_{ny} + \gamma_1 \sigma_{nz} \\ &= \alpha_1^2 \sigma_{xx} + \beta_1^2 \sigma_{yy} + \gamma_1^2 \sigma_{zz} + 2\alpha_1 \beta_1 \sigma_{xy} + 2\beta_1 \gamma_1 \sigma_{yz} + 2\gamma_1 \alpha_1 \sigma_{xz}. \end{aligned}$$

The directions t and t' already introduced may be realized as the legs of a right angle lying in the n -surface in an otherwise arbitrary position. We now project the stress vector (8a) also upon the directions t and t' and obtain the *tangential* or *shear stress* across the n -surface, resolved in a t - and t' -component:

$$(9) \quad \begin{aligned} \sigma_{nt} &= \alpha_2 \sigma_{nx} + \beta_2 \sigma_{ny} + \gamma_2 \sigma_{nz} \\ &= \alpha_1 \alpha_2 \sigma_{xx} + \beta_1 \beta_2 \sigma_{yy} + \gamma_1 \gamma_2 \sigma_{zz} \\ &\quad + (\beta_1 \alpha_2 + \alpha_1 \beta_2) \sigma_{xy} + (\gamma_1 \beta_2 + \beta_1 \gamma_2) \sigma_{yz} + (\alpha_1 \gamma_2 + \alpha_2 \gamma_1) \sigma_{xz} \end{aligned}$$

(for $\sigma_{nt'}$, change subscript 2 into 3). When numerals are introduced instead of the subscripts x, y, z and n, t, t' and α_{ik} is written for the nine

direction cosines, (8) and (9) and the corresponding relation for $\sigma_{n'}$ can be written in the condensed form

$$(10) \quad \sigma'_{i'h} = \sum_i \sum_m \alpha_{i1} \alpha_{hm} \sigma_{1m}.$$

This equation contains no reference to the size of the tetrahedron and gives, therefore, normal and tangential stresses acting across an arbitrary n -plane through O in Fig. 11. Its full significance is obtained if we disregard the particular roles of n , t , and t' . Eq. (10) is then seen to express the stresses acting on a cell parallel to the arbitrary orthogonal triad n, t, t' by the stresses on a cell parallel to x, y, z .

Since (10) has the form of the tensor transformation formulas as derived for the strain tensor in (4.5), we may from now on refer to the *stress tensor* and visualize the state of stress in the neighborhood of a point by means of a stress quadric (ellipsoid, hyperboloid, etc.) Magnitude and direction of the principal stresses are determined by the principal axes of the quadric. Any state of stress can be represented for a sufficiently small neighborhood of the field point as the sum of three mutually "orthogonal" tensors of simplest structure, viz. unidirectional tensions or compressions in correspondence with Helmholtz's theorem for the strains in 1 Eq. (16).

In setting up the equilibrium condition for the infinitesimal *tetrahedron* in (4), only the reactive forces transmitted through the surfaces, but no body forces have been considered. This is justified since the contributions of the latter are proportional to the *volume* while the stresses have the order of magnitude of the areas of the *faces*. The situation is different if we now turn to the equilibrium of external and internal forces for a small *rectangular cell*.* We want to establish a relation that is analogous to the fundamental equation (6.4) of hydrostatics. To secure equilibrium in x -direction as in (6.3) we have to consider the contributions of the normal stresses acting on the positive and negative x -surfaces and, *in addition*, those due to the tangential x -stresses across the positive and negative y - and z -surfaces; the latter do not occur in hydrostatics. The sum must be balanced against the contribution of the body forces represented, per unit of volume, by the vector \mathbf{F} . This yields, after cancellation of the factor $\Delta\tau = \Delta x \Delta y \Delta z$, the equilibrium condition

$$(11) \quad \frac{\partial \sigma_{xx}}{\partial x} + \frac{\partial \sigma_{yx}}{\partial y} + \frac{\partial \sigma_{zx}}{\partial z} + F_x = 0.$$

The corresponding equations for the y - and z -directions are obtained by "rotating" the letters. Note that in (11) the \mathbf{F} term has the same sign as

*Since the area terms due to opposite faces now cancel [cf. the remark following Eq. (2)].

the stress derivatives while in (6.4) the signs were opposite. The reason is obviously that the positive sign now denotes a tension, while it denoted a pressure previously.

The triplet of equations that corresponds to (11) reads in condensed form:

$$(12) \quad \text{Div } \sigma + F = 0.$$

The symbol Div stands for "vector divergence"; it derives a vector from a tensor while the operation div, formally explained in the same way, derives a scalar from a vector. In the general tensor analysis, where tensors of arbitrary order are considered, certain operations that decrease the order of a tensor are studied. The present case occurs there under the heading "differentiation with subsequent contraction".¹²

The definition of the symbol Div contained in (12) is obviously limited to Cartesian coordinates. It can be generalized for arbitrary orthogonal systems by the introduction of the limit of a surface integral as in (2.20). Enclose the field point, at which the p -component of the divergence vector associated with the tensor field σ is to be calculated, in a closed surface f with outward normal n . The generalized definition of Div is then

$$(13) \quad \text{Div}_p \sigma = \lim_{\Delta\tau \rightarrow 0} \frac{1}{\Delta\tau} \int \sigma_{np} df$$

where $\Delta\tau$ is the volume enclosed by f , and σ_{np} the component of the stress that acts across the n -surface element, taken in the direction p .

In the particular case of Cartesian coordinates we take for $\Delta\tau$ the rectangular cell $\Delta x, \Delta y, \Delta z$, and verify the new definition (13) in the same way as in the argument leading from Eq. (2.20) to (2.20a). In the general case of orthogonal coordinates [cf. Eq. (2.22)], the surface f is again chosen as the boundary of the curvilinear rectangular cell $g_1\Delta p_1, g_2\Delta p_2, g_3\Delta p_3$. The component of the vector divergence in the direction dp_3 follows from (13) as

$$(14) \quad \text{Div}_3 \sigma = \frac{1}{g_1 g_2 g_3} \left\{ \frac{\partial}{\partial p_1} (g_2 g_3 \sigma_{13}) + \frac{\partial}{\partial p_2} (g_3 g_1 \sigma_{23}) + \frac{\partial}{\partial p_3} (g_1 g_2 \sigma_{33}) \right\}.$$

The meaning of σ_{ik} is, of course, the component of the stress in the direction of dp_k acting across a surface element that is perpendicular to the direction of dp_i .

To obtain the k^{th} component of the equilibrium condition the expression (14) must be augmented by the component of F acting in the direction

¹²Cf. Appendix I-IV. General tensor analysis has been developed to serve as the adequate mathematical language of the general theory of relativity.

of the coordinate p_k . This sum replaces the left member of Eq. (12) in the case of general coordinates.

But the conditions of equilibrium are not sufficient to determine the tensor field σ from the vector field \mathbf{F} , since the tensor has six independent components while Eq. (12) is only equivalent to three scalar equations. The three missing equations are not supplied by the conditions of the moment equilibrium as one might be tempted to believe, since that condition has already been exploited in establishing the *symmetry* of the stress tensor. For the *determination* of the stress tensor the strain-stress relations must be used as will be done in the following §.

In this connection one may ask for supplementary conditions which together with (12) would ensure that the six quantities σ represent a physically possible state of stress. The answer is found in the *conditions of compatibility*. The same question could have been asked in the case of the strain field, since the six functions ϵ depend on the three displacement components ξ, η, ζ and, of course, may not be chosen arbitrarily.¹³

In conclusion we have again compiled the more frequent notations for the stress tensor:

This book	σ_{xx}	σ_{yy}	σ_{zz}	$\sigma_{xx} = \sigma_{yx}$	$\sigma_{yy} = \sigma_{xy}$	$\sigma_{zz} = \sigma_{zz}$
Many American authors	τ_{xx}	τ_{yy}	τ_{zz}	$\tau_{xx} = \tau_{yx}$	$\tau_{yy} = \tau_{xy}$	$\tau_{zz} = \tau_{zz}$
Love and many English authors	X_x	Y_y	Z_z	$Y_x = X_y$	$Z_y = Y_z$	$X_z = Z_x$

Some English authors	P	Q	R	S	T	U
Engineering usage	σ_x	σ_y	σ_z	$\tau_{xy} = \tau_{yx}$	$\tau_{yz} = \tau_{zy}$	$\tau_{zx} = \tau_{xz}$

9. Strain-Stress Relations, Elastic Constants, Elastic Potential

In the present section the loads are supposed to be sufficiently small so that second and higher powers of the stress and strain components may be neglected. Then the general form of the relations between stress

¹³ Cf. Love, *Mathematical Theory of Elasticity*, 4th ed., Cambridge, 1927, pp. 40 and 135.

and strain components becomes *linear*. Hooke, a contemporary of Newton, was the first to state this "law", although in simpler formulation. About the limits of the linear law (proportional and elastic limits) some remarks will be found in Chap. VIII, 39.

We further assume that the elastic body is isotropic: its physical properties should be the same in all directions. Now it is well known that the structure of most solids such as minerals, metals and engineering materials in general is crystalline or microcrystalline. The following analysis refers therefore to "volume elements" that are large compared to the microstructure of the material, that is, what we call a volume element contains a great number of irregularly oriented microcrystals. The elastic properties of macroscopic crystals will be discussed in Chap. VIII.

A volume element cut parallel to the principal axes of the stress ellipsoid makes a convenient starting point for our analysis. The three pairs of faces are subjected to the principal stresses $\sigma_1, \sigma_2, \sigma_3$, while shear stresses σ_{ik} do not occur. It is then a first consequence of the assumed isotropy, that the shape of the volume element after loading is still rectangular. Thus there are no angular changes, the shear strains ϵ_{ik} are zero, and the state of strain consists in pure extensions along the principal axes of the stress ellipsoid. *Hence the principal axes of the stress quadric coincide with the principal axes of the strain quadric.* The principal extensions will be denoted by $\epsilon_1, \epsilon_2, \epsilon_3$, as in (1.14).

Now by the proposed linearity of the stress-strain relations the following relation between a stress component and the strain components is implied:

$$(1) \quad \sigma_1 = a\epsilon_1 + b\epsilon_2 + c\epsilon_3.$$

Since no axis is preferred, two further equations must be obtainable simply by rotation of the subscripts:

$$(1a) \quad \sigma_2 = a\epsilon_2 + b\epsilon_3 + c\epsilon_1, \quad \sigma_3 = a\epsilon_3 + b\epsilon_1 + c\epsilon_2.$$

Again for reasons of isotropy, c must equal b , in Eq. (1), otherwise the directions (2) and (3) would not be equivalent with regard to the stress σ_1 . It is convenient to rewrite (1) by adding $\pm b\epsilon_1$, viz.

$$\sigma_1 = (a - b)\epsilon_1 + b(\epsilon_1 + \epsilon_2 + \epsilon_3),$$

or, with a change in notation¹⁴

$$(2) \quad \sigma_1 = 2\mu\epsilon_1 + \lambda(\epsilon_1 + \epsilon_2 + \epsilon_3).$$

¹⁴Replacing the factor of ϵ_1 in Eq. (2) by 2μ is an advantage, as will be seen below [Eqs. (16) and (18)].

$$\epsilon_{xx} = \frac{1}{2\mu} \left(\sigma_{xx} - \frac{\lambda}{2\mu + 3\lambda} \Sigma \right) = 2\mu' \sigma_{xx} + \lambda' \Sigma$$

(6a)

$$\epsilon_{xy} = \frac{1}{2\mu} \sigma_{xy} = 2\mu' \sigma_{xy}.$$

or, condensed,

$$(7a) \quad \epsilon_{ik} = 2\mu' \sigma_{ik} + \lambda' \delta_{ik} \Sigma.$$

These are the general strain-stress relations and the constants appearing in (7a) are, in terms of μ and λ ,

$$(7b) \quad 2\mu' = \frac{1}{2\mu}, \quad \lambda' = -\frac{1}{2\mu} \frac{\lambda}{2\mu + 3\lambda}.$$

Eqs. (6) and (6a) show that the isotropic elastic body has *two elastic constants* which are physical characteristics of the material of the body and depend on the temperature. An anisotropic crystal has more than two elastic parameters; depending on the character of its asymmetry there may be up to 21 elastic constants, as will be seen in Chap. VIII. The quantities λ and μ , introduced by Lamé, are known as *Lamé's constants*, or better, *Lamé's moduli*.¹⁶ For general investigations they are the most convenient characteristics of the elastic behavior, but their physical meaning is not immediately obvious. The quantities λ and μ will now be expressed by two other constants that refer in a straightforward way to the simplest type of tension or compression experiment.

A vertical prismatic bar with cross-section F , the upper end of which is rigidly fixed, is subjected to a load P that acts at the lower end. Let the load P be uniformly distributed over the end cross-section. The tension across the end section (and across any other parallel section) is $\sigma = P/F$; σ is a *principal stress* since no side forces, and therefore no shear stresses, are active. The associated *principal extension* ϵ equals $\Delta l/l$, where l is the length of the bar and Δl the displacement of the end cross-section. It turns out that the ratio of stress to extension is a *constant of the material*, that is, it is independent of P , F , and l , as long as the loading is not excessive. This ratio is denoted by E and known as *Young's modulus*.¹⁷

¹⁶It stands to reason to have two different words for the coefficients of the stress-strain and those of the strain-stress relations. Following Voigt, the former, like (λ, μ) , could be called *moduli*, the latter, like (λ', μ') , *constants of elasticity* [cf. 40].

¹⁷Introduced 1807 by Thomas Young, the same who discovered the interference of light.

or *modulus of elasticity*. Thus, for a bar under tension, we have

$$(8) \quad E = \frac{\sigma}{\epsilon},$$

where E has the same dimension [force/area] as σ (ϵ is dimensionless). For steel and wrought iron an average value of E is 2×10^8 kg.-wt./cm².

Elongation, however, is not the only response to the loading that can be observed in the tension experiment; actually, it is always accompanied by a contraction of the cross-section. It is this same contraction which we notice on a much larger scale when a rubber band is stretched, and we take it as the natural adaptation of the material to the loading. Denoting the contraction, which is the same for all fibers of the cross-section, by $-\epsilon'$, in this case a positive number, we define quite generally

$$(9) \quad -\frac{\epsilon'}{\epsilon} = \nu \quad \text{or, using (8),} \quad \epsilon' = -\frac{\nu}{E} \sigma.$$

The quantity ν is also a *constant of the material*. It is called *Poisson's ratio* of transverse contraction to longitudinal extension.¹⁸

Poisson not only introduced this number, but actually determined its value as $\frac{1}{4}$, on the basis of a rather limited molecular theory. Modern lattice theory of the solid state has again taken up this problem and improved on Poisson's calculation; one of the results is that there is no universal theoretical value of ν . In engineering applications the accepted value for iron is $\nu = 1/m = 0.3$.

When the bar is under compression instead of tension, longitudinal contraction is accompanied by transverse dilatation, but E and ν remain the same in spite of the changes of sign that have occurred, provided, of course, that the loading is within the elastic limit (see also 39).

We now apply what we have learned in the simple tension experiment to analyze the general state of stress, which we consider as a superposition of three unidirectional stresses in the principal directions; the effect of each stress is the same as in the bar problem. Because of the linearity of all occurring relations we may superimpose the stresses as well as the associated strains. However, the extension along the principal axis 1 is not solely determined by the stress σ_1 , but in addition (if considered as a transverse contraction) by the stresses acting in the principal directions 2 and 3. In this way one obtains from (8) and (9)

$$\epsilon_1 = \frac{\sigma_1}{E} - \frac{\nu}{E} (\sigma_2 + \sigma_3) = \frac{1+\nu}{E} \sigma_1 - \frac{\nu}{E} (\sigma_1 + \sigma_2 + \sigma_3)$$

¹⁸The preferred letter for Poisson's ratio in American and English literature seems to be ν .

or, in condensed writing,

$$(10) \quad \epsilon_i = \frac{1+\nu}{E} \sigma_i - \frac{\nu}{E} \Sigma$$

On summing the relations (10) for $i = 1, 2, 3$, one has

$$(10a) \quad \Theta = \frac{1-2\nu}{E} \Sigma, \quad \Sigma = \frac{E}{1-2\nu} \Theta,$$

and by substituting Σ in (10) the result

$$(10b) \quad \sigma_i = \frac{E}{1+\nu} \left(\epsilon_i + \frac{\nu}{1-2\nu} \Theta \right)$$

is obtained. The relations which we wish to find result from a comparison between (10b) and (3). This leads to

$$(11) \quad 2\mu = \frac{E}{1+\nu}, \quad \lambda = \frac{\nu E}{(1+\nu)(1-2\nu)},$$

which express Lamé's parameters by E and ν whose physical significance is more immediate.

Let us now take up another particularly simple case of a stress field, viz. *equal pressure in all directions* as it is realized, e.g., inside the cylinder of a hydraulic press. Both the stress and the strain ellipsoid are now spheres [see also 4 after (11)]:

$$\sigma_1 = \sigma_2 = \sigma_3 = -p, \quad \Sigma = -3p, \quad \epsilon_1 = \epsilon_2 = \epsilon_3 = -\frac{1}{3} |\Theta|.$$

Eq. (10b) gives in this case

$$(12) \quad p = \frac{E |\Theta|}{3(1-2\nu)}.$$

We define now in analogy to (8) a *modulus of compression* K by the equation

$$(13) \quad K = \frac{p}{|\Theta|}$$

and infer from (12) and (13) at once

$$(14) \quad K = \frac{1}{3} \frac{E}{1-2\nu}.$$

The *incompressible case* $\Theta = 0$ corresponds to $K = \infty$ or $\nu = \frac{1}{2}$. This value represents the upper limit for the possible values of Poisson's ratio. For $\nu > \frac{1}{2}$ the behavior of the body becomes *unstable*: its response to an

external pressure would be an increase of volume ($\Theta > 0$) instead of a decrease.

We conclude this discussion with another particular stress field, that of pure shearing stress. Take a rectangular parallelepiped, the z -surfaces of which are free of stress while the shearing stress $\sigma_{xz} = \sigma_{zx} = \tau$ acts across the x - and y -surfaces. Our example is one of plain stress, that is, the stress field is independent of z and can be represented by simply drawing a cross-section parallel to the x - y -plane as in Fig. 12a. The

FIG. 12a. Change of shape in pure shear loading.

FIG. 12b. The principal stresses in pure shear loading are equal and opposite.

deformation due to τ changes the original rectangle into a rhomboid, one pair of right angles being diminished, the other pair increased by the angle γ . The stress quadric is, like the strain quadric in pure shear (cf. 4 Fig. 4a, b), a cylinder parallel to the z -axis the basis of which is an equilateral hyperbola. The principal axes form an angle of 45° with the x - and y -directions and the two principal stresses are numerically equal and of opposite sign: $\sigma_2 = -\sigma_1$; σ_3 is, of course, zero. This is a consequence of the invariance of the first scalar of the stress tensor, Σ : for the element considered originally (Fig. 12a), $\sigma_{xx} = \sigma_{yy} = \sigma_{zz} = 0$ by hypothesis, hence an element cut parallel to the principal axes must take tension and compression in equal amounts to make again $\Sigma = \sigma_1 + \sigma_2 = 0$.

The state of pure shear stress serves to define the *shear modulus* which we provisionally denote by G , a notation generally accepted in engineering practice. In partial analogy to (8) and (13) we set

$$(15) \quad G = \frac{\tau}{\gamma}.$$

The analogy is not complete: the denominators in (8) and (13) represent the *extension* and (cubical) *compression* that correspond to the stresses in the numerators, but in the present case, (15), the denominator is the *angular change* produced by the stress that stands in the numerator, and this change is *twice* the strain component obtained according to the definition (1.25).

To find G , that is, to express it by the elastic constants already introduced, we go back to the general relation (6), $\sigma_{xy}/2\epsilon_{xy} = \mu$, which reads in our present notation $\tau/\gamma = \mu$. Thus (15) and (11) yield at once

$$(16) \quad G = \mu = \frac{1}{2} \frac{E}{1 + \nu}.$$

The shear modulus G is identical with Lamé's modulus μ so that the notation G is no longer needed. Also the name *torsion modulus* is in use for this constant because of its significance for the problem of torsional waves (see p. 107) and the torsion problem of a bar, 42.

We are now able to determine completely the stress from the equilibrium condition (8.12). This problem was posed at the end of 8, and it was pointed out that the *three* equilibrium conditions were insufficient for a complete determination of the *six* stress components σ_{ik} . But if we express the σ_{ik} by the ϵ_{ik} and write for the ϵ_{ik} their original definitions (1.11) in terms of the displacements, we obtain three equations just sufficient to determine the displacement vector.

That is an easy job if Cartesian coordinates are used. The x -component of the vector divergence in (8.12) transforms, according to the stress-strain relation (6), into

$$\text{Div}_x \sigma = 2\mu \left(\frac{\partial \epsilon_{xx}}{\partial x} + \frac{\partial \epsilon_{yx}}{\partial y} + \frac{\partial \epsilon_{zx}}{\partial z} \right) + \lambda \frac{\partial \Theta}{\partial x},$$

which becomes, on going back to displacements by means of (1.11),

$$\text{Div}_x \sigma = \mu \left(2 \frac{\partial^2 \xi}{\partial x^2} + \frac{\partial^2 \xi}{\partial y^2} + \frac{\partial^2 \eta}{\partial y \partial x} + \frac{\partial^2 \xi}{\partial z^2} + \frac{\partial^2 \zeta}{\partial z \partial x} \right) + \lambda \frac{\partial \Theta}{\partial x}.$$

This is easily rearranged into

$$(17) \quad \text{Div}_x \sigma = \mu \nabla^2 \xi + (\mu + \lambda) \frac{\partial \Theta}{\partial x}.$$

On substituting (17) in the equilibrium conditions (8.12) and rotating the letters we obtain finally

$$(18) \quad \begin{aligned} \mu \nabla^2 \xi + (\mu + \lambda) \frac{\partial \Theta}{\partial x} + F_x &= 0, \\ \mu \nabla^2 \eta + (\mu + \lambda) \frac{\partial \Theta}{\partial y} + F_y &= 0, \\ \mu \nabla^2 \zeta + (\mu + \lambda) \frac{\partial \Theta}{\partial z} + F_z &= 0. \end{aligned}$$

These three fundamental equations determine the displacement vector ξ, η, ζ everywhere in the interior of the body if its behavior along the body surface is determined by appropriate boundary conditions. When the ξ, η, ζ have been found, the ϵ follow by differentiation and the σ by way of the stress-strain relations. Thus Eqs. (18) are the definitive differential equations of elastic equilibrium. The quantity μ occurs in (18) without the factor 2, which again indicates that the choice of notation in Eq. (9.2) was to the purpose.

Eqs. (18) are limited to Cartesian coordinates. If we wish to write them in general coordinates, we have to interpret the symbol ∇^2 as $\text{grad div} - \text{curl curl}$ according to (3.10a). On denoting the displacement vector ξ, η, ζ by δq as in (4.17)-(4.28), the legitimate vectorial form of Eq. (18) is obtained:

$$\mu \text{ grad div } \delta q - \mu \text{ curl curl } \delta q + (\mu + \lambda) \text{ grad } \Theta + F = 0,$$

Instead of $\text{div } \delta q$ we may write Θ and obtain

$$(19) \quad (2\mu + \lambda) \text{ grad } \Theta - \mu \text{ curl curl } \delta q + F = 0.$$

The transition to general coordinates p_1, p_2, p_3 is now governed by the general expressions (2.24)-(2.26) for grad , etc. Setting $P = \text{curl } \delta q$ for brevity, one has immediately

$$\begin{aligned} (2\mu + \lambda) \frac{1}{g_1} \frac{\partial \Theta}{\partial p_1} - \frac{\mu}{g_2 g_3} \left(\frac{\partial g_3 P_3}{\partial p_2} - \frac{\partial g_2 P_2}{\partial p_3} \right) + F_1 &= 0, \\ (20) \quad (2\mu + \lambda) \frac{1}{g_2} \frac{\partial \Theta}{\partial p_2} - \frac{\mu}{g_3 g_1} \left(\frac{\partial g_1 P_1}{\partial p_3} - \frac{\partial g_3 P_3}{\partial p_1} \right) + F_2 &= 0, \\ (2\mu + \lambda) \frac{1}{g_3} \frac{\partial \Theta}{\partial p_3} - \frac{\mu}{g_1 g_2} \left(\frac{\partial g_2 P_2}{\partial p_1} - \frac{\partial g_1 P_1}{\partial p_2} \right) + F_3 &= 0. \end{aligned}$$

The quantities Θ and P that occur here have according to (2.25) and (2.26) the meaning

$$\begin{aligned} (20a) \quad \Theta &= \frac{1}{g_1 g_2 g_3} \left\{ \frac{\partial}{\partial p_1} (g_2 g_3 \delta q_1) + \dots \right\}, \\ P_1 &= \frac{1}{g_3 g_3} \left(\frac{\partial}{\partial p_2} (g_3 \delta q_3) - \frac{\partial}{\partial p_3} (g_2 \delta q_2) \right), \dots, \dots \end{aligned}$$

The boundary conditions to be added to Eqs. (18) or (20) may refer either to displacements or to stresses, or, as in the problem of 44, partly to

the one and partly to the other (mixed boundary value problem). When the *displacements* are prescribed along the entire surface of the elastic body by

$$(21) \quad \xi = \xi_0, \quad \eta = \eta_0, \quad \zeta = \zeta_0,$$

where ξ_0, η_0, ζ_0 are point functions given along the surface, the boundary value problem is similar to that of potential theory (p. 25) but considerably more complicated. In order to prescribe the *stresses* one assumes a system of external forces distributed over the surface of the body in the form $\mathbf{F} = \mathbf{f}d\sigma$ so that the "surface density" \mathbf{f} of the external forces is a finite point vector given along the surface. The surface stresses developed by the body must be balanced by the given vector \mathbf{f} everywhere on the surface. Hence we have for each surface element with normal direction n

$$(21a) \quad \sigma_{nx} + f_x = 0, \quad \sigma_{ny} + f_y = 0, \quad \sigma_{nz} + f_z = 0.$$

In the particular case that *no external forces* act on the surface, the boundary conditions become

$$(21b) \quad \sigma_{nx} = \sigma_{ny} = \sigma_{nz} = 0.$$

Such is the case for the sides of the bent beam in 41 or for the bar in torsion in 42. When the components of σ are expressed by the ξ, η, ζ in (21a, b), three boundary conditions result for the first derivatives of the ξ, η, ζ . Thus the integration problem is similar to that of the second boundary value problem of potential theory (cf. problem I, 5), but again considerably more difficult.

The uniqueness of solution of the problems mentioned, in particular for a simply connected body, can be proved as in potential theory essentially by an application of Green's theorem (cf. p. 25). In such a proof, homogeneity of the material, hence uniform temperature, and strictly elastic behavior are assumed. In reality, however, internal stresses are present even without external loads: they are caused by imperfections of the casting, inhomogeneous cooling etc. and are a constant source of trouble for the engineer; in applied elasticity, they constitute an unknown element which makes the strict uniqueness proofs of the mathematical theory somewhat unrealistic.

We turn now to the energetic aspect of the stress-strain relation and determine first the *strain-energy* function. The calculation proceeds again in Cartesian coordinates x, y, z and displacement components ξ, η, ζ .

Consider the two x -surfaces of the volume element $\Delta\tau = \Delta x \cdot \Delta y \cdot \Delta z$ while an infinitesimal increment of the displacement

$$\xi, \eta, \zeta \rightarrow \xi + d\xi, \quad \eta + d\eta, \quad \zeta + d\zeta$$

is imposed on the strain field. The work done by the stresses across the negative and positive x -surface is, in the same order,

$$dW_x = -(\sigma_{xx}d\xi + \sigma_{xy}d\eta + \sigma_{xz}d\zeta)\Delta y\Delta z$$

and

$$\begin{aligned} dW_{x+\Delta x} = & +(\sigma_{xx}d\xi + \sigma_{xy}d\eta + \sigma_{xz}d\zeta)\Delta y\Delta z \\ & + \frac{\partial}{\partial x}(\sigma_{xx}d\xi + \sigma_{xy}d\eta + \sigma_{xz}d\zeta)\Delta x\Delta y\Delta z. \end{aligned}$$

The algebraic sum of the two expressions is clearly the second line of the second equation. On adding the work done by the external force \mathbf{F} in x -direction, one obtains

$$(22) \quad \left\{ \frac{\partial}{\partial x}(\sigma_{xx}d\xi + \sigma_{xy}d\eta + \sigma_{xz}d\zeta) + F_x d\xi \right\} \Delta x\Delta y\Delta z.$$

Two analogous expressions are obtained for the work done in the displacement of the y - and z -surfaces. On adding all three contributions and carrying out the indicated differentiations, the terms that contain the (not differentiated) factors $d\xi$, $d\eta$, $d\zeta$ cancel the F -terms, if we make use of the equilibrium condition (8.12). The work dW per unit of volume is thus found as

$$\begin{aligned} (23) \quad dW = & \sigma_{xx}d\frac{\partial\xi}{\partial x} + \sigma_{yy}d\frac{\partial\eta}{\partial y} + \sigma_{zz}d\frac{\partial\zeta}{\partial z} + \sigma_{xy}d\left(\frac{\partial\xi}{\partial y} + \frac{\partial\eta}{\partial x}\right) \\ & + \sigma_{yz}d\left(\frac{\partial\eta}{\partial z} + \frac{\partial\zeta}{\partial y}\right) + \sigma_{zx}d\left(\frac{\partial\zeta}{\partial x} + \frac{\partial\xi}{\partial z}\right). \end{aligned}$$

In this calculation we have employed the symmetry of the stress tensor and the fact that $\partial d\xi$ (the gradient of the incremental displacement) is commutative with $d\partial\xi$ (the increment of the gradient of the displacement) (cf. 4, Fig. 5; d here corresponds to δ there). Eq. (23) can be written in the form

$$\begin{aligned} (24) \quad dW = & \sigma_{xx}d\epsilon_{xx} + \sigma_{yy}d\epsilon_{yy} + \sigma_{zz}d\epsilon_{zz} + 2\sigma_{xy}d\epsilon_{xy} \\ & + 2\sigma_{yz}d\epsilon_{yz} + 2\sigma_{zx}d\epsilon_{zx} = \sum_i \sum_k \sigma_{ik}d\epsilon_{ik}, \end{aligned}$$

when the strain tensor is introduced.

It is possible to express relation (24) in terms of the strain tensor alone, by means of the stress-strain relations. Substitution according to (7) yields the form

$$(25) \quad dW = 2\mu \sum_i \sum_k \epsilon_{ik}d\epsilon_{ik} + \lambda\theta d\theta.$$

This expression is a total differential as long as the "constants" λ and μ remain truly constant in the process of loading. We may then speak of a strain-energy function, without referring to the particular way of loading that starts from the (stress-free) initial state and leads to the final (stressed) state. In other words, the strain-energy is a *function of state*. It reads in terms of the strain components:

$$(26) \quad W = \mu \sum \sum \epsilon_{ik}^2 + \frac{\lambda}{2} \Theta^2.$$

As a function of state, W must be independent of the particular choice of coordinates x, y, z . This can be seen immediately through the following rearrangement:

$$\begin{aligned} \sum \sum \epsilon_{ik}^2 &= (\epsilon_{11} + \epsilon_{22} + \epsilon_{33})^2 \\ &\quad + 2(\epsilon_{12}^2 + \epsilon_{23}^2 + \epsilon_{31}^2 - \epsilon_{11}\epsilon_{22} - \epsilon_{22}\epsilon_{33} - \epsilon_{33}\epsilon_{11}) \\ &= \Theta^2 - 2\Delta, \end{aligned}$$

where Δ is the second scalar of the strain tensor, as explained in Eq. (4.9). Thus, instead of (26), we have the invariant representation

$$(26a) \quad W = \frac{2\mu + \lambda}{2} \Theta^2 - 2\mu\Delta.$$

A more symmetrical expression for W which also makes the invariance evident is

$$(26b) \quad W = \frac{1}{2} \sum \sum \sigma_{ik} \epsilon_{ik}.$$

The right member in this equation is the simplest *simultaneous invariant* of the two tensors σ and ϵ . On expressing σ by ϵ or vice versa [Eqs. (7) or (7a)] one obtains the quadratic forms

$$(27) \quad W(\epsilon) \quad \text{or} \quad W(\sigma).$$

The first is, of course, identical with (26), the second can be obtained from (26) by formally replacing ϵ, Θ by σ, Σ and μ, λ by μ', λ' from (7b).

The factor $\frac{1}{2}$ that occurs, e.g., in (26b) is in obvious connection with Hooke's law, that is, with the assumed *linear* relation between stress and strain.

From the quadratic forms (27) the stress and strain components can be reobtained; they are the partial derivatives of the energy W with respect to the corresponding strain and stress components:

$$\sigma_{ik} = \frac{\partial W(\epsilon)}{\partial \epsilon_{ik}}, \quad \epsilon_{ik} = \frac{\partial W(\sigma)}{\partial \sigma_{ik}}.$$

For this reason, the negative strain-energy W is also called the *elastic potential* per unit of volume.

We have already observed that μ and λ are temperature-dependent parameters. If the temperature is kept constant while the load is applied (isothermal transition), then μ and λ are true constants, and the preceding determination of W is correct. If on the other hand the transition is carried out without heat transfer to or from the individual volume elements of the body (adiabatic transition), then the strain energy can again be shown to be a function of state, but the "adiabatic" values of μ and λ are different from the "isothermal" ones. This difference is, as one would expect, especially noticeable in the gaseous state and will be discussed in 13 when the velocity of sound is calculated. In the more general case, as in a body with non-uniform temperature distribution, the strain energy is *not a function of state*, but depends on the path of the transition; the elastic potential does not exist.

10. Viscous Pressures and Dissipation, Particularly in Incompressible Fluids

The following analysis is based on an assumption about the nature of the viscous forces which, in the special form to be discussed first, is due to Newton. Let the velocity of the fluid $u(y)$ be everywhere parallel to the x -axis, increasing in some way with increasing y . The reactions due to viscous friction that are transferred through a surface normal to the y -axis are, according to Newton, proportional to the velocity gradient, the factor of proportionality μ depending on the nature of the fluid. We refer the reactive forces to the unit of area and designate them as frictional or viscous pressures. Newton's assumption then is

$$(1) \quad p_{yy} = -\mu \frac{\partial u}{\partial y}.$$

The minus sign as well as the notation p_{yy} requires some explanation. In Fig. 13 a surface SS has been indicated which, relative to the lower part of the fluid, is a positive y -surface, since the outward normal points in the direction of the positive y -axis. The fluid above SS , flowing faster, tries to take with it the fluid below SS ; the upper small arrow in Fig. 13 represents therefore the retarding action exerted on the upper fluid body by the lower one. Either arrow should be designated by σ_{yy} if we were to use stresses in our analysis, the upper one representing the $+x$ -traction across a $+y$ -surface, the lower one the $-x$ -traction across a $-y$ -surface. We use pressures, however, and this explains the minus sign in Eq. (1);

p_{yz} is negative for the positive y -surface (since $\partial u/\partial y$ is positive) and positive for the negative y -surface.¹⁹

Our aim is to generalize Newton's formula for the case of an arbitrary fluid flow. To do this we must go back to the fundamental theorem of kinematics of 1, which deals with the resolution of an infinitesimal displacement into translation, rotation, and deformation. The first two, as we know, correspond to rigid body motions and cannot involve internal friction. The friction is entirely due to the third part that can be de-

FIG. 13. Transfer of friction pressures in laminar flow. Newton's hypothesis.

scribed in terms of the strain tensor ϵ . Now, in a fluid the time rate of displacement rather than the displacement itself is the physically important quantity (see 5, p. 39), accordingly, we shall not consider ϵ , but $\dot{\epsilon}$ as responsible for the friction. In anticipation of the result of the subsequent discussion we assume now:

$$(2) \quad p_{ik} = -2\mu \dot{\epsilon}_{ik}, \quad \left. \begin{matrix} i \\ k \end{matrix} \right\} = x, y, z.$$

The factor of proportionality μ which has already occurred in (1) characterizes the internal friction and is called the *coefficient of viscosity*. The value of μ depends on the nature of the fluid and changes very strongly with the temperature (in liquids, increasing temperature makes μ decrease).

We show first that the set (2) is equivalent to (1) for the special flow of Fig. 13 where

$$u = u(y), \quad v = 0, \quad w = 0.$$

Applying (1.11) and the array (1.12) to the deformation velocities u, v, w rather than to the deformations ξ, η, ζ , we obtain

¹⁹Cf. the footnote on p. 30.

$$\begin{pmatrix} 0 & \frac{1}{2} \frac{\partial u}{\partial y} & 0 \\ \frac{1}{2} \frac{\partial u}{\partial y} & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$$

and the content of Eq. (2) reduces to the following equations which are identical with (1):

$$p_{xy} = p_{yx} = -\mu \frac{\partial u}{\partial y};$$

the other p_{ik} vanish.

Assumption (2) is in agreement with the tensor-analytic principles considered in the preceding article. This is at least true for *incompressible fluids*, and we wish to limit the validity of (2) to that case. Then $\Theta = 0$ by (5.1), and the stress-strain relations (9.7) become identical with (2) as soon as the stresses are replaced by the pressures (change of sign) and the strains by the rates of strain. Hence one would conclude from the uniqueness of the stress-strain relations that a tensor-invariant relation between p and $\dot{\epsilon}$ other than (2) cannot exist. (The physical meaning of the viscosity coefficient μ has, of course, nothing to do with Lamé's modulus μ in the last article.)

First, however, the following point must be clarified: in the theory of the elastic solid we were able to show by an equilibrium consideration that σ is a *symmetric* tensor. The corresponding argument is questionable in the case of the viscous tensor p , since the necessary transition to a sufficiently small volume element is no longer legitimate in the present case, as we shall see below. Suppose then one would admit the possibility that

$$p_{ik} \neq p_{ki}.$$

Now, an unsymmetric pressure tensor could always be resolved into a symmetric part \bar{p} and an antisymmetric part π such that

$$\bar{p}_{ik} = \bar{p}_{ki} \quad \text{and} \quad \pi_{ik} = -\pi_{ki}.$$

The latter may be represented by an (axial) vector [cf. Eq. (1.12a)] and can be invariantly connected only with a quantity of the same character. The vortex velocity ω is such a quantity, and it is the only one that can be used. One would then have to postulate a static-kinematic relation of the form

$$(3) \quad \pi_{ik} = -\kappa \omega_{ik}.$$

Hence to admit the possibility of the asymmetry of the viscous tensor p amounts to the acceptance of a "vortex friction" as in (3), but this concept is inadmissible since it leads to a nonsensical result even in the simplest case.

Suppose a drum filled with some viscous liquid is made to revolve about its axis. The liquid starts to rotate at the circumference of the drum and the motion is gradually communicated to the bulk of the fluid. While this goes on a moment is required to overcome the internal friction of the liquid in addition to the moment required for the acceleration of the moving mass. In the *steady state* which is finally reached, the angular velocity ω is everywhere the same; at least, one may safely consider this as the final state since no experience points to the contrary. The liquid rotates as a rigid body and surely *no moment* is needed to sustain the motion if bearing friction etc. is disregarded. In contrast to that, Eq. (3) contends the presence of friction also in the steady state. Originating in the fluid, the friction would be conveyed to the drum and would have to be balanced by an external moment.

This whole discussion is of a *phenomenological nature* in accordance with the general point of view taken in this volume, and the same is true for the preceding tensor-geometric considerations. The deformable medium is being considered as a *continuum* and no attention given to the *molecular* origin of the stresses or pressures. The molecular theory of *compressible* fluids will be dealt with in the kinetic theory of gases. It furnishes a *direct explanation of the frictional pressures* in terms of the transport of momentum by thermal motion or, as it is sometimes put, in terms of the diffusion of momentum. Such a theory is physically altogether more profound; for compressible fluids it leads of *necessity* to the relation (21) between pressure and rate of deformation,⁴⁰ which will be found at the end of this article. That more general relation comprises (2) as a special case if the fluid is incompressible ($\Theta = \dot{\Theta} = 0$). On the other hand, the gas-kinetic concepts do not directly apply to *incompressible* fluids, that is, not unless arbitrary additional assumptions are made. There is, however, no doubt that also in the incompressible case the single volume element is exchanging momentum with more distant volume elements, and that this constitutes the physical cause of fluid friction. But it is just this idea of interaction by exchange of molecules that is in contradiction with the transition to an *isolated* small fluid element as in 8.

In addition to the frictional pressures and superimposed on them, there is a uniform normal pressure of the same nature as the pressure in the

⁴⁰Cf. in particular the critical remarks of E. Fues, Z. f. Physik 118, 409 (1941) and 121, 58 (1943) which start from ideas of Maxwell and Boltzmann, like most investigations in that field.

fluid at rest when the external force \mathbf{F} is present. We denote it by p as before (no subscripts, since it is a scalar), although it is not identical with the hydrostatic p (see below). The total pressure tensor is then

$$(4) \quad P = \begin{pmatrix} p + p_{xx} & p_{xy} & p_{xz} \\ p_{yx} & p + p_{yy} & p_{yz} \\ p_{zx} & p_{zy} & p + p_{zz} \end{pmatrix}$$

We are now ready to state the relation that is the analogue of the equilibrium condition (8.12). Although it is true that we are not concerned with an elastic body at *rest*, but with a *flow* of fluid particles, we may first assume that (in the frame of reference under consideration) the motion proceeds without change of magnitude and direction of the velocity. Each particle is then in a state of mechanical equilibrium, and we can formulate an "equilibrium condition" also in the present case. It is modelled after (8.12) and reads (with the proper change of sign)

$$(5) \quad \text{Div } P = \mathbf{F}.$$

Here Div stands for the "vector divergence", explained in (8.13) in an invariant way. Written in Cartesian coordinates, (5) takes the form

$$(6) \quad \begin{aligned} \frac{\partial p}{\partial x} + \frac{\partial p_{xx}}{\partial x} + \frac{\partial p_{yx}}{\partial y} + \frac{\partial p_{zx}}{\partial z} &= F_x, \\ \frac{\partial p}{\partial y} + \frac{\partial p_{xy}}{\partial x} + \frac{\partial p_{yy}}{\partial y} + \frac{\partial p_{zy}}{\partial z} &= F_y, \\ \frac{\partial p}{\partial z} + \frac{\partial p_{xz}}{\partial x} + \frac{\partial p_{yz}}{\partial y} + \frac{\partial p_{zz}}{\partial z} &= F_z. \end{aligned}$$

These equations determine a steady fluid motion as soon as we express the six unknowns p_{ik} through the three velocity components u, v, w by means of (2). We obtain first

$$(7) \quad \frac{\partial p}{\partial x} - 2\mu \frac{\partial^2 u}{\partial x^2} - \mu \left(\frac{\partial^2 v}{\partial x \partial y} + \frac{\partial^2 u}{\partial y^2} \right) - \mu \left(\frac{\partial^2 w}{\partial x \partial z} + \frac{\partial^2 u}{\partial z^2} \right) = F_x,$$

which reduces on account of the condition of incompressibility

$$(8) \quad \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0$$

to

$$(8a) \quad \frac{\partial p}{\partial x} - \mu \nabla^2 u = F_x.$$

The corresponding equations for the y - and z -directions are

$$(8b) \quad \frac{\partial p}{\partial y} - \mu \nabla^2 v = F_v,$$

$$\frac{\partial p}{\partial z} - \mu \nabla^2 w = F_z.$$

Eqs. (8), (8a), (8b) form a system of *four* equations for the four unknowns u, v, w, p . The pressure p is, of course, not equal to the hydrostatic pressure value, but is to be found from the quadruplet of equations simultaneously with the unknowns u, v, w .

The same Eqs. (8)-(8b) can also be considered as approximate equations for a flow where the particle accelerations do not exactly vanish, but are so small that their omission appears to be justifiable. This type of fluid motion—"creeping" one might call it—will be studied in 35, 36.

In both cases (either exactly or approximately free of acceleration), boundary conditions must be added to the differential equations to specify a problem, but there is a fundamental difference between the boundary conditions to be imposed on a perfect and on a viscous fluid. While in the first case only the boundary condition $v_n = 0$ is to be fulfilled and arbitrary tangential velocities v_t may be admitted along the rigid walls, we must stipulate in the second case that the fluid adheres to the surface of the rigid boundaries. This implies, of course, that v_t approaches zero *continuously* in the neighborhood of the boundary, since a jump of v_t would mean an infinitely large gradient of v_t and, consequently, *infinitely large values of the viscous pressures p_{xx}* . Experiments on the flow in narrow tubes (see below) have justified this form of boundary conditions which we state once more:

$$(9) \quad v_n = 0, \quad v_t = 0.$$

The fundamental difference between perfect and viscous fluids makes it understandable that the transition from small friction to the limit of vanishing friction is not without analytical difficulties. We shall come back to this point in 33 (Prandtl's boundary layer).

We now discuss the simplest application of the equilibrium conditions (8) and boundary conditions (9), viz., the classical Hagen-Poiseuille flow³¹ in a capillary tube. Let the horizontal tube have circular cross section with a radius a , so small as to make the flow proceed in straight stream

³¹G. Hagen, Poggendorffs Ann. 46 (1839). J. Poiseuille, Comptes Rendus 11 (1840) 12 (1841). Hagen was superintendent of works in Berlin, Poiseuille a physician in Paris. Both found independently the law (15), essentially by experimental investigations.

lines parallel to the axis of the tube (for more details about laminar flow and the conditions of its stability, cf. 16). When the axis of the tube is taken as x -axis and the distance $r = \sqrt{y^2 + z^2}$ from the x -axis is introduced, the velocity distribution is

$$(10) \quad v = w = 0, \quad u = u(r).$$

Eq. (8) shows then that u is independent of x ; because of the cylindrical symmetry, u is a function of r alone. Gravity may be neglected in our case, hence the force \mathbf{F} is zero. Eq. (8b) gives now

$$(11) \quad \frac{\partial p}{\partial y} = \frac{\partial p}{\partial z} = 0, \quad \text{therefore} \quad p = p(x).$$

Since the first term of (8a) depends only on x , the second only on r , and their difference is zero, either term must be a constant, say $-A$. Thus we have

$$(11a) \quad \frac{dp}{dx} = -A, \quad \nabla^2 u = -\frac{A}{\mu}.$$

According to this, the constant A is the pressure gradient along the tube, or, if multiplied with the length of the tube l , the pressure difference Π between beginning and end of the tube. We substitute for $\nabla^2 u$ its value in cylinder coordinates (problem I, 3) and note that there is no dependence on φ and on the axial coordinate:

$$\nabla^2 u = \frac{1}{r} \frac{d}{dr} r \frac{du}{dr}.$$

The conclusions following from (11a) are then

$$\frac{d}{dr} r \frac{du}{dr} = -\frac{A}{\mu} r, \quad r \frac{du}{dr} = -\frac{A}{\mu} \frac{r^2}{2} + C_1.$$

Here C_1 must vanish since otherwise du/dr would become infinite for $r = 0$. A second integration yields

$$(12) \quad u = -\frac{A}{4\mu} r^2 + C_2.$$

The constant C_2 is to be determined from the boundary condition (9) which now reads

$$(13) \quad u = 0 \quad \text{for} \quad r = a.$$

The liquid sticks to the wall of the tube. There is no doubt that (13) is correct: it follows unequivocally from the observations and holds for water as

well as for non-wetting liquids such as mercury on glass. According to (12),

$$C_2 = \frac{A}{4\mu} a^2,$$

so that (12) takes the form

$$(14) \quad u = \frac{A}{4\mu} (a^2 - r^2).$$

The velocity profile is parabolic (cf. Fig. 14). The particles that are at the time $t = 0$ on a plane cross-section, lie at $t > 0$ on a paraboloid of rotation

FIG. 14. Laminar flow in a capillary tube; the liquid adheres to the wall, the velocity profile is parabolic.

the vertex of which travels in the direction of the flow while the points of contact with the wall remain fixed.

The volume discharge Q per unit of time is

$$(15) \quad Q = 2\pi \int_0^a ur \, dr = \frac{\pi}{8} \frac{A}{\mu} a^4.$$

This formula has served as the basis for most determinations of viscosity constants in the last hundred years. The velocity of flow averaged over the cross section

$$(16) \quad u_m = \frac{Q}{\pi a^2} = \frac{A}{8\mu} a^2$$

is half the maximum velocity u_{\max} , [Eq. (14) with $r = 0$]; the pressure loss follows from (15) and (16) as

$$(17) \quad \Pi = 8\mu l \frac{u_m}{a^2}.$$

The pressure loss due to friction is proportional to the mean flow velocity and inversely proportional to the square of the radius. This law which, in modified form, is also correct for other laminar flows (cf. problems II, 3 and 4 and Figs. 19 and 19a on p. 121) is in characteristic contrast to the law for turbulent flow (see 16) where the pressure loss is approximately proportional to the square of the average velocity and inversely proportional to the radius of the tube.

We turn to the discussion of the energetic aspect of viscous flow. To calculate the work done by the friction forces we can use Eq. (9.22) as a starting point. Replacing the stresses σ by the pressures p (change of sign)

and the *virtual* displacements $d\xi$, $d\eta$, $d\zeta$, by the quantities $u dt$, $v dt$, $w dt$, which now are *actual motions occurring in the time element dt* , we obtain in place of (9.22)

$$\left\{ -\frac{\partial}{\partial x} [(p + p_{xx})u + p_{xy}v + p_{xz}w] + F_x u \right\} dt \Delta x \Delta y \Delta z.$$

This is the work done by the uniform pressure p and the friction pressures p_{ik} on the x -faces augmented by the work of the x -component of the external force. On adding the corresponding expressions in y and z and carrying out the differentiations, the resulting expression can be reduced by applying the conditions of equilibrium and incompressibility (6) and (8), and becomes after division by $dt \Delta x \Delta y \Delta z$

$$\begin{aligned} & -p_{xx} \frac{\partial u}{\partial x} - p_{xy} \frac{\partial v}{\partial y} - p_{xz} \frac{\partial w}{\partial z} \\ (18) \quad & -p_{xy} \left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right) - p_{yz} \left(\frac{\partial v}{\partial z} + \frac{\partial w}{\partial y} \right) - p_{zx} \left(\frac{\partial w}{\partial x} + \frac{\partial u}{\partial z} \right). \end{aligned}$$

This energy is, as it were, abundant, it has no mechanical equivalent since no energy is needed for the maintenance of a steady fluid motion; it must therefore appear in the form of heat. *Expression (18) thus represents the heat produced by friction per unit of time and of volume (dissipation).*

Introducing a notation similar to the thermodynamic usage, we designate by dq the heat transferred to the unit of volume during the time dt . Using the definition of the strain components ϵ_{ik} in (1.11), we can transform (18) into

$$(19) \quad \frac{dq}{dt} = - \sum_i \sum_k p_{ik} \dot{\epsilon}_{ik}.$$

On applying the relations (2) between the p_{ik} and the $\dot{\epsilon}_{ik}$, we obtain for the dissipation

$$(20) \quad \frac{dq}{dt} = 2\mu \sum_i \sum_k \dot{\epsilon}_{ik}^2.$$

The quantity dq defined by (20) is, of course, *not* a total differential like the elastic dW of the corresponding equation (9.25), whence there is no thermal variable of state $\int dq$ that would correspond to the elastic strain energy (9.26).

In conclusion we wish to point out very briefly the changes which the foregoing considerations require in the case of *compressible* fluids. In the first place, comparison with the stress-strain relations in the form of (9.7) shows that the assumption (2) should be replaced by

$$(21) \quad p_{ik} = -2\mu \dot{\epsilon}_{ik} - \lambda \delta_{ik} \dot{\Theta}$$

because of $\dot{\Theta} = 0$. Thus we have a second coefficient of viscosity,²² λ , which is associated with the rate of dilatation $\dot{\Theta}$.

The equilibrium conditions (5) and (6) remain valid, if only \mathbf{F} is replaced by $\rho\mathbf{P}$ as in (7.3), but the form (8a) of these conditions must now be changed to

$$(22) \quad \frac{\partial p}{\partial x} - \mu \nabla^2 u - (\mu + \lambda) \frac{\partial}{\partial x} \dot{\Theta} = \rho P_x.$$

This equation together with the two others that are obtained by rotating the letters, and the equation of continuity (5.4) determine the four unknowns u , v , w , and p provided that a p, ρ -relation is prescribed. That the present set of equations is more involved is seen even in the case of the Hagen-Poiseuille problem for gases; one does not obtain an equation for u as above, but two simultaneous equations for u and ρ . As for the dissipation (20), it changes, as one would expect, to

$$(23) \quad \frac{dq}{dt} = 2\mu \sum \dot{\epsilon}_{ik}^2 + \lambda \dot{\Theta}^2.$$

²²No further determination of this quantity is intended here. In the literature one finds usually $\lambda = -2\mu/3$ on the basis of a gas-kinetic argument valid for monatomic gases (Enskog, Uppsala thesis, 1917). It is not difficult to draw the general conclusion from (21) that in the case of uniform compression an isotropic frictional pressure of the magnitude $(2\mu/3 + \lambda) \cdot \dot{\Theta}$ arises. The number $2\mu/3 + \lambda$ can therefore be designated as volume viscosity, in distinction from μ which could be called laminar viscosity. According to Enskog the volume viscosity of monatomic gases is zero, but the generalization of this result to gases whose molecules contain more than one atom is not justified.

CHAPTER III

DYNAMICS OF DEFORMABLE BODIES

11. Euler's Equations for a Perfect Incompressible Fluid

The transition from statics to dynamics is accomplished by adding the inertial resistances to the external forces in accordance with d'Alembert's principle. The inertial resistance of a particle with mass Δm is

$$-\Delta m \frac{d\mathbf{v}}{dt} = -\rho \Delta \tau \frac{d\mathbf{v}}{dt}.$$

Hence the inertial resistance per unit of volume becomes

$$(1) \quad -\rho \frac{d\mathbf{v}}{dt}.$$

This quantity must be added to the external force per unit of volume \mathbf{F} in the equilibrium conditions (6.4) if one wishes to obtain the equations of motion. Transposing the inertia term (1) to the other side of the equation, we have

$$(2) \quad \rho \frac{d\mathbf{v}}{dt} + \text{grad } p = \mathbf{F}.$$

Here one must carefully distinguish between the *total* or *material* acceleration $d\mathbf{v}/dt$ and the *local* acceleration $\partial\mathbf{v}/\partial t$. Take for instance the x -component of the velocity $u(x, y, z, t)$. While the particle moves through $d\mathbf{s} = i dx + j dy + k dz$ in the time dt , the change of u is

$$du = \frac{\partial u}{\partial t} dt + \frac{\partial u}{\partial x} dx + \frac{\partial u}{\partial y} dy + \frac{\partial u}{\partial z} dz,$$

where the particle coordinates x, y, z are to be considered as functions of t . Accordingly, the material acceleration in x -direction along the path $dx = u dt, dy = v dt, dz = w dt$ becomes

$$(3) \quad \frac{du}{dt} = \frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z},$$

and the difference between material and local acceleration in x -direction is

$$(3a) \quad \frac{du}{dt} - \frac{\partial u}{\partial t} = u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z},$$

the meaning of the local acceleration being the rate of change of the velocity at a *specified point* of the flow. To illustrate the difference by an example, take the steady flow through a pipe of varying cross-section. Let the axis of the pipe coincide with the x -axis; then we are mainly concerned with the velocity component u . By hypothesis the flow is steady: hence $\partial u/\partial t = 0$ everywhere, but by no means du/dt . On the contrary, the velocity of flow increases where the pipe becomes narrower and decreases where it widens. The difference between the two accelerations is given by the right member of (3a), in particular, by the first term because of the assumed preponderance of u . The terms on the right side of (3a) are often called the *convective terms of the acceleration*.

Writing (2) in Cartesian components by means of (3) and the corresponding expressions obtained by rotation of letters, one finds

$$\begin{aligned}
 & \rho \left(\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z} \right) + \frac{\partial p}{\partial x} = F_x, \\
 (4) \quad & \rho \left(\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + w \frac{\partial v}{\partial z} \right) + \frac{\partial p}{\partial y} = F_y, \\
 & \rho \left(\frac{\partial w}{\partial t} + u \frac{\partial w}{\partial x} + v \frac{\partial w}{\partial y} + w \frac{\partial w}{\partial z} \right) + \frac{\partial p}{\partial z} = F_z.
 \end{aligned}$$

The fourth differential equation is the condition of incompressibility

$$(4a) \quad \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0.$$

The quadruplet of equations (4), (4a) constitute *Euler's equations¹ of perfect fluid motion*. The pressure p is not to be confused with the hydrostatic pressure; it appears as the fourth unknown beside u , v , w .

It suggests itself to abbreviate Euler's equations by writing them in the symbolic form

$$(5) \quad \rho \left(\frac{\partial}{\partial t} + (\mathbf{v} \text{ grad}) \right) \mathbf{v} + \text{grad } p = \mathbf{F},$$

where the symbol $(\mathbf{v} \text{ grad})$ could be replaced by $(\mathbf{v} \nabla)$ as on p. 23. But this form is misleading as soon as one tries to use it, as it stands, for non-Cartesian coordinates (see problem III, 1). The operation grad applies only to scalars and must not operate on vectorial quantities. We may,

¹Leonhard Euler (1707-1783). His first two papers on the equilibrium and motion of fluids appeared 1755 in Vol. 11 of the Berlin Academy, a later treatment 1770 in Vol. 14 of the Petrograd Academy.

however, define the *pseudo-vectorial symbol* $(\mathbf{v} \text{ grad}) \mathbf{v}$ by explaining it through a *legitimate vector formula*. The definition we have in mind reads

$$(6) \quad (\mathbf{v} \text{ grad}) \mathbf{v} = \text{grad} \frac{\mathbf{v}^2}{2} - \mathbf{v} \times \text{curl} \mathbf{v}.$$

In fact, the x -component of the first member of (6) can be rearranged in the form

$$\begin{aligned} u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z} \\ = \frac{1}{2} \frac{\partial}{\partial x} (u^2 + v^2 + w^2) + v \left(\frac{\partial u}{\partial y} - \frac{\partial v}{\partial x} \right) + w \left(\frac{\partial u}{\partial z} - \frac{\partial w}{\partial x} \right) \end{aligned}$$

which establishes right away the identity with the x -component of the second member of (6). The corresponding relations for the y - and z -components follow by rotating the letters.

Now we may replace Eq. (5) by

$$(7) \quad \rho \left(\frac{\partial \mathbf{v}}{\partial t} - \mathbf{v} \times \text{curl} \mathbf{v} \right) + \text{grad} \left(\rho \frac{\mathbf{v}^2}{2} + p \right) = \mathbf{F}.$$

Adding the condition of incompressibility

$$(7a) \quad \text{div} \mathbf{v} = 0,$$

we have obtained Euler's equations in invariant form that can be specialized for any sort of curvilinear coordinates (e.g. polar coordinates) by the use of the expressions for grad, div, and curl in (2.24)-(2.26), or of the ready formulas in the tabulated solutions of problem I, 3.

Considering the mathematical character of Euler's equations we notice immediately their *non-linearity* which distinguishes them from the many linear equations of mathematical physics, as e.g. in potential theory, heat conduction, electrodynamics, etc. The non-linearity which is caused by the presence of the convective terms

$$u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z} \quad \text{etc., or} \quad \mathbf{v} \times \text{curl} \mathbf{v} + \text{grad} \frac{\mathbf{v}^2}{2}$$

makes the integration incomparably more difficult, for we can no longer use the *principle of superposition* of solutions by which more general integrals are found in the form of a combination of particular integrals. The integration of Euler's hydrodynamic equations is thus a considerably more difficult mathematical problem than, for example, that of the seemingly more complicated equations of Maxwell in electromagnetic theory.

Only in the case of *irrotational* flow is it possible to give immediately a first integral of Euler's equations. The condition is

$$(8) \quad \omega = \frac{1}{2} \operatorname{curl} \mathbf{v} = 0;$$

it is sufficient that Eq. (8) be fulfilled at a certain time instant only, since in an inviscid fluid it then remains permanently fulfilled as will be shown in Chap. IV.

We shall at first consider a still more restricted case, viz. steady flow, so that

$$(8a) \quad \frac{\partial \mathbf{v}}{\partial t} = 0.$$

It is further assumed as in (6.5) that the external force \mathbf{F} has a potential

$$(8b) \quad \mathbf{F} = - \operatorname{grad} U.$$

Then (7) becomes

$$\operatorname{grad} \left(\rho \frac{v^2}{2} + p + U \right) = 0$$

and can be integrated to

$$(9) \quad \rho \frac{v^2}{2} + p + U = \text{const}$$

which is Bernoulli's famous equation.² It was found *before* the discovery of Euler's equations by an argument which could be considered as an anticipation of the energy principle. For Bernoulli, no other potential energy than that of gravity would count; with $U = \rho g z$ (z pos. upwards), Eq. (9) would read

$$(9a) \quad \frac{v^2}{2} + \frac{p}{\rho} + g z = \text{const.}$$

Bernoulli's equation is the most important theorem in elementary fluid dynamics and finds application in the solution of numerous technical problems of turbine design, aerodynamics, etc. The first term of Eq. (9) is the kinetic energy per unit of volume, the third term the potential energy of the external force, again per unit of volume. The pressure p in (9) appears, as it were, as the potential energy of internal forces that are active in the unit volume cell and account for the dynamic interaction

²Daniel Bernoulli, *Hydrodynamica*, Strasbourg 1738. This work contains also the first attempt at a molecular theory of gases and the first treatment of the bending of a beam (cf. 41).

between neighboring incompressible fluid elements. A deeper mathematical interpretation of p will be the object of the next article.

Let us now illustrate the physical content of (9a) by some simple examples. Imagine a tank filled with liquid having an orifice at the level of the bottom. Let the free surface be $z = 0$ and the bottom $z = -h$. As long as the orifice is closed, $v = 0$ everywhere in the tank and $p = 0$ at the surface (where p denotes the overpressure relative to the atmosphere). The constant in (9a) is then equal to zero, the pressure $p = \rho gh = \gamma h$ at the bottom and is identical with the hydrostatic pressure in 6. When the orifice is opened we may assume that, at the surface, v remains approximately zero so that $\text{const} = 0$ as before. But since p is now zero also at the orifice, Eq. (9a) gives for $z = -h$

$$(10) \quad v = \sqrt{2gh}$$

as in the case of a freely falling body. This is the well known content of *Torricelli's theorem*.³

Another example is the steady flow through a horizontal tube of variable cross-section. Since the volume flux through each cross section is the same for an incompressible fluid, v increases with decreasing cross section and vice versa, as already observed on p. 84. (The present v is essentially the same as the axial component u there). According to (9a) the pressure must exhibit the converse change; this is easily demonstrated if the tube is furnished with a series of vertical open manometers in which the liquid is allowed to rise. The levels in the manometer tubes indicate the variations of the pressure along the tube, showing smaller pressure when the cross-section is smaller. The comparison with the behavior of a crowd of people trying to force their way through a narrow passage is inevitable: the way the fluid does it is more rational.

The following little experiment which can be improvised at any time may also serve as an illustration of Bernoulli's equation. Put a piece of paper (say 2×2 inches) on your left hand and hold the second and third finger of your right hand closely above it. Blow now vigorously through the narrow slit formed by the two fingers against the center of the paper. Contrary to expectation, the paper is not pressed against the left hand but lifted toward the fingers of the right hand where it remains floating for some time. Explanation: the air that emerges between the fingers and the paper flows in a channel of increasing cross section (cf. Fig. 15). Its velocity decreases, hence the pressure increases. At the end of the channel there is atmospheric pressure, p_0 , hence the pressure in

³Torricelli was a pupil of Galilei, he lived before Bernoulli's time and could not have used Bernoulli's equation in obtaining this result.

the channel $p < p_0$. Since underneath the paper there is atmospheric pressure p_0 , an overpressure $p_0 - p$ acts from below, or as one might also put it, there is suction from above. When this experiment is carried out on a larger scale with a jet of compressed air directed against a plate that is constrained to move normal to the jet, then the plate can be heavily loaded, e.g., with one's own weight.

In this experiment and in the preceding one we have applied Bernoulli's equation to air, although the formulation given in (9) is only correct for incompressible fluids. Yet the error caused in this way is not very great as long as the velocity of flow is not too large. In general, the

FIG. 15. Suction produced by blowing against a piece of paper through the slit formed by two fingers. The paper is not blown away but lifted toward the fingers.

corrections due to compressibility are small when the velocity of flow is small compared to the velocity of sound (cf. 13, and Appendix).

We have still to set up the generalized form of Bernoulli's equation in the case of a non-steady flow. Accordingly, we drop assumption (8a), but maintain (8) (irrotationality) and (8b) (\mathbf{F} has a potential). Now (8) is the necessary and sufficient condition for the expression $u dx + v dy + w dz$ to be a total differential, hence we may put

$$(11) \quad u dx + v dy + w dz = -d\Phi$$

and call Φ the *velocity potential*. Then

$$u = -\frac{\partial \Phi}{\partial x}, \quad v = -\frac{\partial \Phi}{\partial y}, \quad w = -\frac{\partial \Phi}{\partial z},$$

or, more briefly,

$$(12) \quad \mathbf{v} = -\text{grad } \Phi \quad \text{and therefore also} \quad \frac{\partial \mathbf{v}}{\partial t} = -\text{grad } \frac{\partial \Phi}{\partial t}.$$

It will be noticed that the negative sign in (11) and (12) is unessential;⁴ it is put in only to maintain the analogy with the potential of a force as in (8b).

Because of $\text{div } \mathbf{v} = 0$, Φ satisfies the potential equation (3.17)

$$(13) \quad \nabla^2 \Phi = 0.$$

⁴Its use has, in fact, been discontinued by many authors.

On account of (8), (8b), and (12), Euler's equations (7) take now the form

$$(14) \quad \text{grad} \left(-\rho \frac{\partial \Phi}{\partial t} + \rho \frac{v^2}{2} + p + U \right) = 0,$$

which is integrated to

$$(15) \quad -\frac{\partial \Phi}{\partial t} + \frac{1}{2} D\Phi + \frac{1}{\rho} (p + U) = \text{const.}$$

Here we have used the notation (3.9c) for the first differential parameter.

Eq. (15) is the *generalization of Bernoulli's equation for non-steady motions*. Like (9), it is a first integral of Euler's equations. Since (15) is found by spatial integration of (14), the constant in (15) is certainly independent of x, y, z , but it may in general still depend on the time. In other words, *const* is a function of t that has a uniform value for all points of the fluid. It must be found from the boundary conditions which may very well change with time. It will be noticed that this time dependence can be included in the definition of the velocity potential Φ since the potential equation (13) determines only the spatial, but not the temporal behavior of Φ .

So far we have only considered the case of *irrotational motion*; the question remains what can be done in the more general case where $\text{curl } \mathbf{v}$ is not zero.

A glance at equation (7) shows that also in this case integration becomes possible if one integrates in the *direction of a stream line*, or, in the non-steady case along the field line of the vector field \mathbf{v} . When this is done, the integral over the second term of the left member of (7) vanishes since $\mathbf{v} \times \text{curl } \mathbf{v}$ is perpendicular to \mathbf{v} and does not contribute anything to the integration. If we, moreover, maintain conditions (8a) and (8b) (steady flow in a field of force that has a potential) Eq. (9) is still correct, but in a different sense: the constant on the right side has no longer a uniform value for the entire space filled by the fluid, but changes from *one streamline to the next*. We shall call the equation (9), if understood in this sense, the *modified Bernoulli equation*. Its generalization for non-steady motion will not be discussed here.

12. Derivation of Euler's Equations from Hamilton's Principle The Pressure, a Lagrange Multiplier

There is no doubt that the concept of pressure in an *incompressible* fluid presents certain difficulties to the physical understanding. The pressure is considered a variable of state, but is denied any influence upon the way in which the fluid occupies the space, a difficulty, which is not

present in a compressible fluid where the pressure determines the density. We shall therefore try another approach toward understanding the concept of pressure in the case of an incompressible fluid, using the ideas of Hamiltonian mechanics.

We subject the mass particles of our fluid in motion to a *virtual* displacement

$$\delta \mathbf{s} = \delta \xi, \delta \eta, \delta \zeta,$$

which must not violate, however, the condition of incompressibility, $\Theta = 0$ (1.24). The expression

$$(1) \quad \delta \Theta = \frac{\partial \delta \xi}{\partial x} + \frac{\partial \delta \eta}{\partial y} + \frac{\partial \delta \zeta}{\partial z} = \text{div } \delta \mathbf{s}$$

must therefore vanish. This can be taken care of by providing (1) with a Lagrange multiplier λ and adding it to the integrand of Hamilton's principle. This we write in the form of Eq. (33.10) of Vol. I and obtain⁵

$$(2) \quad \int_{t_0}^{t_1} dt \int d\tau (\delta T + \delta W + \lambda \delta \Theta) = 0.$$

The integration with respect to $d\tau$ refers to the entire volume of the fluid. The variation of the kinetic energy δT and the virtual work of the external forces δW refer to the unit of volume in the same way as $\delta \Theta$ in (1). Hence we have

$$(3) \quad T = \frac{\rho}{2} \mathbf{v}^2, \quad \delta T = \rho \mathbf{v} \cdot \delta \mathbf{v}$$

and obtain for the virtual work

$$(4) \quad \delta W = \mathbf{F} \cdot \delta \mathbf{s}.$$

In (3) we substitute for the actual velocity

$$(4a) \quad \mathbf{v} = \frac{d\mathbf{s}}{dt}$$

and, accordingly, for its virtual variation

$$(4b) \quad \delta \mathbf{v} = \delta \frac{d\mathbf{s}}{dt} = \frac{d}{dt} \delta \mathbf{s}.$$

We now transform the term δT by partial integration with respect to t , observing that $\delta \mathbf{s}$ vanishes at the limits t_0 and t_1 according to the operational rules of Hamilton's principle. Thus we obtain

⁵See Jeffreys and Jeffreys, *op. cit.*, 10.06.

$$(5) \quad \int_{t_0}^{t_1} \rho \mathbf{v} \cdot \delta \mathbf{v} \, dt = \int_{t_0}^{t_1} \rho \mathbf{v} \cdot \frac{d}{dt} \delta \mathbf{s} \, dt = - \int_{t_0}^{t_1} \rho \frac{d\mathbf{v}}{dt} \cdot \delta \mathbf{s} \, dt.$$

The last term in the integrand of (2) is transformed according to the relation

$$\lambda \operatorname{div} (\delta \mathbf{s}) = \operatorname{div} (\lambda \delta \mathbf{s}) - \operatorname{grad} \lambda \cdot \delta \mathbf{s}.$$

On integrating and using Gauss's theorem we obtain

$$(6) \quad \int \lambda \operatorname{div} (\delta \mathbf{s}) \, d\tau = \int \lambda \delta s_n \, d\sigma - \int \operatorname{grad} \lambda \cdot \delta \mathbf{s} \, d\tau.$$

The surface integral on the right side will be taken up eventually; right now we are only concerned with

$$(7) \quad \int \lambda \operatorname{div} (\delta \mathbf{s}) \, d\tau = \dots - \int \operatorname{grad} \lambda \cdot \delta \mathbf{s} \, d\tau.$$

Introducing (1), (4), (5) and (7) in Hamilton's integral (2), we have

$$(8) \quad \int_{t_0}^{t_1} dt \int d\tau \left[\left(-\rho \frac{d\mathbf{v}}{dt} + \mathbf{F} - \operatorname{grad} \lambda \right) \cdot \delta \mathbf{s} \right] + \dots = 0.$$

Thanks to the introduction of the multiplier λ the variation $\delta \mathbf{s}$ may be chosen arbitrarily within the volume element τ and the time interval t_0 to t_1 ; but, with arbitrary displacements, Eq. (8) can only be fulfilled, if the volume and the surface integral vanish separately. Thus the factor of $\delta \mathbf{s}$ in the scalar product must be zero everywhere inside the domain of integration:

$$(9) \quad \rho \frac{d\mathbf{v}}{dt} + \operatorname{grad} \lambda = \mathbf{F}.$$

This is Euler's equation written in the form (11.2) provided λ is identified with the pressure p ; hence from the point of view of general mechanics, the hydrodynamic pressure represents the reaction against the condition of incompressibility, since λ was introduced to eliminate that condition. This corresponds to the way in which λ was interpreted in the case of the spherical pendulum in Vol. I. Eq. (18.7) where the constraint was a rigid spherical surface on which the mass point had to remain. The multiplier λ turned out to be a measure of the force that keeps the mass point on the constraint. In the present investigation, the condition of incompressibility has also been shown to have the character of a rigid constraint without energetic consequence; this may help to remove the difficulty associated with the concept of pressure in an incompressible fluid.*

*See e.g., Joos, G., *Theoretical Physics*, Hafner, New York, 1934, p. 110.

We should, however, be able to base our argument on the usual form of the incompressibility condition and its variation

$$(10) \quad \operatorname{div} \mathbf{v} = 0. \quad \delta \operatorname{div} \mathbf{v} = \operatorname{div} \delta \mathbf{v} = 0$$

rather than on condition (1). Retaining the expressions (3) and (4) for δT and δW , we rewrite Hamilton's principle (2) in the form

$$(11) \quad \int_{t_0}^{t_1} dt \int d\tau \{ \rho \mathbf{v} \cdot \delta \mathbf{v} + \mathbf{F} \cdot \delta \mathbf{s} + \lambda' \operatorname{div} \delta \mathbf{v} \} = 0.$$

We have denoted the multiplier by λ' to indicate that it is not identical with our previous λ (if for no other, then for dimensional reasons). We must now transform the middle term in (11) so as to have the same independent variation $\delta \mathbf{v}$ everywhere. We put

$$(12) \quad \bar{\mathbf{F}} = \int \mathbf{F} dt$$

and obtain

$$\int_{t_0}^{t_1} dt \int d\tau \mathbf{F} \cdot \delta \mathbf{s} = - \int_{t_0}^{t_1} dt \int d\tau \bar{\mathbf{F}} \cdot \delta \mathbf{v};$$

in the last transformation Eq. (4b) was used and the fact applied that the terms, which occur in the partial integration and refer to the limits t_0 and t_1 , vanish as before in (5). When we also transform the term with the factor λ' as in (7), the volume integral in (11) becomes

$$\int_{t_0}^{t_1} dt \int d\tau (\rho \mathbf{v} - \bar{\mathbf{F}} - \operatorname{grad} \lambda') \cdot \delta \mathbf{v}.$$

The same conclusion that leads from (8) to (9) leads now to

$$(13) \quad \rho \mathbf{v} - \bar{\mathbf{F}} - \operatorname{grad} \lambda' = 0.$$

It is only necessary to differentiate this equation with respect to t and to observe the meaning of $\bar{\mathbf{F}}$ in (12), to reobtain Euler's equations (ρ is, of course, independent of t because of the incompressibility). The result is

$$(14) \quad \rho \frac{d\mathbf{v}}{dt} + \operatorname{grad} p = \mathbf{F} \quad \text{with} \quad p = - \frac{d\lambda'}{dt}.$$

In this argument the pressure is again given by the *Lagrange multiplier* λ' although in a form different from the one we had before. This should not be surprising in view of the remark following (11).

We still have to consider the surface integral occurring in Eq. (6) which should give us the *surface conditions* required for the complete

determination of the pressure. On replacing λ by p and δs_n by δv , the integral reads

$$(15) \quad \int p \delta v d\sigma.$$

Before continuing, we wish to broaden the physical basis of this argument by considering another expression of the same structure as (15) which takes care of the cohesion of the fluid. In doing so we must for once resort to ideas taken from molecular physics. The fluid particles act upon each other not only with the pressure p (a consequence of their permanent volume as we may put it now), they also interact with their close neighbors through short range attractive forces which have their origin in the electrical structure of the molecules. For an inner volume element these forces cancel each other because they are in average directionally uniform. Not so for an element adjacent to the surface, where these forces add up to a resultant N in the direction of the inward surface normal. If N is referred to the unit of surface layer, the virtual work done by N in the displacement δv equals

$$\delta W = -N d\sigma \delta v.$$

Thus there appears in Hamilton's principle in addition to the *volume* integral over δW , in which the cohesive forces cancel, the *surface* integral

$$(16) \quad \int \delta W d\sigma = - \int N \delta v d\sigma.$$

This and the surface integral (15) (which resulted from the condition of incompressibility) can be written as one integral, viz.

$$(17) \quad \int (p - N) \delta v d\sigma.$$

According to Hamilton's principle the time integral of (17) must vanish together with the first term in (8), whence

$$(18) \quad \int_{t_0}^{t_1} dt \int (p - N) \delta v d\sigma = 0.$$

The conclusions to be drawn from (18) can be arranged according to the following three types of possible boundaries:

- a) The fluid is bounded by a rigid wall.
- b) The fluid has a free surface; it is bounded by vacuum or air.
- c) The fluid is bounded by another fluid, e.g., oil above water, but the boundary surface may have arbitrary shape.

a) A rigid wall prevents the fluid from moving perpendicularly to it; if this be true for the real motion, it must also be valid for the virtual displacement. Hence $\delta v = 0$ and condition (18) is automatically fulfilled. *The rigid wall does not provide a surface condition for the pressure.*

b) At a free surface δv is arbitrary. Eq. (18) requires then

$$(19) \quad p = N$$

for each element $d\sigma$ of the free surface at any time t .

c) At the surface of separation between fluid 1 and 2 with hydrodynamic pressures p_1 , p_2 and cohesive pressures N_1 , N_2 , we first require according to (18) that for any $d\sigma$ and any t

$$(20) \quad (p_1 - N_1)\delta v_1 + (p_2 - N_2)\delta v_2 = 0.$$

However, the contact of the fluids must not be disturbed by the virtual displacements. In other words, there must be

$$\delta v_1 = -\delta v_2,$$

the negative sign originating in our convention about the direction of n . Thereupon (20) gives

$$(21) \quad p_1 - p_2 = N_{12}, \quad N_{12} = N_1 - N_2.$$

Along the surface of separation of two fluids there is a pressure difference caused by the cohesive forces. It depends on the nature of the fluids and on the shape of the surface of separation, but is independent of the motion of the fluids.

Thus not only the differential equations of the problem (in the present case Euler's equations) follow from Hamilton's principle, but also such surface conditions for the pressure as may be imposed, can be found in the same way; this will be taken up again in 17 (surface tension).

13. Euler's Equations for the Perfect Compressible Fluid and Their Application to Acoustics

The transition from statics to dynamics is made as before in 11 by adding the inertial resistance to the external force. We have found it an advantage in the compressible case, to refer the external force to the unit of mass rather than to the unit of volume, hence we should do the same with the inertial resistance which is then simply $-dv/dt$. Replacing P in the equilibrium condition (7.5) by $P - dv/dt$, we obtain

$$(1) \quad \frac{dv}{dt} + \frac{1}{\rho} \text{grad } p = P.$$

These equations supplemented by the equation of continuity (5.4)

$$(2) \quad \frac{\partial \rho}{\partial t} + \operatorname{div}(\rho \mathbf{v}) = 0$$

constitute *Euler's equations for the compressible fluid*. The p, ρ -relation may be represented by the sufficiently general polytropic relation (7.1). The pressure p as well as the density ρ do now depend on x, y, z , and t .

In acoustics we are usually concerned only with *small oscillations* of the air. The difficulties arising from the non-linear terms (11.3a) in Euler's equations can then be avoided: we replace

$$\frac{d\mathbf{v}}{dt} \quad \text{by} \quad \frac{\partial \mathbf{v}}{\partial t}.$$

Quadratic terms must be kept, however, when we investigate, as in 37, shock-like phenomena such as occur in the firing of a gun. In the present case it is useful to take the normal atmospheric pressure p_0 as reference pressure for p ; p_0 will then not occur in (1), since it is constant in space and drops out if the gradient is formed, while p has the character of a small disturbance of p_0 . As we neglect terms of second order, we may write ρ_0 instead of ρ in (1) and in the second term of (2), ρ_0 being the normal density. In other words, we consider p , the derivatives of ρ , and the components of \mathbf{v} as small quantities. Finally, it is permitted in acoustics to neglect body forces altogether, i.e., to set $\mathbf{P} = 0$.

Thus we obtain the simple system of equations

$$(3) \quad \rho_0 \frac{\partial \mathbf{v}}{\partial t} + \operatorname{grad} p = 0,$$

$$(4) \quad \frac{\partial \rho}{\partial t} + \rho_0 \operatorname{div} \mathbf{v} = 0.$$

Instead of $\operatorname{grad} p$ we may write

$$(5) \quad \operatorname{grad} p = \left(\frac{dp}{d\rho} \right)_0 \operatorname{grad} \rho = c^2 \operatorname{grad} \rho, \quad c^2 = \left(\frac{dp}{d\rho} \right)_0,$$

where the constant c is related to the normal state of the atmosphere. On substituting in (3) we obtain

$$(6) \quad \rho_0 \frac{\partial \mathbf{v}}{\partial t} + c^2 \operatorname{grad} \rho = 0.$$

We are now ready to eliminate \mathbf{v} from (4) and (6). Taking the partial derivative of (4) with respect to t and substituting for $\rho_0 \partial \mathbf{v} / \partial t$ according

to (6), we obtain

$$(7) \quad \frac{\partial^2 \rho}{\partial t^2} = c^2 \operatorname{div} \operatorname{grad} \rho = c^2 \nabla^2 \rho.$$

The same equation is valid for p , since $\operatorname{grad} p$, and therefore $\nabla^2 p$ and $\partial^2 p / \partial t^2$ are equal to the corresponding expressions in ρ if the latter quantities are multiplied with c^2 [cf. (5)]. Thus

$$(8) \quad \frac{\partial^2 p}{\partial t^2} = c^2 \nabla^2 p.$$

The same differential equation also governs the velocity field. It is, of course, not the velocity \mathbf{v} that satisfies equation (8), but the velocity potential Φ , provided it exists. For, on putting $\mathbf{v} = -\operatorname{grad} \Phi$ according to (11.12), (4) and (6) become⁷

$$\frac{\partial \rho}{\partial t} = \rho_0 \nabla^2 \Phi \quad \text{and} \quad \rho_0 \frac{\partial \Phi}{\partial t} = c^2 \rho.$$

Here ρ can be eliminated by differentiation as before, and the result is

$$(8) \quad \frac{\partial^2 \Phi}{\partial t^2} = c^2 \nabla^2 \Phi.$$

Equations of the type (7), (8), (9) are called *wave equations*. They play a very important part in the fundamentals of mathematical physics in the form of the *equation of the vibrating string* (one-dimensional, $\nabla^2 = \partial^2 / \partial x^2$) or *vibrating membrane* (two-dimensional, $\nabla^2 = \partial^2 / \partial x^2 + \partial^2 / \partial y^2$).

Our present problem reduces to the equation of the vibrating string if we consider a process that depends on one coordinate only. Eq. (8), for instance, takes the form

$$(10) \quad \frac{\partial^2 p}{\partial t^2} = c^2 \frac{\partial^2 p}{\partial x^2}.$$

The integral of this equation can be given in the form of *d'Alembert's solution*

$$(11) \quad p = F_1(x + ct) + F_2(x - ct),$$

where F_1 and F_2 are real functions, entirely arbitrary except for certain continuity requirements (existence of first and second derivatives). In fact, any function of $x \pm ct$ satisfies the differential equation (10); the

⁷In the second of the two following equations a "constant," independent of x, y, z but dependent on t should be added; it can be absorbed in the definition of Φ , however. (cf. p. 89).

same is true for a linear combination of such functions thanks to the fact that we neglected the quadratic terms in Euler's equations.

Expression (11) is the *general* solution of the one-dimensional wave equation, since it can be adapted to an arbitrarily given initial state. Let it be required that for $t = 0$

$$p = f_1(x), \quad \frac{\partial p}{\partial t} = f_2(x).$$

Then we have only to make

$$F_1(x) + F_2(x) = f_1(x), \quad F_1'(x) - F_2'(x) = \frac{1}{c} f_2(x).$$

This gives directly

$$(12) \quad F_{1,2}(x) = \frac{1}{2} \left(f_1(x) \pm \frac{1}{c} \int_{x_0}^x f_2(\xi) d\xi \right).$$

The result is illustrated by Fig. 16 in which $f_2 = 0$ is assumed. Half of the initial pressure disturbance $f_1(x)$ moves to the right and half of it to the left, both travel without change of shape (undistorted, as one says) with the velocity c . The physical meaning of the constant c becomes now apparent; it is the *velocity of sound*. In Fig. 16 the initial disturbance is

FIG. 16. Illustrating d'Alembert's solution. The initial pressure distribution (solid curve at the center) travels with constant velocity to both sides so that the ordinates of the two pressure hills are half the original ordinates, the width being the same. At first, the two hills partly overlap, (dotted curve) later they leave an undisturbed space between each other (solid curves left and right).

represented by the "hill" in the middle. A later state is illustrated by the half size pressure hills left and right. In terms of acoustics, the figure illustrates the propagation of a *noise*; the initial disturbance may have any shape as a function of x , the pressure being the same at all points of a plane normal to x . Or, in terms of the vibrating string, the string is

plucked (rather, distorted into an arbitrary plane curve) at the time $t = 0$ and then left alone. In the latter case we should have to complete the picture by adding the reflections that the disturbances suffer at the ends of the (finite) string.

In acoustics of speech and music one is not so much concerned with a single but with a periodically sustained excitation of the air. Denoting the pitch (= frequency) by $\nu = 1/\tau$ and introducing $\omega = 2\pi\nu$, we assume F_1 and F_2 in the form of trigonometric functions

$$\begin{aligned} F_2(x - ct) &= a \cos(kx - \omega t + \alpha), \\ F_1(x + ct) &= b \cos(kx + \omega t + \beta). \end{aligned} \quad (13)$$

(a and b are amplitudes, α and β phase constants, $k = \omega/c = 2\pi/\lambda$ is the *wave number*, that is, the number of waves on a segment of length 2π). The plane wave F_2 travels in the positive and the wave F_1 in the negative x -direction. A superposition of the two waves results in a standing wave if the amplitudes a , b are equal. Note the formula

$$c = \frac{\omega}{k} = \frac{\lambda}{\tau} = \lambda\nu. \quad (14)$$

First we wish to learn something about the actual motion of the particles whose oscillations constitute these waves. According to (5), the gradient of ρ has the same direction as the gradient of p , that is, the $\pm x$ -direction; the particle acceleration $d\mathbf{v}/dt$ points in this direction at any time according to (6), hence the vector \mathbf{v} has the $\pm x$ -direction. The direction of the oscillations coincides therefore with the direction of propagation (or with the opposite direction, depending on the phase): *our waves are longitudinal; transversal waves do not exist in perfect fluids*. The process illustrated in Fig. 16 is, of course, also a longitudinal wave.

Complex notation of periodic phenomena is the most convenient symbolism and very widely used today. When complex exponentials are substituted for the trigonometric functions, solution (13) takes the form

$$\begin{aligned} Ae^{i(kx - \omega t)}, \quad A &= ae^{i\alpha}, \\ Be^{-i(kx + \omega t)}, \quad B &= be^{-i\beta}. \end{aligned} \quad (15)$$

Physically meaningful is, of course, only the real part of either expression; it agrees with the corresponding right member in (13). This leaves the sign of i still undetermined; it has been chosen in (15) so as to make the time dependent term in both expressions equal to $e^{-i\omega t}$. One may even suppress the time factor altogether, and obtains then the following symbols

(15a) Ae^{ikx} , a plane wave traveling in positive x -direction

Be^{-ikx} , a plane wave traveling in negative x -direction

This representation is valid for pressure, density and velocity potential with the correspondingly changed meaning of A and B . It will contribute greatly to shorten our formulas in Chap. V.

We still have to say something about the *numerical value of the sound velocity*. Under the assumption of an isothermal change of state the polytropic exponent n equals 1. Then from (7.1)

$$\frac{dp}{d\rho} = \frac{p_0}{\rho_0},$$

and by (5)

$$(16) \quad c = \sqrt{\frac{p_0}{\rho_0}}.$$

On the basis of standard pressure and temperature we have (p. 44)

$$p_0 = 1033 \times 981 \frac{\text{gr-wt}}{\text{cm sec}^2}, \quad \rho_0 = 1.293 \times 10^{-3} \frac{\text{gr}}{\text{cm}^3},$$

and consequently

$$c = \sqrt{\frac{1012}{1.293}} \times 10^3 \frac{\text{cm}}{\text{sec}} = 280 \frac{\text{m}}{\text{sec}}.$$

Newton had already obtained this value which is much too small. The theoretical formula upon which he based his calculation is

$$(16a) \quad c = \sqrt{\frac{\text{Elasticity}}{\text{Density}}},$$

which requires some clarification. Actually, the term elasticity means in the present case the same as modulus of compression. For an elastic solid, this is given by (9.13); the corresponding definition for a gas would be

$$K = \left| \frac{dp}{d\Theta} \right| \quad \text{with} \quad d\Theta = - \frac{dp}{\rho},$$

or,

$$(16b) \quad K = \rho \frac{dp}{d\rho}.$$

Thus (16a) becomes

$$c = \sqrt{\frac{dp}{d\rho}} = \sqrt{\left(\frac{dp}{d\rho}\right)_0},$$

in accordance with definition (5).

The question arises, however, whether the assumption of an *isothermal* change of state can be justified. It was Laplace who first noticed that heat exchange between the fluid particles should be practically impossible because of the rapidity of the oscillations; hence the change of state should be considered *adiabatic*. The polytropic exponent is then no longer 1 but 1.4 (p. 50) and we have from (7.1)

$$(17) \quad \left(\frac{dp}{d\rho}\right) = n \frac{p_0}{\rho_0},$$

The value of the velocity of sound takes up the factor $\sqrt{1.4}$ and turns out to be

$$(17a) \quad c = \sqrt{1.4} \times 280 = 332 \frac{\text{m}}{\text{sec}},$$

in satisfactory agreement with the experiment.^a

In conclusion we wish to generalize d'Alembert's method of integration for a *spherical wave*. Let the origin of the wave coincide with the origin O of a system of polar coordinates r, ϑ, φ , and assume a spherically symmetric distribution of pressure (no dependence on ϑ and φ). The expression for $\nabla^2 p$ (problem I, 3) is then

$$\nabla^2 p = \frac{1}{r} \frac{\partial^2(rp)}{\partial r^2}$$

and equation (8) takes the form

$$\frac{\partial^2(rp)}{\partial t^2} = c^2 \frac{\partial^2(rp)}{\partial r^2}.$$

Exactly as in (11) the integral is

$$rp = F_1(r + ct) + F_2(r - ct).$$

Any distribution of p and $\partial p/\partial t$ given for $t = 0$ and $r > 0$ can be represented according to this formula and continued for $t > 0$; the values of F_2 for negative argument must be adjusted so as to keep p finite for $r = 0$.

^aThis difference in the two values of c , which is due to a difference in K , illustrates well the fact that the parameters of elasticity depend on the character of the change of state (see end of §).

Here again, we are mainly concerned with the periodic case which we now write according to (15), but without the time factor $e^{-i\omega t}$

$$(18) \quad p = \frac{A}{r} e^{ikr} \quad \text{and} \quad (18a) \quad p = \frac{B}{r} e^{-ikr} \quad \text{respectively.}$$

The same representation is valid for ρ and Φ . Since the gradient of Φ coincides with the r -direction the oscillation is *longitudinal* also in this case.

Eq. (18) represents an outgoing spherical wave: the spherical surfaces of equal phase $kr - \omega t = \text{const}$ travel away from O with a phase velocity

$$\frac{dr}{dt} = \frac{\omega}{k} = c.$$

Such a radiation process can be considered as produced by a pulsating sphere at O .

On the other hand, (18a) means an incoming spherical wave. The surfaces of equal phase $-kr - \omega t = \text{const}$ travel with the velocity

$$\frac{dr}{dt} = -\frac{\omega}{k} = -c$$

toward the origin, but this radiation pattern can hardly be realized physically.

Appendix

*Comparison of Compressible and Incompressible Flows.**

Since the analysis of flows of compressible fluids presents much greater difficulties because of the variable density, the question arises: *when is it permissible to consider a compressible medium as incompressible within given limits of accuracy?* This means that a certain prescribed error is admitted for the quantity of interest which may be either ρ or p or v .

We restrict the following discussion to steady flow and start from the equation of continuity. Cross-sections of stream filaments in the compressible case do not change in the same way as in the incompressible case, which is a consequence of the different form of the continuity equation, viz., $\text{div}(\rho \mathbf{v}) = 0$ according to (5.4). On integrating the divergence of the mass flow over a stream tube between the small cross-sections F and F_0 , assumed to be orthogonal to the streamlines, one obtains by Gauss's theorem

* Cf. also Prandtl-Tietjens, *Fundamentals of Hydro- and Aeromechanics*, McGraw-Hill, New York, p. 224.

$$(19) \quad \rho F v = \rho_0 F_0 v_0 = \text{const} = M$$

where v , v_0 and ρ , ρ_0 are the absolute velocity and density values at F and F_0 .

In the incompressible case, (19) reduces to

$$(19a) \quad F v = F_0 v_0 = \text{const} = V.$$

The quantities M and V in (19) and (19a) are the mass flux and the volume flux through the stream tube.

We now compute the pressure in the steady flow of a compressible fluid and compare it with the pressure in an incompressible flow. Bernoulli's equation (with no other body force than gravity) is according to (11.9a) and (7.6b)

$$(20) \quad \frac{1}{2} (v^2 - v_0^2) + g(h - h_0) + \int_{v_0}^v \frac{dp}{\rho} = 0,$$

but in an incompressible medium one would have instead of (20)

$$(20a) \quad \frac{1}{2} (v^2 - v_0^2) + g(h - h_0) + \frac{p - p_0}{\rho} = 0.$$

The quantities without subscripts refer to an arbitrary cross-section of a stream tube while the subscript 0 denotes the reference cross-section of the same stream tube. The evaluation of the integral in (20) according to the polytropic assumption $p = C\rho^n$ yields

$$(21) \quad \begin{aligned} \int_{v_0}^v \frac{dp}{\rho} &= \frac{n}{n-1} \left(\frac{p}{\rho} - \frac{p_0}{\rho_0} \right) = \frac{n}{n-1} \frac{p_0}{\rho_0} \left[\left(\frac{p}{p_0} \right)^{n-1} - 1 \right] \\ &= \frac{n}{n-1} \frac{p_0}{\rho_0} \left[\left(\frac{p}{p_0} \right)^{(n-1)/n} - 1 \right]. \end{aligned}$$

Substituting this in (20) and solving for p , we obtain first

$$(21a) \quad p = p_0 \left[1 - \frac{n-1}{n} \frac{\rho_0}{p_0} \left\{ \frac{1}{2} (v^2 - v_0^2) + g(h - h_0) \right\} \right]^{n/(n-1)}.$$

If we assume

$$(21b) \quad \frac{1}{2} (v^2 - v_0^2) + g(h - h_0) < \frac{n}{n-1} \frac{p_0}{\rho_0},$$

we may expand the right member of (21a) according to the binomial theorem and have

$$(21c) \quad p = p_0 \left[1 - \frac{\rho_0}{p_0} \left\{ \frac{1}{2} (v^2 - v_0^2) + g(h - h_0) \right\} + \frac{1}{2n} \frac{\rho_0^2}{p_0^2} \left\{ \quad \right\}^2 \pm \dots \right].$$

If all but the linear term of the series are neglected, one reobtains the result (20a) as one would expect.

Let us now estimate the error in the important case of the flow past a rigid body. The reference point p_0, v_0 is assumed to be at a great distance from the body, and differences in altitude are from now on neglected so that $h = h_0$. With a view to the later Figs. 46 and 48 we compute the pressure p at the stagnation point or simply the "stagnation pressure" $p - p_0$. Since $v = 0$ [cf. also the definition of the stagnation point in (29.7)], we obtain from (21c)

$$p - p_0 = \frac{1}{2} \rho_0 v_0^2 + \frac{1}{2n} \frac{\rho_0}{p_0} \frac{\rho_0 v_0^4}{4} \mp \dots$$

Here we introduce the *sound velocity associated with the polytrope under consideration*. At the reference point which we identify with what was called the normal state in (13.17), the sound velocity is

$$(21d) \quad c_0 = \sqrt{\left(\frac{dp}{d\rho}\right)_0} = \sqrt{n \frac{p_0}{\rho_0}}.$$

Thus the previous equation takes the form

$$(22) \quad p - p_0 = \frac{1}{2} \rho_0 v_0^2 \left(1 + \frac{v_0^2}{4c_0^2} \mp \dots\right),$$

and can be compared with (20a), which we now write

$$(22a) \quad p - p_0 = \frac{1}{2} \rho_0 v_0^2.$$

The error incurred in computing the stagnation pressure from (22a) instead of from (22) amounts to 1% at the most if $v_0 \leq 0.2c_0$. In the case of standard air ($n = 1.4$, $c_0 = 332$ m/sec) this means $v_0 \leq 66.4$ m/sec; if, on the other hand, an error of 10% is admitted, v_0 should be kept smaller than $0.63c_0 = 209$ m/sec. These estimates have been carried out on the basis of the quadratic term in (22).

The change of density associated with the pressure change is obtained from (21a) by the polytropic relation. The analogous expansion yields

$$(23) \quad \rho = \rho_0 \left(1 - \frac{v^2 - v_0^2}{2c_0^2} + \dots\right).$$

We now determine the change of v along the stream tube. In the incompressible case (20a) gives with $h = h_0$

$$(24) \quad v = \sqrt{v_0^2 + \frac{2\Delta p}{\rho_0}} \quad \text{with} \quad \Delta p = p_0 - p \quad \text{and} \quad \rho = \rho_0.$$

On the other hand, (20) gives, with the last value of the integral (21),

$$(24a) \quad v = \sqrt{v_0^2 + \frac{2n}{n-1} \frac{p_0}{\rho_0} \left[1 - \left(\frac{p}{p_0} \right)^{(n-1)/n} \right]}$$

in the compressible case. On putting again $p = p_0 - \Delta p$ and expanding as before, one has

$$(24b) \quad v = \sqrt{v_0^2 + \frac{2\Delta p}{\rho_0} \left(1 + \frac{1}{2n} \frac{\Delta p}{p_0} + \dots \right)},$$

which agrees with (24) except for the quadratic term in Δp .

Returning once more to the stream tube cross-section in Eqs. (19) and (19a), we obtain by logarithmic differentiation of the equation of continuity (19)

$$(25) \quad \frac{d\rho}{\rho} + \frac{dF}{F} + \frac{dv}{v} = 0,$$

Bernoulli's equation (20) with $h = h_0$ can also be written in differential form, viz.

$$(26) \quad v dv + \frac{dp}{\rho} = 0,$$

and so can the polytropic equation:

$$(27) \quad \frac{dp}{p} = n \frac{d\rho}{\rho}.$$

On substituting for the differentials dp and $d\rho$ in (25) from (27) and (26), one has

$$(28) \quad \frac{dF}{F} = \frac{dp}{\rho v^2} \left(1 - \frac{\rho v^2}{np} \right) = \frac{dp}{\rho v^2} \left(1 - \frac{v^2}{c^2} \right).$$

Note however that c is now the sound velocity at the cross-section of interest, F . The corresponding relation for the incompressible case is obtained by putting $d\rho = 0$ in (27), or $c \rightarrow \infty$ in (28):

$$(28a) \quad \frac{dF}{F} = \frac{dp}{\rho v^2}.$$

Comparison of the two results shows first that the laws governing the change of cross-section are practically identical as long as $v \ll c$, similarly to the laws for the pressure changes given in (22) and (22a). But Eqs. (28) and (28a) allow another important conclusion to be drawn. *For an incompressible fluid, dF and dp have always the same sign, i.e., the cross-*

section enlarges with increasing pressure and becomes smaller with decreasing pressure. For a compressible fluid this is only true if $v < c$, i.e., in subsonic flow. In supersonic flow ($v > c$) the cross-section enlarges with decreasing pressure and becomes smaller with increasing pressure. It is this fact that is responsible for the fundamental difference between supersonic and subsonic flows of compressible fluids, a difference which does not exist for incompressible fluids for which the sound velocity is infinitely large according to the definition $c = \sqrt{dp/d\rho}$. We also infer from (28) that the cross-section of a stream tube has an extremum when the sound velocity is reached ($v = c$), and we can easily see that it must be a *minimum*.

Formulas (19) and (19a) play an important role in hydraulics. They serve to determine such flow cross-sections as occur in piping systems, valves, turbine bladings, etc. Eqs. (24) and (24a) serve to calculate the velocity of discharge from the nozzle of a pressure tank where p_0 is the (constant) inside pressure and p the (constant) external pressure; v_0 may be assumed ~ 0 in good approximation.—Formula (24a) is named after de Saint-Venant and Wantzel (1839).

The Laval¹⁰ nozzle is of particular interest in this connection. It serves to change energy of high pressure and low velocity into energy of low pressure and high velocity as any nozzle does, but the peculiar feature of the Laval nozzle is that the velocity of discharge can exceed the sound velocity. In accordance with our results, its design must be such that the cross-sections decrease until sonic speed is reached and then increase again.

14. Dynamics of the Elastic Body

The dynamic equations of the elastic body follow again from the static equilibrium condition by adding the inertia force to the external force \mathbf{F} . Displacements in a solid can always be considered as small (only at the yield point, that is, beyond the limit of purely elastic behavior considerable displacements occur, cf. 39). The material derivative may, therefore, be identified with the local derivative and the inertia force per unit of volume becomes $-\rho \partial^2 \mathbf{s} / \partial t^2$, where $\mathbf{s} = i\xi + j\eta + k\zeta$.

Writing the static equilibrium condition in the form (8.12), we obtain as the differential equation of elasticity

$$(1) \quad \rho \frac{\partial^2 \mathbf{s}}{\partial t^2} = \text{Div } \boldsymbol{\sigma} + \mathbf{F},$$

¹⁰Devised by the Swedish engineer de Laval, who also invented a good separator and the first usable steam turbine.

or, spelled out in Cartesian coordinates as in (8.11),

$$\begin{aligned}
 (1a) \quad \rho \frac{\partial^2 \xi}{\partial t^2} &= \frac{\partial \sigma_{xx}}{\partial x} + \frac{\partial \sigma_{yx}}{\partial y} + \frac{\partial \sigma_{zx}}{\partial z} + F_x, \\
 \rho \frac{\partial^2 \eta}{\partial t^2} &= \frac{\partial \sigma_{xx}}{\partial x} + \frac{\partial \sigma_{yy}}{\partial y} + \frac{\partial \sigma_{zz}}{\partial z} + F_y, \\
 \rho \frac{\partial^2 \zeta}{\partial t^2} &= \frac{\partial \sigma_{xx}}{\partial x} + \frac{\partial \sigma_{yy}}{\partial y} + \frac{\partial \sigma_{zz}}{\partial z} + F_z.
 \end{aligned}$$

Using, however, form (9.18) of our fundamental equation which is preferable for what follows, we obtain the elastic differential equation in the form

$$(1b) \quad \rho \frac{\partial^2 \mathbf{s}}{\partial t^2} = (\mu + \lambda) \text{grad } \Theta + \mu \nabla^2 \mathbf{s} + \mathbf{F}, \quad \Theta = \text{div } \mathbf{s}.$$

This equation refers to Cartesian coordinates; a more general equation is obtained when one starts from Eq. (9.19) instead of (9.18).

We are here mainly interested in free oscillations, therefore put $\mathbf{F} = 0$. From (1b) it follows directly that there will be waves of dilatation as well as of distortion, the first having *longitudinal*, the latter *transversal character*.

Waves of dilatation. On taking the divergence of every term in (1b), we obtain

$$\rho \frac{\partial^2 \Theta}{\partial t^2} = (\mu + \lambda) \nabla^2 \Theta + \mu \text{div } \nabla^2 \mathbf{s}$$

and may replace

$$\text{div } \nabla^2 \mathbf{s} \quad \text{by} \quad \nabla^2 \text{div } \mathbf{s} = \nabla^2 \Theta.$$

In this way we obtain the simple scalar equation

$$(2) \quad \rho \frac{\partial^2 \Theta}{\partial t^2} = (2\mu + \lambda) \nabla^2 \Theta.$$

By comparison, e.g. with (13.8), the *velocity of propagation of the waves of dilatation*, which we denote by a , is seen to be

$$(3) \quad a^2 = \frac{2\mu + \lambda}{\rho}.$$

For a one dimensional or spherically symmetric state the periodic solutions obtained by d'Alembert's method (13.11) for the infinite elastic body are of the form

$$(4) \quad e^{ikx} \quad \text{or} \quad \frac{1}{r} e^{ikr}, \quad k = \frac{\omega}{a}.$$

They are plane or spherical waves with circular frequency ω that travel with the constant velocity a .

Waves of distortion. On taking the curl of Eq. (1b) term by term and putting as in (2.19)

$$\text{curl } \mathbf{s} = 2\dot{\phi},$$

Eq. (1b) yields because of $\text{curl grad} = 0$

$$(5) \quad \rho \frac{\partial^2 \phi}{\partial t^2} = \mu \nabla^2 \phi.$$

Here ϕ represents in magnitude and axis the angle of torsion of the volume element under consideration. Comparison with (13.8) shows that the velocity of propagation of the waves of distortion, which we denote by b , is given by

$$(6) \quad b^2 = \frac{\mu}{\rho}.$$

This is the reason why Lamé's modulus μ is sometimes called the torsion modulus, as already mentioned on p. 68. Again d'Alembert's method gives plane and spherical waves that are represented by (4) in the same way as the compression waves, provided that the wave number k is now ω/b . The comparison of (3) and (6) shows immediately that

$$a > b, \quad \text{since} \quad \frac{a^2}{b^2} = 2 + \frac{\lambda}{\mu} = \frac{2 - 2\nu}{1 - 2\nu};$$

as for the last term, cf. (9.11). For iron with ν about 0.3 (see p. 65), we obtain $a/b = \sqrt{7/2} = 1.87$.

The meaning of this is obvious: the elastic resistance of solids against changes of volume is considerably larger than that against changes of the relative orientation. The absolute value of b in a solid is, of course, still much larger than the sound velocity c in air. With the data of pp. 65, 68, and with $\rho = 7.8 \text{ gr/cm}^3$ for iron, the value of b is found to be 3100 m/sec. Both formulas (3) and (6) for a and b can be subsumed under Newton's rule (13.16a), provided the term elasticity is suitably specified in each case.

The compressional waves and the waves of distortion considered here are *three-dimensional waves* progressing in an elastic body without boundaries. In addition, there exist *surface waves* that are bound to the free surface of the body and have a special importance for seismic phenomena; they are dealt with in 45. The surface waves travel more slowly than the three-dimensional waves, that is to say, the earth puts up more elastic resistance against the latter than the former. They constitute the principal parts of the observed earthquakes, while the three-dimensional waves that arrive earlier are observed as preliminaries.

15. The Quasi-Elastic Body as Model of the Ether

In 19th century physics, a material carrier was assumed for the optical phenomena, equipped as far as possible with the properties of ordinary elastic bodies. This construction, however, led to difficulties even in the most elementary problem of reflexion and refraction, about which more in 45. As early as 1839 MacCullagh tried to drop the connection with the ordinary theory of elasticity with the aim to develop a representation of optics that would be free of the difficulties mentioned. It turned out later that his theory agreed formally with Maxwell's electro-magnetic optics (1864), in particular as far as the optics of transparent bodies is concerned. The following remarks should be considered as an interpretation of MacCullagh's equations.

Let us go back to the beginning of 1. There the general locomotion of a continuous medium was decomposed into the three parts of translation, rotation, and deformation. The elastic body responds to a deformation with a stress tensor which is determined by the deformation tensor; it is not sensitive to rotation (and, of course, not to translation). We now try to imagine a "quasi-elastic" body, supposedly insensitive to deformations but *responsive to rotations relative to absolute space*! Since the rotation has the character of an antisymmetric tensor (1.12a) we shall assume that the stress acting on the volume element as a result of the rotation is also an antisymmetric tensor, as indicated in the following array:

$$(1) \quad \begin{pmatrix} 0 & \sigma_{xy} & \sigma_{xz} \\ \sigma_{yx} & 0 & \sigma_{yz} \\ \sigma_{zx} & \sigma_{zy} & 0 \end{pmatrix}, \quad \sigma_{ih} = -\sigma_{hi}.$$

The *stress-rotation relation* here assumed is illustrated in Fig. 17. Let the volume element $\Delta\tau$ be twisted through the angle φ_z (indicated by the right hand screw arrow about the positive z -axis). To produce or to maintain this rotation we need—this is our hypothesis—a moment about the z -axis

$$(2) \quad M_z = k\varphi_z\Delta\tau.$$

The quantity k could be called the "twist modulus" of the quasi-elastic body. The moment is associated with two shear stresses σ_{xy} and $-\sigma_{yx}$ across the positive x - and y -surfaces and with corresponding anti-parallel shear stresses across the negative x - and y -surfaces, all indicated in the figure. In order to be in accordance with (2) and (1) we have to put

FIG. 17. Strain and rotation in the "quasielastic" body.

$$(3) \quad \sigma_{xy} = -\sigma_{yx} = \frac{k}{2} \varphi_z.$$

This assumed, the moment originating at the two x -surfaces (see the analogous argument that accompanies Fig. 10) is

$$2\sigma_{xy}\Delta y\Delta z \cdot \frac{\Delta x}{2} = \frac{k}{2} \varphi_z \Delta \tau$$

and the moment originating at the two y -surfaces

$$-2\sigma_{yx}\Delta x\Delta z \cdot \frac{\Delta y}{2} = \frac{k}{2} \varphi_z \Delta \tau,$$

so that the total moment is in fact that of equation (2). By rotation of the letters we obtain from (3)

$$(3a) \quad \sigma_{yz} = -\sigma_{zy} = \frac{k}{2} \varphi_x, \quad \sigma_{zx} = -\sigma_{xz} = \frac{k}{2} \varphi_y.$$

The equation of motion of the quasi-elastic body follows now from (14.1a). In applying this equation we have to assign inertia to the volume element of the ether and to consider its displacement as small, since we previously neglected the quadratic convective terms in putting $du/dt = \partial u/\partial t$. We also disregard any external forces ($F = 0$). In this way we obtain from (14.1a) with the use of (3) and (3a)

$$\rho \frac{\partial u}{\partial t} = \frac{\partial \sigma_{yz}}{\partial y} + \frac{\partial \sigma_{xz}}{\partial z} = -\frac{k}{2} \left(\frac{\partial \varphi_x}{\partial y} - \frac{\partial \varphi_y}{\partial z} \right),$$

or, written in vector form,

$$(4) \quad \rho \frac{\partial \mathbf{v}}{\partial t} = -\frac{k}{2} \text{curl } \boldsymbol{\phi}.$$

This is the equation of motion of the ether; it must be supplemented by the relation between \mathbf{v} and the angular velocity $\boldsymbol{\omega}$, which reads

$$(5) \quad \frac{\partial \boldsymbol{\xi}}{\partial t} = \frac{1}{2} \text{curl } \mathbf{v}$$

where $\boldsymbol{\omega} = d\boldsymbol{\xi}/dt$ was replaced by $\partial \boldsymbol{\xi}/\partial t$. As a further assumption we add the incompressibility of the ether; we also note that $\boldsymbol{\xi}$, being the curl of the displacement vector, has no divergence. Thus \mathbf{v} and $\boldsymbol{\xi}$ are subject to the following conditions

$$(6) \quad \text{div } \mathbf{v} = 0, \quad \text{div } \boldsymbol{\xi} = 0.$$

The system of equations (4), (5) and (6) is of impressive simplicity and symmetry. It is formally identical with *Maxwell's equations for the empty space!*

Before elaborating this statement, let us introduce the following notations: \mathbf{E} = electric field strength, \mathbf{H} = magnetic field strength; α, β = factors of proportionality that depend on the choice of units for E and H . Now we put

$$\text{either} \quad a) \quad \mathbf{v} = \pm \alpha \mathbf{E}, \quad \boldsymbol{\xi} = \mp \beta \mathbf{H},$$

$$\text{or} \quad b) \quad \mathbf{v} = \pm \alpha \mathbf{H}, \quad \boldsymbol{\xi} = \pm \beta \mathbf{E}.$$

The signs in these equations depend on the signs chosen for the units of the electric charge and magnetic pole strength. Eqs. (4), (5), and (6) assume then the form

$$(7) \quad \epsilon_0 \frac{\partial \mathbf{E}}{\partial t} = \text{curl } \mathbf{H}, \quad \text{div } \mathbf{E} = 0,$$

$$\mu_0 \frac{\partial \mathbf{H}}{\partial t} = - \text{curl } \mathbf{E}, \quad \text{div } \mathbf{H} = 0$$

for the choice a) as well as for the choice b). The abbreviations ϵ_0, μ_0 are known as the dielectric constant and permeability of the vacuum; in our notation they are given by

$$(a) \quad \epsilon_0 = \frac{\rho}{k} \frac{2\alpha}{\beta}, \quad \mu_0 = \frac{2\beta}{\alpha},$$

$$(b) \quad \mu_0 = \frac{\rho}{k} \frac{2\alpha}{\beta}, \quad \epsilon_0 = \frac{2\beta}{\alpha}.$$

Their product is independent of the choice of the units α, β , since we have in either case

$$(8) \quad \epsilon_0 \mu_0 = \frac{4\rho}{k} = \frac{1}{c^2}.$$

The quantity c defined in (8) has, physically, the meaning of the *velocity of light in vacuum*. It can be included in Newton's rule (13.16a) in analogy to the sound velocities in 13 and 14, when the word elasticity is given the meaning of one fourth of the "twist modulus" k .

It is by no means our intention to assign any physical reality to this "ether model". Physicists had convinced themselves by the turn of the century that all attempts at a mechanical explanation of Maxwell's equations were doomed to failure. What we mean here is not a mechanical *explanation* but, at best, a mechanical *analogy*. Maxwell's equations are among the fundamentals of the electrical theory of matter, so one should not expect that they can be derived from the macroscopic properties of ponderable bodies. On the contrary, they seem to stem from the same root as general gravitation, that is, from the space-time metric, according to a recent paper by Schrödinger.¹¹ Our remarks, however, may have some justification inasmuch as they show: if we were to construct an "ether" as a substratum for Maxwell's equation, then we would have to furnish it with qualities that are diametrically opposed to those of ordinary matter, viz., an *absolute directional orientation relative to space* in contrast to the *relative orientation of the volume elements toward each other* possessed by elastic bodies.

The following historical remark may be of interest. In an extension of MacCullagh's ideas Lord Kelvin,¹² in the eighties, developed the concept of the quasi-elastic or, as he sometimes put it, "quasi-rigid" ether. He was not satisfied, only to postulate an ether with reactive responses (2), but attempted to construct a gyroscopic model that actually would react in the required way. As is well known, a fast spinning top can be so arranged as to acquire directional stability and will then respond to fairly strong moments with small angular changes only. But an ether model, based on gyroscopic effects, becomes desperately complicated. Each volume element has to be equipped with several tops that must be oriented relative to each other in such a way that the desired rotational stiffness is achieved not only for one but for all three axes. A construction as complicated as that would be the only way to realize a "gyrostatic" ether.

Lord Kelvin took the point of view marked by a) on p. 110 and correlated the "twist" of his gyrostatic ether to the magnetic vector \mathbf{H} . He

¹¹E. Schrödinger, Proc. R. Irish Academy 49, 43 (1943).

¹²Sir William Thomson (Lord Kelvin), Mathematical and Physical Papers, Vol. 3, Art. 49, 50, 52.

did not commit himself to a definite interpretation of the electric vector \mathbf{E} , thus abstaining from a complete mechanical representation of Maxwell's equations. There is no doubt that standpoint a) is physically more evident, since \mathbf{H} has the character of an axial vector like \mathfrak{g} , while \mathbf{E} possesses that of a polar vector like \mathbf{v} . On the other hand, standpoint b) seemed to recommend itself because it took care of the pure ether and the insulators, but also left space for the conductors in the quasi-elastic picture.¹³ It was Boltzmann¹⁴ who pointed out the difficulties involved in standpoint b) which are caused by the existence of the *true electric charge*. Disregarding the electrodynamics of conductors, we shall only pursue assumption a) somewhat further in the following. In 20 we shall come back to the correlation b) in connection with Helmholtz's vortex theory.

For the ponderable insulator the two principal equations (7) are still valid as in vacuum, only the values ϵ_0 , μ_0 must now be replaced by ϵ , μ . The divergence conditions, however, undergo an essential change. Instead of $\text{div } \mathbf{H} = 0$ we have now

$$(9) \quad \text{div } \mathbf{B} = 0, \quad \mathbf{B} = \mu \mathbf{H} = \text{magnetic induction}$$

and we would therefore correlate \mathbf{B} rather than \mathbf{H} with the rotation \mathfrak{g} , which would introduce no difficulty. On the other hand the condition $\text{div } \mathbf{E} = 0$ must be altered into

$$(10) \quad \text{div } \mathbf{D} = \rho_e, \quad \mathbf{D} = \epsilon \mathbf{E} = \text{dielectric displacement.}$$

Here ρ_e is the spatial density of the true electric charge. When we now correlate \mathbf{D} instead of \mathbf{E} to the flow velocity \mathbf{v} and set up suitable relations between the constants ϵ , μ and k , ρ , α , β we are still able to obtain complete formal analogy with Maxwell's equations for the ponderable insulator. It is clear, however, that the existence of the true charge causes difficulty also for the standpoint a), if it is desired to maintain the incompressibility of the ether. There is, of course, a mathematically permissible but physically rather drastic remedy for this difficulty. One simply prescribes that the quasi-elastic fluid leaves or enters the field at points that carry true charges according to the signs. Where the fluid goes or whence it comes is left in the dark. As an apology for this assumption one could quote the example of the great Bernhard Riemann¹⁵ who makes the same hypothesis in an attempt at a theory of gravitation and electrostatics, in his paper: "Neue mathematische Prinzipien der Naturphilosophie", but

¹³A. Sommerfeld, Ann. d. Phys. 46, 139 (1892).

¹⁵Ges. Werke, 2nd ed., Teubner, Leipzig, 1892, p. 523. The paper was written shortly after Riemann had obtained the doctorate, and published posthumously.

it seems to be more correct to admit that no mechanical or quasi-mechanical picture is a suitable representation of the fundamental fact of the electric charge.

We shall have no reason to come back in Vol. III to the model of the ether discussed here. The electric charge and the structure of the electromagnetic field must be accepted as entities that transcend mechanics.

16. Dynamics of Viscous Fluids. Hydrodynamics and Hydraulics. Reynolds' Criterion of Turbulence

In order to set up the general equations of motion of viscous fluids, we have to introduce the inertia force in the equations of uniform motion (10.8a,b). \mathbf{F} must be replaced by

$$\mathbf{F} - \rho \frac{d\mathbf{v}}{dt} = \mathbf{F} - \rho \left\{ \frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \text{ grad}) \mathbf{v} \right\}.$$

In this way we obtain the Navier-Stokes equations¹⁰

$$(1) \quad \rho \frac{\partial \mathbf{v}}{\partial t} + \rho (\mathbf{v} \text{ grad}) \mathbf{v} - \mu \Delta \mathbf{v} + \text{grad } p = \mathbf{F}$$

which are written here in pseudo-vectorial form. In order to put them in invariant shape one has to make use of Eqs. (11.6) and (3.10a), viz.

$$(\mathbf{v} \text{ grad}) \mathbf{v} = \text{grad } \frac{v^2}{2} - \mathbf{v} \times \text{curl } \mathbf{v}$$

and

$$\nabla^2 \mathbf{v} = \text{grad div } \mathbf{v} - \text{curl curl } \mathbf{v}.$$

Eq. (1) has to be supplemented in the incompressible case by

$$(1a) \quad \text{div } \mathbf{v} = 0.$$

In the case of compressible fluids, (1a) must be replaced by (5.4); at the same time the additional term $-(\mu + \lambda) \text{grad } \dot{\theta}$, that is $-(\mu + \lambda) \text{grad div } \mathbf{v}$, has to be added to the left member of (1) according to (10.22).

Today we consider the Navier-Stokes equations as fundamental for the entire theory of fluid flow. Engineers throughout the 19th century were, on the contrary, convinced that there was a big discrepancy between theoretical hydrodynamics on the one side and hydraulics on the other side. It was the British engineer and physicist Osborne Reynolds

¹⁰Navier, 1822, Stokes, 1845.

who bridged the gap with his profound experimental¹⁷ and theoretical¹⁸ investigations.

He experimented with glass tubes of various diameters at varying pressure gradients which amounts to changing the average velocities of the flow. (Average velocity means here the mean value of the velocity with respect to the cross-section.) Introducing a colored fluid filament into the entrance cross-section he observed the behavior of this filament throughout the tube. At small diameters and not too large average velocities the colored filament remains straight and parallel to the axis of the tube. At a larger diameter or larger velocity there appear irregular deviations that have a tendency to fill the whole tube. The initially straight filament becomes fuzzy and finally indistinguishable. In the first case the motion is called *laminar* (proceeding in regular laminations as in the Hagen-Poiseuille flow), in the last case it is called *turbulent*, as suggested by Reynolds.

Reynolds would not have been able to bring order in his experimental results, if he had not considered them from the point of view of a "*law of similitude*." Considerations of this character already appear in the first beginnings of western physics, as in the work of Galilei.¹⁹ Generally speaking, they consist in the comparison of two experimental arrangements differing only in scale.

In our case, consider two tubes of radii a_1 and a_2 . Putting

$$(2a) \quad a_2 = \alpha a_1,$$

the number α is the change of the scale of length in the transition from experiment 1 to experiment 2. It pertains not only to the radii, but to all dimensions of length, such as the coordinates of two "corresponding points" in the two tubes. Any two such points are thus connected by

$$x_2 = \alpha x_1, \quad y_2 = \alpha y_1, \quad z_2 = \alpha z_1.$$

The average velocities in corresponding cross-sections being v_1 and v_2 , we put

$$(2b) \quad v_2 = \beta v_1.$$

¹⁹In his last work "Discorsi e Dimostrazioni Matematiche," 1638.

The dimension of velocity being length/time, the number β determines also the change of the time scale in our transition; this change is evidently α/β , according to (2a) and (2b). In addition we allow the two tubes to carry two different liquids of different density and viscosity and put

$$(2c) \quad \rho_2 = \gamma \rho_1.$$

The factor γ defines the change of the mass scale which is $\gamma\alpha^3$ because of (2a) and (2c).

It is more convenient to use instead of the coefficient of viscosity μ the *kinematic* viscosity ν defined by

$$\nu = \frac{\mu}{\rho}.$$

Again we put

$$(2d) \quad \nu_2 = \delta \nu_1.$$

We finally compare the pressures in corresponding cross-sections by setting

$$(2e) \quad p_2 = \epsilon p_1.$$

Obviously, ϵ could be expressed by α , β , γ , because of the dimension of p .

We now write Eq. (1) after division by ρ once more in a schematic way and omit the external force which is here immaterial:

$$(3) \quad \text{acceleration} \quad -\nu \nabla^2 \mathbf{v} + \frac{1}{\rho} \text{grad } p = 0.$$

The dimension of the acceleration term may be written either as velocity/time or velocity²/length. In the transition from (1) to (2), this term takes up, according to (2a) and (2b), the factor

$$(4a) \quad \frac{\beta^2}{\alpha};$$

according to (2b) and (2d) the second term of (3) takes up the factor

$$(4b) \quad \delta \frac{\beta}{\alpha^2},$$

since the repeated differentiation with respect to the coordinates occurring in $\nabla^2 \mathbf{v}$ means obviously a repeated division by a length. The change of scale in the last term of (3) is finally [by (3), (2a), (2c), (2e)]

$$(4c) \quad \frac{1}{\gamma} \frac{\epsilon}{\alpha}.$$

Suppose now, Eq. (3) is obeyed by the flow in the experimental arrangement 1. If it is to be obeyed also by the flow 2, the ratio of the three factors (4a, b, c) must be equal to one:

$$(5) \quad \frac{\beta^2}{\alpha} : \delta \frac{\beta}{\alpha^2} : \frac{1}{\gamma} \frac{\epsilon}{\alpha} = 1 : 1 : 1.$$

This amounts to the following two relations:

$$(5a) \quad \frac{\beta\alpha}{\delta} = 1. \quad (5b) \quad \frac{\epsilon}{\gamma\beta^2} = 1.$$

The meaning of (5a) in terms of the experimental parameters involved is because of (2a, b, d)

$$(6) \quad \frac{v_1 a_1}{\nu_1} = \frac{v_2 a_2}{\nu_2}.$$

Similarly, (5b) leads by (2b, c, e) to

$$(7) \quad \frac{p_1}{\rho_1 v_1^2} = \frac{p_2}{\rho_2 v_2^2}.$$

Eqs. (6) and (7) constitute the results of Reynolds theory of similitude. In the literature the term *Reynolds criterion* is usually applied to equation (6) only, although (7) is a part of it as well, as we have just seen. It is the two relations together that furnish the necessary and sufficient conditions of hydrodynamic similitude. In what follows we shall make extensive use also of equation (7).

If these two criteria are satisfied, the flows 1 and 2 are either both laminar or both turbulent, since the experimental arrangement 2 is nothing but a "mechanical image" of 1 on a different scale.

The dimensionless expression defined by (6) is known as Reynolds number and denoted²⁰ by R :

$$(8) \quad R = \frac{va}{\nu},$$

where the length a may designate any linear dimension characteristic of the experiment (such as a distance of two plates, a depth of a channel, radii of falling spheres, etc.). The number defined by (7) will be denoted by S so that

$$(9) \quad S = \frac{p}{\rho v^2}.$$

²⁰Sometimes denoted by Re .

The transition from laminar to turbulent flow in particular is a mechanically *similar* event for the tubes 1 and 2 which is therefore characterized by the same numerical value of R . This is the *critical Reynolds number*:

$$(10) \quad R_{crit} = \left(\frac{va}{\nu} \right)_{crit}.$$

Its value is rather sensitive to the particular form of the entrance section of the tube. When a well rounded entrance section in the form of a trumpet bell is used, a laminar flow is established from the start and stays laminar up to rather large values of R . If the fluid enters the tube from the tank through a straight, sharp edged connection, the initial flow is disturbed by lateral components which are not damped out by friction at once; the transition to full turbulence occurs then at a comparatively low R . The critical Reynolds number is between 1200 (very irregular inlet) and 20,000 (mouth piece with a well-rounded fairing). Thus our statement regarding the constancy of the critical Reynolds number should actually be restricted to flows with similar initial conditions.

The question arises: what is the cause of the transition from laminar to turbulent flow and vice versa? Our treatment of the laminar flow in capillary tubes on p. 78ff does not point to anything like a limitation of the flow pattern to small diameters or small velocities; on the contrary, it appears that the Hagen-Poiseuille flow is a possible form of the motion under all circumstances, but no longer *stable* if $R > R_{crit}$. Thus Reynolds's criterion appears as a *stability criterion* dictated by experience; the following remarks should help to bring it closer to our physical understanding:

Viscosity tends to smooth out lateral components either initially present or produced by the roughness of the tube, it thus favors the laminar pattern. The inertia of the fluid requires the conservation of such side components once they have come into existence, thus it acts in favor of turbulence. In the static treatment of the capillary flow in 10, there was no inertia, and side components were entirely out of consideration; thus it appeared as if the results obtained there could be extended to arbitrarily large tubes and arbitrarily fast flows. Note also the antagonism between viscosity and inertia that becomes apparent even in the structure of the expression $\nu = \mu/\rho$ which occurs in the denominator of (8): An increase of μ permits one to increase the value of va without leaving the region of stability; increasing ρ diminishes that value and favors turbulence.

This view is also in accordance with the apparent lack of definition of the transition point, a fact that could be compared with the well known thermo-dynamic phenomenon of super-cooled water. Water can be cooled

below 0°C without freezing provided that it is left entirely undisturbed. Similarly, the regime of the laminar flow can be extended to larger R by carefully avoiding the production of lateral components at the inlet or by the roughness of the walls.

In order to decide whether there exists at all a sharply defined ideal value of the critical Reynolds number one would have to proceed as follows: one studies the flow in a sufficiently long tube with sufficiently smooth walls at a sufficiently large distance from the inlet. Initial flow irregularities in the region of the inlet will have enough time to attenuate in the stable case without the interference of side components newly created at the wall. If now at certain R -values laminar and at other R -values turbulent flow is observed and if the upper limit of the *former* R -values agrees with the lower limit of the *latter* R -values, the common limit would appear as the ideal value of R_{crit} .²¹ Such an experiment cannot be carried out practically, therefore the large variation of the values of R_{crit} given in the literature.²²

The transition to turbulent flow becomes apparent not only in the change of the flow pattern, but also in the change of the *pressure-law*, to which we now turn. Here the second law of similitude (9) comes into the foreground. We replace p in (9) by the pressure difference Π between the beginning and the end of the tube observing that the dimensions of Π and p are, of course, the same. In doing so the length l of the tube must now also be considered (the tube in Eq. (9) could have had any arbitrary length). Now l cannot be related to the dimensionless number in (9), but we may use the ratio l/a to rewrite the definition of S as

$$(11) \quad \Pi = \rho v^2 \frac{l}{a} S,$$

which is valid for the similar motions 1 and 2 at the same S -value but for different subscripts of Π , ρ , v , l , a .

We now compare (11) with the formula used in hydraulics to compute the loss of pressure head in pipe or channel systems:

$$(11a) \quad h = \lambda \frac{v^2}{2g} l \frac{U}{F}.$$

²¹It seems not impossible that with improved experimental conditions (better regulation at the inlet and smoother walls) R_{crit} may be raised to arbitrarily high values. If this should be true, an ideal value would not exist and Reynolds's stability limit would only be of practical value, depending on experimental conditions. On the other hand, there seems to exist a definite Reynolds number below which turbulent flow cannot be maintained.

²²They have been systematically investigated according to inlet conditions by L. Schiller.

Here λ is a pure number, the "hydraulic friction coefficient", F is the cross-sectional area of the flow, U the wetted circumference of the conduit. For a circular cross-section filled with fluid, U/F becomes $2/a$ so that

$$(11b) \quad h = \lambda \frac{v^2 l}{g a}.$$

On identifying S with λ and expressing Π by the hydrostatic level difference h ($\Pi = \gamma h = \rho g h$), (11b) becomes identical with (11).

If, on the other hand, S is identified with the pure number $8/R$, so that

$$S = \frac{8\nu}{va} = \frac{8\mu}{\rho va},$$

the Hagen-Poiseuille formula

$$(12) \quad \Pi = 8\mu l \frac{v}{a^3},$$

is obtained with the only difference that, previously, we had the more precisely defined average velocity u_m where we now have v .

In (11b) and (12) the different forms of the pressure dependence in laminar and turbulent flow that was already mentioned on p. 80, become again apparent: in (11b) the dependence on v and a is in the form v^2/a , in (12) in the form v/a^3 . We have been able to overcome this contrasting behavior by choosing the number S in two different ways. (Note that the definition of S in (9) does not, in itself, teach anything about the interdependence of the flow parameters; only the identification of S with another non-dimensional combination of flow parameters has the character of a physical law.)

It will be noticed that the hydraulic formula (11a) has the same structure as a law of air resistance that had already been used by Newton. According to this law, a body having the velocity v relative to air experiences a resistance proportional to v^2 (the same is true for the wind pressure against a surface at rest). Also in ballistics the resistance law is, at subsonic velocities, nearly a v^2 -law.

A more accurate representation of the pressure losses observed in turbulent flow through smooth pipes is possible within the framework of Eq. (11) if a *weak* dependence of S on R is assumed, (that is, S is supposed neither independent of R as in (11b) nor $\sim R^{-1}$ as in (12)). The following assumptions have been tested for larger R -values

$$(13) \quad S = \lambda R^{-\kappa} \quad \text{and} \quad S = \lambda_0 + \lambda_1 R^{-\kappa}$$

with $\kappa = 1/4$ to $1/5$ in the first formula (13) and with somewhat larger values of κ in the second one.

The hydraulic v^2 -law (11a) is modified by the first formula (13) (Blasius formula, $\kappa = 1/4$) to $v^{2-\kappa}$ which agrees almost exactly with old observations of Hagen and Reynolds (cf. also problem III, 2). For more details about the pressure in the transition region and the influence of roughness see L. Prandtl's "Strömungslehre", Braunschweig 1949, which can be considered as a source book in this field.²³

The change of the pressure law at the critical limit is schematically represented in Fig. 18: At small velocities $v < v_{crit}$ the linear law of

FIG. 18. The pressure gradient as a function of the mean velocity v . At the critical point A the laminar flow becomes turbulent.

Hagen-Poiseuille, at velocities $v > v_{crit}$ the increase according to $v^{2-\kappa}$. The broken line that continues the straight branch beyond A represents the possible increase of the stability limit A .

The change of the pressure law at A is accompanied ("caused" would perhaps be the better word) by a noticeable change of the velocity distribution over the cross-section. In contrast to the parabolic distribution of the laminar case, the time average of the velocity in turbulent flow is practically constant over the interior of the tube; only in the close vicinity of the wall it drops quickly to zero, satisfying the boundary condition $v = 0$.

The contrast laminar-turbulent occurs not only in circular tubes or pipes with other cross-sections, but can also be observed in the flow between two plates at rest. This flow pattern, a two-dimensional analogy to the Hagen-Poiseuille flow, was treated in problem II, 3a. The parabolic velocity profile which is also characteristic for this case is shown in Fig. 19.

If the parabolic cylinder of Fig. 19 is cut along the symmetry plane $y = h$, that is, if only the lower half of the flow pattern is considered, one obtains the velocity distribution in a stream in laminar motion (strictly speaking, the stream is infinitely wide). Let the bottom of the stream form the angle α with the horizontal (Fig. 19a), so that the component of gravity $\rho g \sin \alpha$ replaces the pressure gradient of the previous figure. L. Hopf²⁴ (Munich thesis, 1909) made a careful investigation of

²³For pipe flow compare J. C. Hunsaker and B. G. Rightmire, Engineering application of Fluid Dynamics, McGraw-Hill, New York, 1947, Chap. VIII.

²⁴Partly published in Ann. d. Phys. 32, 777 (1910).

the experimental realization of such a laminar stream stabilized by viscous forces, and of the limits of its stability. The critical Reynolds number in this investigation was found to be $R_{crit} = \nu h/\nu \cong 330$.

An even simpler case of laminar motion develops from Fig. 19 when one of the plates is at rest while the other moves with constant velocity

FIG. 19. Laminar flow between two plates at rest.

FIG. 19a. The "river in laminar flow" under the influence of gravity; free surface at $y = 0$.

U . The velocity profile is here linear for laminar flow (cf. Fig. 19b). On denoting the flow velocity by u , we have

$$(14) \quad u = \frac{y}{h} U \quad \text{and, of course,} \quad v = w = 0.$$

The flow proceeds parallel to the x -direction; it should be noticed, however, that this flow is not irrotational although there seems to be no rotation involved in it:

$$2\omega_z = \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} = -\frac{U}{h}.$$

Because of its particular analytic simplicity, (14) is the preferred flow for theoretical investigations of stability (cf. 38).

Following Couette,²⁵ an elegant realization of this flow can be made by means of two coaxial cylinders. When the inner cylinder is at rest and the outer cylinder moves with a circumferential velocity U , transition to turbulent flow occurs according to Couette at a Reynolds number $R_{crit} = Uh/\nu = 1900$ where h is the thickness of the fluid layer. The converse case where the inner cylinder moves has been thoroughly investigated by Taylor.²⁶

In this discussion we have only scratched the surface of the turbulence problem. Central questions such as: "What is the reason for the instability?" "Is it possible to give a mathematical description of the turbulent fluctuations of the velocity?" "Is the turbulent state contained among

²⁵M. Couette, Ann. Chim. Phys. 21 (1890).

²⁶Sir G. I. Taylor, Phil. Trans. 223, 289 (1923).

the solutions of the Navier-Stokes equations?" have not been touched. No complete answer to these questions to which we shall return in 38 seems possible today.

FIG. 19b. The laminar rectilinear flow between a plate at rest and in motion may be considered as the limiting case of the Couette flow between coaxial cylinders.

17. Some Remarks on Capillarity²⁷

The molecular forces of cohesion that are responsible for the phenomena of capillarity have already been encountered at the end of 12 in the form of the normal pressure N acting on the fluid surface (Laplace's theory). For the purpose of a short survey, however, it is more convenient not to adopt Laplace's²⁸ starting point but to follow Gauss²⁹ who proceeds from a minimum principle for the surface energy; the normal pressure N of Eq. (12.16) will be derived from this minimum principle.

We stipulate that there acts within the surface F of the fluid an everywhere equal *surface tension* T in tangential direction: F is, as it were, covered by a membrane which does not by itself possess elasticity of form. Its resistance against deformation (comparable with that of a thin rubber skin) is furnished solely by a tangential tension T that acts along the border of the membrane in the direction that is normal to the border and lies in the tangential plane.

We start with a simplified case, restricting ourselves to a *cylindrical* fluid surface or, which amounts to the same, to a membrane of cylindrical form. The tension equilibrium in such a membrane is the same as that of a *vibrating string* the instantaneous shape of which coincides with the profile of the cylinder.

Let u be the displacement of the string between two neighboring points P and P' and Δs their distance. We separate this segment from the rest of the string by cuts at P and P' (cf. Fig. 20a). To make up for the

²⁷Since we wish to treat the phenomena of capillarity only to such extent as is indispensable in a textbook on general hydrodynamics, we refer for a more complete representation to H. Minkowski's carefully written article in *Enzyklopädie d. Math. Wiss.* Vol. V, 1 p. 558; there the reader will also find a molecular-theoretical explanation of capillarity which is more complete and cuts deeper than our purely phenomenological remarks.

²⁸*Mécanique céleste*, Supplément de l'action capillaire, 1806.

²⁹*Principia generalia theoriae fluidorum in statu aequilibrii*, (1830).

effect of the two remaining pieces, we introduce the tensions T and T' acting in the tangential directions of the string.³⁰ They are both equal in magnitude to the tension to which the string is subjected (say, by the peg at the end) but are not parallel to each other. Let $\Delta\epsilon$ be the change

FIG. 20a. The tension T of a vibrating string and the corresponding restoring force N . At the same time this is a cross-sectional diagram of a cylindrical liquid surface.

of the slope corresponding to Δs , and ΔT the closing side of the force triangle with sides T and T' (insert of Fig. 20a). The magnitude of the vector ΔT is then

$$\Delta T = T |\Delta\epsilon|$$

and its direction is perpendicular to the arc element Δs . The resultant force acting on Δs equals $-\Delta T$. Instead of this, we introduce the resultant force per unit of length N so that $N\Delta s = -\Delta T$ and consequently

$$(1) \quad N\Delta s = T |\Delta\epsilon|.$$

On the other hand, the curvature $1/R$ is given by

$$(2) \quad \pm \frac{1}{R} = \lim_{\Delta s \rightarrow 0} \frac{\Delta\epsilon}{\Delta s} = \frac{\frac{\partial^2 u}{\partial x^2}}{\left(1 + \left(\frac{\partial u}{\partial x}\right)^2\right)^{3/2}}$$

where u is the deflection of the string and x the abscissa taken along the undeflected string; in the denominator of the last member we must take the positive value of the square root if s increases with x , which we assume.

Eqs. (1) and (2) determine the magnitude of N :

$$N = \frac{1}{|R|} T.$$

The direction of N points always to the concave side of the string.

³⁰Note that the dimension of T here is that of a force while in the following two-dimensional case T has the dimension force/length.

Let us now slightly extend the meaning of N by providing it with a $+$ or $-$ sign according to whether $\Delta\epsilon$ is negative or positive. (In Fig. 20a, N is thus positive.) If, in addition, we adopt the lower sign in (2) which makes $R \geq 0$ if $\Delta\epsilon \leq 0$, we may rewrite the last equation for the modified N :

$$(3) \quad N = \frac{1}{R} T,$$

or, for sufficiently small deflection,

$$(4) \quad N = - \frac{\partial^2 u}{\partial x^2} T.$$

From (4) we derive immediately the differential equation of the vibrating string mentioned in the context of Eq. (13.9). We have only to state the equilibrium between the external force in $+u$ -direction (that is $-N$) and the inertia force of the unit length of the string $-\rho \partial^2 u / \partial t^2$, and obtain

$$(5) \quad \rho \frac{\partial^2 u}{\partial t^2} = T \frac{\partial^2 u}{\partial x^2}$$

where ρ is the linear density of the string.

If we now pass from a cylindrical to a surface of double curvature, (4) has to be replaced by

$$(6) \quad N = \left(\frac{1}{R_1} + \frac{1}{R_2} \right) T,$$

where R_1 and R_2 are the two principal radii of curvature at the surface point under consideration. While in general the surface normals at two infinitesimally distant surface points do not intersect, but are skew to

FIG. 20b. A vibrating membrane of double curvature; R_1 and R_2 are the radii of curvature of the two principal sections. At the same time this represents a liquid surface of the same shape.

each other, surface normals along the principal directions do intersect, and it is exactly this circumstance that defines the principal directions. The radii R_1 , R_2 are then explained as the reciprocals of the curvatures of the two principal (normal) sections. Denoting their centers of curvature by C_1 and C_2 respectively (see Fig. 20b), we now investigate the equilibrium of the surface tensions T acting on the infinitesimal rectangle $\Delta s_1 \Delta s_2$ of Fig. 20b oriented parallel to the principal directions 1 and 2. If one constructs the force triangles for either principal section as in Fig. 20a one obtains two concluding sides ΔT_1 and ΔT_2 and from them two normal pressures N_1 and N_2 as in equation (4). The normal pressure N in Eq. (6) is evidently obtained by adding N_1 and N_2 .

From (6), the differential equation of the vibrating membrane follows directly in the form mentioned in the context of Eq. (13.9), if one puts according to (3) and (4)

$$(7) \quad \frac{1}{R_1} \sim -\frac{\partial^2 u}{\partial x^2}, \quad \frac{1}{R_2} \sim -\frac{\partial^2 u}{\partial y^2}$$

and substitutes for N the inertia force

$$N = -\rho \frac{\partial^2 u}{\partial t^2}, \quad (\rho = \text{surface density}).$$

The equation thus obtained from (6)

$$(8) \quad \frac{\partial^2 u}{\partial t^2} = c^2 \left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} \right), \quad c^2 = \frac{T}{\rho}$$

is not only correct for coordinates taken in the principal directions, but because of the invariance of the ∇^2 -operator for arbitrary Cartesian coordinates x, y , too.

The quantity

$$(9) \quad M = \frac{1}{R_1} + \frac{1}{R_2}$$

that occurs in (6) is the *mean curvature* of the surface, while the measure of the curvature³¹ introduced by Gauss

$$(9a) \quad K = \frac{1}{R_1 R_2}$$

is called *Gauss's or total curvature*.

³¹Minkowski *loc. cit.* defines the mean curvature $M = 1/2 (1/R_1 + 1/R_2)$ which corresponds better to the idea of a "mean" curvature. We retain the usual definition (9), which is, of course, irrelevant for the following results.

Our remarks about the vibrating string and membrane seem to be a digression from the subject of capillarity, but actually Eqs. (4) or (6) are applicable, as they stand, for the capillary surface skin in a cylindrical or more general form. They can be introduced in Eqs. (12.19) or (12.21), which were derived from Hamilton's principle, and determine therefore the surface condition for the hydrodynamic pressure p .

Let us first take a *free surface* such as water bounded by air; then $p = N$ according to (12.19). For a cylindrical surface (realized by a capillary wave traveling, e.g., in x -direction), N is given by (3) or (4), and we have

$$(10) \quad p = \frac{T}{R} \quad \text{or} \quad p = -T \frac{\partial^2 u}{\partial x^2},$$

where in the second equation the displacement u relative to the rest position is supposed to be sufficiently small. We shall come back to this equation in 25. Likewise we have for a surface of general shape according to (6)

$$(11) \quad p = T \left(\frac{1}{R_1} + \frac{1}{R_2} \right).$$

Here as well as in (10) p is the (hydrodynamic) pressure in the fluid over which the capillary lamina is spread out.³²

A soap film subtended by a rigid boundary curve (a wire loop bent in some way) can be considered as an isolated capillary lamina devoid of the fluid body by which it is otherwise supported. Since the air pressure on both sides cancels, $p = 0$, and according to (11) the mean curvature M is then also zero. The same condition would, of course, be true for an actual membrane in equilibrium if subjected to the same boundary conditions; the equilibrium condition $\nabla^2 u = 0$ as it follows from (8) agrees with (11) when $p = 0$, provided the membrane is approximately plane.

The vanishing of M means that the two principal radii of curvature are numerically equal but opposite. A surface with this property is called a *minimal surface*. Its area F is smaller than that of any neighboring surface with the same boundary curve. This is easily understood from the capillary standpoint: The tensional energy U stored in the capillary film is

$$(12) \quad U = T \cdot F.$$

³²As a supplement to Eqs. (10) and (11) we should like to emphasize that there is also a pressure load on the plane, undisturbed surface termed internal pressure by van der Waals. As indicated on p. 93, it is a consequence of the molecular attraction. The surface tension T is present on a plane surface too, but it becomes active only on a wavy surface where it changes direction from point to point.

A virtual displacement at constant T with the boundary kept fixed produces a change of energy

$$(13) \quad \delta U = T\delta F.$$

This, on the other hand, is the virtual work which is supposed to vanish in equilibrium. Therefore $\delta F = 0$ is the equilibrium condition, indicating that the surface F occurring in the energy expression (12) must be a surface of smallest area.

This is shown in the following well known experiment:³³ on a plane soap film with an otherwise arbitrary boundary a loop of thread is placed. The film inside the loop is destroyed, e.g., by piercing it. Upon that, the loop is immediately pulled out into circular form. Since the circle is the curve of maximum area for a given circumference the remaining part of the membrane has the smallest area for the given (rigid) boundary and length of thread.

In the interior of a *closed soap bubble* there is overpressure relative to the external pressure. The shape of the bubble is spherical if gravity is neglected; since for reasons of symmetry $R_1 = R_2$, the radius of the bubble is by (11)

$$R = \frac{2T}{p}.$$

In a structure consisting of many adjacent bubbles (*foam*), the pressures in the single bubbles or cells will be slightly different. The pressure difference along the walls of the structure is therefore constant for any region that bounds not more than two cells. According to (11) the entire structure is then composed of surface pieces of *constant mean curvature*.

Condition (13) applies also to phenomena involving the *angle of contact*. Consider e.g. an arrangement as in Fig. 21 and suppose that, of the three

FIG. 21. Equilibrium between a liquid (1), air (2), and a rigid wall (3); ϑ is the angle of contact.

media abutting on each other at P , 1 is a liquid, 2 is air and 3 a solid. P is a point of the contact line which we imagine perpendicular to the plane of the drawing; if the point P is given a virtual displacement up-

³³A great many other experiments with accurate description of the soap bubble technique in C. V. Boys, *Soap Bubbles*, London (1931).

ward, δw , the surface of separation F_{12} is increased per unit of length of the contact line by

$$\delta F_{12} = \cos \vartheta \cdot \delta w \cdot 1,$$

where ϑ is the angle of contact, and the surface of contact F_{13} is increased by

$$\delta F_{13} = \delta w \cdot 1.$$

As in (13) we stipulate

$$T_{12}\delta F_{12} + T_{13}\delta F_{13} = (T_{12} \cos \vartheta + T_{13})\delta w = 0,$$

or, since δw is an arbitrary variation,

$$(14) \quad \cos \vartheta = - \frac{T_{13}}{T_{12}}.$$

In order to obtain an acute angle for ϑ (water and glass), T_{13} must be negative and $|T_{13}| < T_{12}$. For non wetting liquids (mercury and glass) ϑ is obtuse.

Capillary elevation and depression are caused by the combined action of gravity and surface tension, cf. problem III, 5. As familiar a phenomenon, however, as a liquid droplet under the action of gravity leads to a complicated differential equation that admits only approximate solutions. A less complicated problem is the theory of the beautiful phenomena known as "water bells".³⁴

A complete theory of capillarity is not possible without the use of thermodynamic considerations (Gibbs).

We should like to add that in the original theory of Laplace there is, beside the surface contribution to the capillary energy [our equation (12)], a second term which is proportional to the *volume* of the liquid. This term is essential in van der Waals's theory of the liquid state; it corresponds to the constant a that occurs in van der Waals's equation of state of a real gas.

³⁴A vertical jet is directed centrally against a circular plate. The liquid leaves the plate as a thin film in the form of a surface of revolution, sometimes in the shape of a bell. See E. Buchwald and H. König, Ann. d. Phys. 23, 557 (1935) and 26, 650 (1936).

CHAPTER IV

VORTEX THEORY

18. Helmholtz's Vortex Theorems

In the paper of 1858 in which Helmholtz gives the kinematic analysis of vortex motion (cf. the footnote on p. 1) he also completes the dynamic theory of vortices in its essentials. Simplifications in method were found in the following decades, but new results were not discovered.

The main content of Helmholtz's theory are the conservation laws:¹ *It is impossible to produce or destroy vortices*, or, expressed in more general terms, *the vortex strength is constant in time*. This theorem is correct under the following conditions: the fluid is inviscid and incompressible; the external forces possess a single-valued potential within the space filled by the fluid. Apart from the conservation of the vortex strength *in time* we shall see that there is also a *spatial* conservation: the vortex strength is constant *along each vortex line or vortex tube*, which must be either closed or end at the boundary of the fluid.

1. The Differential Form of the Conservation Theorem

Following Helmholtz we start from Euler's equations in the form (11.2). Since the external force \mathbf{F} has a potential U by hypothesis, Euler's equations can be written

$$(1) \quad \frac{d\mathbf{v}}{dt} = - \text{grad} \left(\frac{p + U}{\rho} \right).$$

The differential quotient on the left side is again the material acceleration, that is, the total rate of change of the velocity of the material particle under consideration. This leads to the form (11.7) of Euler's equations which can now be written in the following way:

$$(2) \quad \frac{\partial \mathbf{v}}{\partial t} - \mathbf{v} \times \text{curl } \mathbf{v} = - \text{grad} \left(\frac{\mathbf{v}^2}{2} + \frac{p + U}{\rho} \right).$$

¹Corresponding theorems have been found in posthumous papers of Lejeune Dirichlet, +1859, and were published by Dedekind who edited Dirichlet's collected works.

We take the curl of this equation: the right member vanishes because of $\text{curl grad} = 0$. On setting $\omega = \frac{1}{2} \text{curl } \mathbf{v}$ we obtain

$$(3) \quad \frac{\partial \omega}{\partial t} - \text{curl} (\mathbf{v} \times \omega) = 0.$$

We make use of the following well known formula to transform the vector product of any two vectors ω and \mathbf{v} :

$$(4) \quad \text{curl} (\omega \times \mathbf{v}) = (\mathbf{v} \text{ grad}) \omega - (\omega \text{ grad}) \mathbf{v} + \omega \text{ div } \mathbf{v} - \mathbf{v} \text{ div } \omega.$$

(This formula is proved, just as the related formula (11.6), by verification in Cartesian coordinates.)

In our case, (4) simplifies on account of

$$\text{div } \mathbf{v} = 0 \quad \text{and} \quad \text{div } \omega = \text{div curl } \mathbf{v} = 0,$$

and one obtains by substitution in (3)

$$(5) \quad \frac{\partial \omega}{\partial t} + (\mathbf{v} \text{ grad}) \omega = (\omega \text{ grad}) \mathbf{v}.$$

The left member is the material rate of change of ω so that (5) can also be written as

$$(6) \quad \frac{d\omega}{dt} = (\omega \text{ grad}) \mathbf{v}.$$

The material rate of change of ω is zero wherever ω is zero. From this point Helmholtz immediately proceeds to the conclusion, that *fluid particles which were vortex-free at some time remain so for ever*. The reasoning he may have had in mind could be this: Let $\omega = 0$ for $t = t_0$, then by (6) $d\omega/dt = 0$. These two statements seem to imply that, for the mass particle under consideration, ω is still zero for $t = t_0 + \Delta t$. Then (6) implies $d\omega/dt = 0$ also for $t_0 + \Delta t$, which is equivalent to $\omega = 0$ for $t = t_0 + 2\Delta t$, and so on.

For a rigorous mathematical proof we need more preparation: Let \mathbf{A} be a vector associated with the moving fluid (not a "point function",

FIG. 22. The flux of a vector through a surface element σ that moves with the fluid.

but a "particle function") and $d\sigma$ a surface element that likewise moves with the fluid, changing its shape and position in the course of time. Let A_n denote the component of \mathbf{A} normal to $d\sigma$ and consider the flux of \mathbf{A} through $d\sigma$ at successive instances t_1 and t_2 . Corresponding line elements

ds_1 and ds_2 of the boundaries of $d\sigma_1$ and $d\sigma_2$ are correlated to each other by the displacement $w = vdt$, which is the length of the infinitesimal region in Fig. 22. Its top and bottom surfaces are $d\sigma_2$ and $d\sigma_1$ and its volume $d\tau = w_n d\sigma$. (In view of the limiting process we are going to perform, it does not make any difference whether we identify $d\sigma = d\sigma_1$ and $w_n \perp d\sigma_1$, or $d\sigma = d\sigma_2$ and $w_n \perp d\sigma_2$).

Gauss's theorem or the definition of the divergence (both amount to the same) yields

$$(7) \quad \int A_n d\sigma = \text{div } \mathbf{A} d\tau = (\text{div } \mathbf{A}) w_n d\sigma.$$

The integral to the left refers to the boundary of the volume swept by $d\sigma$ in the time dt . Note, however, that the vector field \mathbf{A} is for the present kept constant in time. (Think of it as "frozen" at the instant t_1 .)

In Fig. 22 one element of the *side surface* of $d\tau$ has been marked. Its contribution to the integral is

$$\mathbf{A} \cdot (d\mathbf{s} \times \mathbf{w}) = d\mathbf{s} \cdot (\mathbf{w} \times \mathbf{A}) = ds(\mathbf{w} \times \mathbf{A})_n,$$

where the subscript s to the last term denotes the component in the direction of $d\mathbf{s}$, which makes a right hand screw with the outward normal of the top surface. The integral over the side wall thus becomes equal to the line integral over the boundary of the surface

$$(7a) \quad \int ds (\mathbf{w} \times \mathbf{A})_n = d\sigma \text{curl}_n (\mathbf{w} \times \mathbf{A}),$$

a transformation that corresponds to Stokes's theorem.

The contributions of the top and bottom surfaces to the integral in (7) are simply

$$(A_n d\sigma)_2 - (A_n d\sigma)_1 = \delta(A_n d\sigma)$$

(note the opposite orientation of the normals). The right member $\delta(A_n d\sigma)$ denotes the change of the \mathbf{A} -flux due to the motion and distortion of $d\sigma$. From (7) and (7a) this change is now found as

$$(7b) \quad \delta(A_n d\sigma) = (\mathbf{w} \text{div } \mathbf{A} - \text{curl } (\mathbf{w} \times \mathbf{A}))_n d\sigma.$$

We have still to take account of the change of the field \mathbf{A} itself. The change of flux due to this cause is during the time dt

$$\frac{\partial A_n}{\partial t} dt d\sigma$$

On denoting the total change of flux by

$$\frac{d}{dt} (A_n d\sigma) dt$$

and substituting for the displacement \mathbf{w} its value $\mathbf{v} dt$, we obtain finally

$$(7c) \quad \frac{d}{dt} (A_n d\sigma) = \left(\frac{\partial A}{\partial t} + \mathbf{v} \operatorname{div} \mathbf{A} - \operatorname{curl} (\mathbf{v} \times \mathbf{A}) \right)_n d\sigma.$$

This formula, too, was found by Helmholtz,² but in another connection. It appears in his posthumous paper about the principle of least action in electrodynamics.

Upon identifying the vector \mathbf{A} with the vortex vector $\boldsymbol{\omega}$, Eq. (7c) which is correct for any direction of the normal \mathbf{n} of $d\sigma$, becomes

$$(8) \quad \frac{d}{dt} (\omega_n d\sigma) = \left(\frac{\partial \omega}{\partial t} - \operatorname{curl} (\mathbf{v} \times \boldsymbol{\omega}) \right)_n d\sigma$$

since $\operatorname{div} \boldsymbol{\omega} = 0$. The right member vanishes because of (3), thus

$$(9) \quad \frac{d}{dt} (\omega_n d\sigma) = 0.$$

This equation expresses the theorem of *conservation of vortices*. The flux of the vortex vector has a certain unalterable value for every surface element that moves with the fluid. *Vortices cannot be created or destroyed, or, the vorticity is a convective quantity of the flow; it adheres to the individual fluid particle and moves along with it.*

2. The Integral Form of the Conservation Theorem

We start from the concept of *circulation* (p. 17) established by Lord Kelvin³ with the aim of simplifying Helmholtz's vortex theory. Identifying the general vector \mathbf{A} of (2.21) with our \mathbf{v} , we consider the circulation

$$(10) \quad \Gamma = \oint \mathbf{v} \cdot d\mathbf{s} = \oint (\mathbf{v} \cdot d\mathbf{s}) = \oint (u dx + v dy + w dz)$$

around a circuit, i.e., a closed oriented curve in the fluid; we think of it as of a "material curve" that consists, like a string of beads, of *material fluid particles*, and floats along with them. Let C be the circuit at the

²Ges. Werke, Vol. III, p. 476, cf. particularly the equations (8a), (8b) that refer to the vector of the virtual displacement $\mathbf{A} = \{\delta\xi, \delta\eta, \delta\zeta\}$. Helmholtz writes everything in components, which does not add to lucidity; our notation and derivation corresponds to H. A. Lorentz's presentation in *Enzykl. d. Math. Wiss.* Vol. V, 2, p. 75, Eq. (5); there the equation is shown to be of fundamental importance in the electrodynamics of moving bodies.

³W. Thomson (Lord Kelvin), On Vortex Motion, *Transactions R. Soc. Edinburgh*, Vol. 25 (1869). Reprinted in *Mathem. and Phys. Papers*, Vol. IV, p. 13. In the same volume on p. 1, there is also the paper on vortex atoms often referred to in the popular literature: the vortex atoms left no impression on the development of atomic physics.

instant t and C' the distorted circuit at $t + \Delta t$ (see Fig. 23). Let ds be an arc element of C and ds' the corresponding element of C' . The straight arrows in the figure represent the paths of the fluid particles during Δt , drawn for two neighboring particles i and $i + 1$; the lengths are

$$v_i \Delta t \quad \text{and} \quad v_{i+1} \Delta t.$$

The arrows correspond, of course, to the vector \mathbf{w} in Fig. 22. Fig. 23 differs from Fig. 22 only in that the infinitesimal boundary curves of the elements $d\sigma$ are now pulled out into finite circuits C and C' . The following calculation is likewise closely related to the previous one.

FIG. 23. Illustrating the concept of circulation.

First, we see from the quadrilateral formed by the arrows in Fig. 23 that

$$v_i \Delta t + ds' = ds + v_{i+1} \Delta t$$

or

$$(11) \quad \frac{ds' - ds}{\Delta t} = v_{i+1} - v_i.$$

We now calculate

$$(12) \quad \frac{d\Gamma}{dt} = \lim_{\Delta t \rightarrow 0} \frac{\Gamma' - \Gamma}{\Delta t} = \frac{d}{dt} \oint \mathbf{v} \cdot d\mathbf{s} = \oint \frac{d\mathbf{v}}{dt} \cdot d\mathbf{s} + \oint \mathbf{v} \cdot \frac{d}{dt} d\mathbf{s},$$

where Γ' stands for the circulation about C' . The expression that appears in the last integrand

$$\frac{d}{dt} d\mathbf{s}$$

is nothing else but the limit of the first member of (11) for $\Delta t \rightarrow 0$. An approximate value of the integral itself is thus found in the sum

$$\sum_i \mathbf{v}_i \cdot (\mathbf{v}_{i+1} - \mathbf{v}_i).$$

If we now go to the limit $i \rightarrow \infty$, the polygon $\cdots i, i + 1 \cdots$ approaches the circuit C and our sum approaches the line integral over C

$$\oint \mathbf{v} \cdot d\mathbf{v} = \frac{1}{2} v^2 \Big|_A^B,$$

where A is the arbitrary starting point (corresponding to $i = 0$) and B the end point of the integration, which coincides with A . Thus the second integral in the last member of (12) vanishes.

But the first integral vanishes likewise. According to Euler's Eqs. (1) it equals the line integral of $-\text{grad} [(p + U)/\rho]$, that is

$$\frac{p + U}{\rho} \Big|_B^A = 0.$$

Thus we have according to (12)

$$(13) \quad \frac{d\Gamma}{dt} = 0, \quad \Gamma = \text{const.}$$

The circulation taken about an arbitrary circuit that consists of material particles retains its initial value throughout the flow.

The circulation is directly connected with the vorticity present in the fluid as we shall show now. According to Stokes's theorem (3.2) we have

$$(14) \quad \Gamma = \oint \mathbf{v} \cdot d\mathbf{s} = \oint v_s ds = \int \text{curl}_s \mathbf{v} d\sigma = 2 \int \omega_s d\sigma.$$

If we now consider an arbitrary surface bounded by the circuit C and take at every element $d\sigma$ the normal component of the vortex vector ω , Γ equals twice the vorticity that passes the surface σ . Hence the flux of the vortex vector through the surface σ remains constant throughout the flow. Helmholtz's vortex theorem appears here in the form of Kelvin's circulation theorem; the contents of both are identical.*

It is, of course, not necessary to follow a particular surface σ chosen in (14) throughout its motion, since any surface through C gives the same vortex flux $\omega_s d\sigma$. This is again a consequence of Stokes's theorem which

*It is now easy to see that the assumption $\rho = \text{const}$ is not necessary for the validity of the conservation theorem. There is only one point in the foregoing proof that has not a purely kinematic character, and this is the vanishing of $\oint (dv/dt) \cdot ds$ in (12); here the compressibility might have an effect. But in the compressible case the integrand may be written in the form $-\text{grad} (\Phi + V)$ when the notation of Eqs. (7.6b) and (7.7) is used, provided that a p, ρ -relation is given.

The condition for the validity of Helmholtz's (or Kelvin's) theorem is therefore the existence of a single-valued "acceleration potential"

$$\int_{P_1}^{P_2} \frac{1}{\rho} (\text{grad } p + \mathbf{F}) \cdot d\mathbf{s},$$

and it does exist when

1. the fluid is inviscid
2. the external force per unit of mass, \mathbf{F}/ρ , has a single-valued potential V
3. a p, ρ -relation exists.

permits us to use an *arbitrary* surface σ . But it is required that the circuit C consist permanently of the same material particles.

Eqs. (13) and (14) become obviously identical with the previous Eq. (9) when σ becomes infinitesimal. Conversely, we could have derived the present result from (9) by an integration over $d\sigma$, but the reasoning used here is simpler and less abstract than the previous one and might be considered as a supplement not entirely superfluous.

While Eqs. (1) and (2) represent the *differential form* of Euler's equations, the circulation theorem (13) could be called their *integral form*, using a terminological distinction taken from electrodynamics. Likewise Eqs. (7) appearing in 15 represent the *differential form of Maxwell's equations*. Besides, there is an integral form of the same equations expressing their physical content in the form of relations between line and surface integrals, more suitable for a number of purposes.

3. The Spatial Distribution of the Vorticity

Following an idea of Helmholtz we consider now the field lines of the vector field ω : The vector ω determines at a given time at every point of the field of flow a certain positive direction of the vorticity. Proceeding from one point to the next along these directions we describe a *vortex line* in exactly the same way as we describe a line of force in a field of force by proceeding along the force directions. Now we take a surface element Δq perpendicular to the vortex line which we let pass through a border point of Δq , and construct the vortex lines that go through the other border points of Δq . In this way a *vortex tube* is obtained. The circulation about the boundary of Δq is according to (14)

$$(15) \quad \Gamma = 2\mu \quad \text{with} \quad \mu = \omega \Delta q.$$

The flux of the vortex vector through the tube or the *vortex strength*,* as we shall also call it, has been denoted by μ . According to (13), μ is constant in time regardless of the changes experienced by the vortex tube and the vortex lines of which its boundary consists.

However, the vortex strength remains constant also in space, that is,

*The vortex carried by an element Δq can be characterized by $2\omega\Delta q$ as well as by $\omega\Delta q$. When the first possibility is chosen, the term *vorticity* is frequently used as a name for $2\omega\Delta q$, so that the differential circulation $\Delta\Gamma$ is directly equal to the vorticity. In this book $\omega\Delta q$ has been chosen as the characteristic quantity and the term *vortex strength* introduced to denote it, while the term vorticity is regarded as synonymous with the term vortex vector $\omega = \frac{1}{2} \text{curl } v$.

This definition of μ also presupposes that the boundary of Δq is oriented so as to form a right hand screw with ω ; μ is then essentially positive. In the two-dimensional case it is more convenient to give a sign to μ [cf. (19.8) and 21].

as long as one proceeds along the same vortex tube (cf. Fig. 24). Since $\text{div } \omega = 0$, we obtain, by applying Gauss's theorem to a piece of the vortex tube between the normal cross-sections Δq and $\Delta q'$,

$$(16) \quad 0 = \int \text{div } \omega \, d\tau = \int \omega_n \, d\sigma$$

where the integration to the right includes Δq and $\Delta q'$ and the side walls of the tube segment. But ω_n vanishes on the side wall according to the

FIG. 24. The flux of the vortex vector through an orthogonal and an oblique cross-section of a vortex tube.

definition of the vortex tube. Furthermore, the component ω_n has the value $-\omega$ at Δq and the value $+\omega'$ at $\Delta q'$, where ω and ω' are the amounts of ω at the respective places. Thus Eq. (16) means

$$(17) \quad 0 = \omega' \Delta q' - \omega \Delta q, \quad \text{that is} \quad \mu' = \mu.$$

This finishes the proof. Note also that the same value μ is obtained when the tube is cut in oblique direction. With $\Delta q''$ denoting the area of such a cut and ω''_n the normal component of ω at $\Delta q''$, Gauss's theorem gives as before

$$\omega''_n \Delta q'' = \omega \Delta q = \mu.$$

Thus the product of the area of the cut and the normal component of the vortex vector is the same for an arbitrary cut through the vortex tube. This points to an *analogy* between vortex tubes and electric currents which will be discussed in 20.

It is an immediate consequence of the constancy of the vortex strength that a vortex tube can never end within the fluid. *It either reaches the boundary or it must be closed.*

So far we have silently assumed that ω is continuously distributed in space; the vortex strength μ is then of the same order of magnitude as the tube cross-section Δq . But we can consider the limiting case, that ω is concentrated at single, infinitely narrow, linear regions, in analogy to the so-called linear conductors in electricity. The vortex vector ω becomes infinitely large within those regions while it may have any finite value outside, in particular it may be zero. In the latter case we speak of a

vortex filament. Its strength has a finite value that does not go to zero with Δq and can be written as

$$(18) \quad \mu = \lim_{\Delta q \rightarrow 0} \omega \Delta q.$$

19. Two- and Three-dimensional Potential Flow

A flow that is in general irrotational is called a *potential flow*. The term "*in general*" means here "with the possible exception of singular points or lines." As discussed already in 11, p. 88, the condition of irrotationality, $2\omega = \text{curl } \mathbf{v} = 0$, implies the existence of a *velocity potential* Φ ; in the preceding article we found in addition that a flow remains irrotational if it starts out as an irrotational flow. In the present article, however, we shall consider only *steady* flow problems so that the question of time dependence of Φ does not arise. Since we shall further assume an incompressible fluid all through this chapter, the potential equation (11.13)

$$(1) \quad \nabla^2 \Phi = 0;$$

is in general fulfilled in the space filled by the fluid. (For the meaning of "in general" see above.)

We wish to investigate the properties of the flow that result from (1). This is particularly simple in the case of two-dimensional flow where

$$(2) \quad \frac{\partial^2 \Phi}{\partial x^2} + \frac{\partial^2 \Phi}{\partial y^2} = 0.$$

Let us first compare (2) with the wave equation (13.9)

$$(2a) \quad \frac{\partial^2 \Phi}{\partial x^2} - \frac{1}{c^2} \frac{\partial^2 \Phi}{\partial t^2} = 0.$$

By putting $t = y$ and $c^2 = -1$, (2a) is changed into (2). Since the general integral of (2a) is known, viz. d'Alembert's solution (13.11)

$$(2b) \quad \Phi = F_1(x + ct) + F_2(x - ct),$$

we also know the *general solution* of (2); it is:

$$(3) \quad \Phi = \frac{1}{2} \{f(x + iy) + f^*(x - iy)\}.$$

The two arbitrary functions of (2b) must be assumed as conjugate complex in (3) (indicated by *) in order to make Φ real; besides, we have added the factor $\frac{1}{2}$ so that Φ is directly equal to the real part of $f(x + iy)$.

The general solution of (2) is therefore given by the *real part of an arbitrary analytic function* f of the complex variable $z = x + iy$. It is then convenient to write this function in the form

$$(4) \quad f(z) = \Phi(x, y) + i\Psi(x, y).$$

The imaginary part Ψ , that is, the function conjugate to Φ , is sometimes called the conjugate potential. In hydrodynamics ψ is known as the *stream function*.

To find interrelations between Φ and Ψ we differentiate (4) once with respect to x and once with respect to y , indicating the differentiation with respect to the complex argument z by $f'(z)$ as usual. This gives

$$(4a) \quad \frac{\partial}{\partial x} f(z) = f'(z) \frac{\partial z}{\partial x} = f'(z) = \frac{\partial \Phi}{\partial x} + i \frac{\partial \Psi}{\partial x},$$

$$\frac{\partial}{\partial y} f(z) = f'(z) \frac{\partial z}{\partial y} = i f'(z) = \frac{\partial \Phi}{\partial y} + i \frac{\partial \Psi}{\partial y}.$$

By elimination of $f'(z)$ results

$$\frac{\partial \Phi}{\partial x} - \frac{\partial \Psi}{\partial y} + i \left(\frac{\partial \Psi}{\partial x} + \frac{\partial \Phi}{\partial y} \right) = 0.$$

Since Φ and Ψ are real, this relation is equivalent to the two relations

$$(5) \quad \frac{\partial \Phi}{\partial x} = \frac{\partial \Psi}{\partial y}, \quad \frac{\partial \Phi}{\partial y} = - \frac{\partial \Psi}{\partial x},$$

the *Cauchy-Riemann equations of theory of complex functions*. They can be expressed in the comprehensive form of one symbolic equation

$$(5a) \quad \frac{\partial \Phi}{\partial s} = \frac{\partial \Psi}{\partial n},$$

valid for an arbitrary pair of orthogonal line elements of the x, y -plane that follow each other in the same sense as the positive real and the positive imaginary axes. When ds coincides with the x -direction (and dn consequently with the y -direction), (5a) becomes identical with the first

FIG. 25. Equipotential lines $\Phi = \text{const}$ and streamlines $\Psi = \text{const}$ in two-dimensional irrotational flow.

equation (5); when ds coincides with the y -direction and dn with the negative x -direction, (5a) becomes the second Eq. (5). That the relation between the directional derivatives (5a) is correct for any other pair ds, dn can be easily derived from (5). Thus (5a) is the appropriate vectorial

expression of the Cauchy-Riemann equations in invariant writing. When the direction ds is made to coincide with a contour line of the velocity potential as indicated in Fig. 25, the derivative $\partial\Phi/\partial s = 0$; hence, by (5a), the contour line of the stream function coincides with the n -direction since in this case

$$(6) \quad \frac{\partial\Psi}{\partial n} = 0.$$

Thus it is seen that the *two families of curves* $\Phi = \text{const}$ and $\Psi = \text{const}$ are *orthogonal to each other*. This is usually shown by cross multiplication of Eqs. (5), resulting in

$$(6a) \quad \text{grad } \Phi \cdot \text{grad } \Psi = 0,$$

but (5a) is a direct expression of that fact as we have just seen.

To justify the term *stream function*, we turn again to Fig. 25. If ds coincides with the contour line of the velocity potential as above, the vector $\mathbf{v} = -\text{grad } \Phi$ points in the direction of dn , but this is the direction of the curve $\Psi = \text{const}$ by (6); hence the lines $\Psi = \text{const}$ are the *stream lines* of the flow.

The families $\Phi = \text{const}$ and $\Psi = \text{const}$ are not only *orthogonal* but also *isometric*, that is, the rate at which the functions Φ and Ψ increase in the directions ds and dn respectively are equal; in other words, if the increments of both functions are equal, say $\delta = d\Phi = d\Psi$, then $ds = dn$ according to (5a). This means geometrically that the curves $\Phi = c_1$, $\Psi = c_2$, $\Phi = c_1 + \delta$, $\Psi = c_2 + \delta$ form an infinitesimal *square*. As a consequence, the image of an infinitesimal figure drawn in the $x + iy$ -plane appears geometrically similar in the $\Phi + i\Psi$ -plane: The mapping of the $x + iy$ -plane on the $\Phi + i\Psi$ -plane is conformal, that is, geometrically similar in the small. The scale of the mapping is given by $|f'(x + iy)|$; it changes from point to point, but, at a given point, is independent of the direction.⁵

⁵It is no exaggerated claim that the theory of analytic functions of a complex variable is identical with two-dimensional potential theory or, in terms of hydrodynamics, with two-dimensional theory of potential flow. In particular the methods introduced by Riemann in his dissertation (1851), where analytic functions are characterized by their intrinsic properties such as singularities, connectivities at branch points, etc. rather than by their analytic expressions, have been prompted by his deep interest in mathematical physics. The following story reveals in a characteristic way the attitudes of two great minds of the epoch toward Riemann's discovery. On a vacation trip in Switzerland, sometime in the seventies, Helmholtz meets Weierstrass, the great mathematician. The latter, recently engaged in the study of Riemann's dissertation, complains that R.'s methods were so hard to understand. Upon this Helmholtz borrows the paper and when he meets Weierstrass next time, he declares that Riemann's ideas appear to him perfectly natural and self-evident.

The simplest example in which we apply the methods of the theory of functions to hydrodynamics is the *line vortex* discussed on p. 35. We put

$$(7) \quad f(z) = iA \log z \quad (A \text{ real}).$$

Setting $z = re^{i\varphi}$ we obtain

$$f(z) = \Phi + i\Psi = -A\varphi + iA \log r,$$

and consequently

$$(7a) \quad \Phi = -A\varphi, \quad \Psi = A \log r.$$

The stream lines are given by $\Psi = \text{const}$ or $r = \text{const}$. The flow velocity follows from $\mathbf{v} = -\text{grad } \Phi$. Since in our case Φ depends only on φ , the velocity

$$(7b) \quad \pm v = v_\varphi = -\text{grad}_\varphi \Phi = -\frac{1}{r} \frac{\partial \Phi}{\partial \varphi} = \frac{A}{r}, \quad v_r = 0$$

in agreement with (4.29).

The origin is a singular point of the flow since v becomes infinite there. This singularity appears already in Eq. (7) since $f(z)$ goes logarithmically to infinity for $z = 0$.

The flow is everywhere irrotational except for $r = 0$. This must be so by virtue of its derivation from a complex function f , and can be verified by computing the vortex vector ω , which is here normal to the x, y -plane, in application of the results of problem I, 3:

$$2\omega = \frac{1}{r} \frac{\partial(rv_\varphi)}{\partial r} - \frac{1}{r} \frac{\partial v_r}{\partial \varphi} = 0.$$

The corresponding calculation in Cartesian coordinates is unnecessarily involved; it is carried out here for once:

$$v_x = \mp v \sin \varphi = \mp v \frac{y}{r} = -A \frac{y}{r^2},$$

$$v_y = \pm v \cos \varphi = \pm v \frac{x}{r} = +A \frac{x}{r^2}.$$

Thus we have at every point with the exception of the origin

$$2\omega = \frac{\partial v_y}{\partial x} - \frac{\partial v_x}{\partial y} = \frac{A}{r^2} - \frac{2Ax^2}{r^4} + \frac{A}{r^2} - \frac{2Ay^2}{r^4} = 0.$$

According to the invariant definition in (2.21), ω can always be computed from the circulation around an infinitely small circuit enclosing the point under consideration. This implies that *the circulation around any*

point with the exception of $r = 0$ vanishes provided the circuit is sufficiently close to the point. If on the other hand the circulation is taken around any finite (arbitrarily small) circle enclosing the origin one obtains from (18.10)

$$(8) \quad \Gamma = \oint \mathbf{v} \cdot d\mathbf{s} = \int_0^{2\pi} v r d\varphi = 2\pi A.$$

Γ is independent of r and therefore the same for any two circles r_1 and r_2 ; this is necessarily so since the circular ring between the two is vortex-free. The entire vorticity is thus concentrated at the singular origin. The vortex strength* at this point is according to our definition of μ in (18.15)

$$(8a) \quad \mu = \pi A.$$

Viewed in three dimensions, the singular point corresponds to a *vortex filament* normal to the x, y -plane. A second vortex filament of opposite strength $\mu = -\pi A$ is at infinity, when infinity is considered as a point of the complex plane as one usually does in theory of functions. Note the formula following from (7b) and (8a):

$$(9) \quad v_\varphi = \frac{\mu}{\pi r}.$$

We can have both vortex filaments located in a finite domain, e.g., at the points $z = \pm c$, if we subject z to a bilinear transformation. Consider instead of (7) the function

$$(10) \quad f(z) = iA \log \frac{z - c}{z + c}.$$

and put

$$(10a) \quad z - c = r_1 e^{i\varphi_1}, \quad z + c = r_2 e^{i\varphi_2},$$

Defining the *bipolar* coordinates ρ and φ by

$$(10b) \quad \rho = \log \frac{r_1}{r_2}, \quad \varphi = \varphi_1 - \varphi_2,$$

we obtain according to (4)

$$(11) \quad \Phi = -A\varphi, \quad \Psi = A\rho = A \log \frac{r_1}{r_2}.$$

Since all angles φ subtended by the segment $(-c, +c)$ have their vertices on a circular arc, the equipotential lines $\Phi = \text{const}$ are circles through the singular points $z = \pm c$; but the streamlines $\Psi = \text{const}$ are

*In the two-dimensional case, we take all circulation integrals in the same sense ("enclosed" area to the left hand); the vortex strength μ can then be positive or negative.

also circles since the locus of constant ratio of distances from two given points is a circle. Note that the intersection points of any circle $\Psi = \text{const}$ with the real axis separate the points $-c, +c$ harmonically. Fig. 26 shows the orthogonality of the two families of circles, it also gives an idea of the network of infinitesimal quadratic meshes that is obtained if one allows the parameters of either family of circles to change in equal increments δ .

Problem IV, 1 shows how to handle bipolar coordinates. They are infrequently used in mathematical physics, one of the reasons being that

FIG. 26. Superposition of two vortices of equal strength and opposite orientation. The diagram also shows bipolar coordinate lines.

the two-dimensional wave equation is not "separable" in these coordinates; this is discussed in the same problem.

Our present function $f(z)$ can be obtained by the superposition of two simple vortices of the type (7), one having the center $z = +c$ and the constant $+A$, the other the center $z = -c$ and the constant $-A$:

$$(12) \quad f(z) = iA \log(z - c) - iA \log(z + c).$$

A circuit of arbitrary shape enclosing $+c$, but not $-c$, gives according to (8)

$$(12a) \quad \Gamma_1 = 2\pi A$$

A circuit of arbitrary shape enclosing $-c$, but not $+c$, gives according to (8)

$$(12b) \quad \Gamma_2 = -2\pi A$$

A circuit that encloses both or none of the two singularities gives $\Gamma = 0$. As in (8a), the strength of the vortex filament in $+c$ or $-c$ is

$$(13) \quad \mu_1 = \pi A \quad \text{or} \quad \mu_2 = -\pi A.$$

The field belonging to our present function $f(z)$ can also be obtained by the superposition of two fields of the type (9) if r is replaced by $|z - c|$ and $|z + c|$, respectively. One obtains by superposition

$$(14) \quad \mathbf{v} = \frac{\mu \hat{\phi}_1}{\pi |z - c|} - \frac{\mu \hat{\phi}_2}{\pi |z + c|} = \frac{\mu \hat{\phi}_1}{\pi r_1} - \frac{\mu \hat{\phi}_2}{\pi r_2}$$

Here $\hat{\phi}_1$ and $\hat{\phi}_2$ are unit vectors in the direction of increasing angles φ_1 and φ_2 . This result will be compared in problem IV, 2 with the representation of the same flow in bipolar coordinates according to (11)

$$(14a) \quad \mathbf{v} = A \operatorname{grad} \varphi = \frac{\mu}{\pi} \operatorname{grad} \varphi.$$

We turn now to confocal elliptic coordinates, which are of importance for the flow patterns to be treated in Chapter VI. A simple approach to these orthogonal coordinates takes on the form of a geometrical analysis of the mapping of the plane $z = x + iy$ on the plane $\zeta = \xi + i\eta$ given by the following relation

$$(15) \quad z = c \cosh \zeta$$

which may also be written as

$$(15a) \quad x + iy = \frac{c}{2} (e^{\xi+i\eta} + e^{-\xi-i\eta}).$$

The substitution

$$e^{-i\eta} = \cos \eta \pm i \sin \eta,$$

leads immediately to

$$x + iy = c (\cosh \xi \cos \eta + i \sinh \xi \sin \eta).$$

Separation of real and imaginary parts on both sides gives now

$$(16) \quad x = c \cosh \xi \cos \eta, \quad y = c \sinh \xi \sin \eta.$$

From (16), η can be eliminated by the use of $\cos^2 \eta + \sin^2 \eta = 1$, resulting in

$$(17a) \quad \frac{x^2}{c^2 \cosh^2 \xi} + \frac{y^2}{c^2 \sinh^2 \xi} = 1.$$

The elimination of ξ from (16) by the use of $\cosh^2 \xi - \sinh^2 \xi = 1$ gives

$$(17b) \quad \frac{x^2}{c^2 \cos^2 \eta} - \frac{y^2}{c^2 \sin^2 \eta} = 1.$$

For constant ξ , (17a) represents an ellipse with the semi-axes

$$a = c \cosh \xi, \quad b = c \sinh \xi.$$

Its eccentricity is given by

$$(18a) \quad \sqrt{a^2 - b^2} = c,$$

and thus independent of ξ . Thus, if ξ varies, one obtains a system of confocal ellipses with foci $x = \pm c, y = 0$. On the other hand, for constant η (17b) represents a hyperbola with the semi-axes

$$a = c \cos \eta, \quad b = c \sin \eta;$$

its eccentricity is

$$(18b) \quad \sqrt{a^2 + b^2} = c$$

therefore independent of η and equal to that of the ellipses given in (18a). With variable parameter η , (17b) represents a system of hyperbolas, confocal among themselves and with the system of ellipses, cf. Fig. 27.

FIG. 27 (left). The system of confocal ellipses and hyperbolas $\xi = \text{const}$ and $\eta = \text{const}$.

FIG. 27a (above). The mapping of the $(x + iy)$ -plane on the $(\xi + i\eta)$ -plane.

It is of interest to consider the limiting parameter values $\xi = 0$ and $\xi = \infty$ in the family of ellipses: the value $\xi = 0$ gives by (17a) the focal line

$$y = 0, \quad -c < x < +c$$

and the value $\xi = \infty$ gives an infinitely extended ellipse.

As regards the parameter η , note the particular values

$$\eta = 0, \quad \eta = \pm \frac{\pi}{2}, \quad \eta = \pm \pi.$$

The value $\eta = 0$ characterizes, by (17b), the part of the real axis to the right of c : $y = 0, x > c$. $\eta = \pm \pi/2$ corresponds to $x = 0$, the hyperbola coincides with the y -axis. $\eta = \pm \pi$ gives the part of the x -axis to the left of c : $y = 0, x < -c$.

In order to obtain a unique relation between the coordinates ξ , η and the points of the x, y -plane, ξ and η must be restricted to a certain domain. One way of doing this is to assign the values $0 < \eta < \pi$ to the upper halves of the hyperbolas, and the values $-\pi < \eta < 0$ to the lower halves. By this rule the entire x, y -plane is mapped on the strip of the ξ, η -plane

$$(19) \quad 0 < \xi < +\infty, \quad -\pi < \eta < +\pi$$

indicated in Fig. 27a. Note that the one-to-one correspondence between the x, y -plane and the ξ, η -strip does not include the boundary of the strip; either the upper or the lower half of the borderline must be omitted. Or one might also consider boundary points that are mapped on the same point in the x, y -plane as identical (viz. $0, \pm\eta$; $\xi \neq 0, \pm\pi$).

The advantage of elliptic over bipolar coordinates with regard to the separability of the wave equation will be discussed in connection with problem IV,3. In Chapter VI problems arising from the flow past a plate will be treated by means of elliptic coordinates. We shall use a complex potential of the form

$$(20) \quad \Phi + i\Psi = f(\zeta), \quad \text{where} \quad f(\zeta) = \text{const} \cdot \sinh \zeta.$$

Here, ζ is thought to be related to z according to Eq. (15) so that $f(\zeta)$ becomes a complex function of z .

Let us return once more to the simple potential (7), but without the factor i on the right hand side. Then

$$(21) \quad f(z) = A \log z, \quad \Phi = A \log r, \quad \Psi = A\varphi.$$

The rays $\varphi = \text{const}$ originating at O are now the streamlines. The contour lines of the potential are the circles $r = \text{const}$ about O . Depending on the sign of A , O is either a source or a sink. Note in this connection that the general central symmetric solution of the potential equation is the logarithmic potential $\Phi = \log r$, save for a multiplicative and an additive constant.

A few remarks about the potential flow in space follow here as a supplement.

The central symmetric solution of the potential equation in space is the so-called Newtonian potential

$$(22) \quad \Phi = \frac{A}{r}.$$

No historical implication is intended, and Newton never spoke of this potential; the term should imply that (22) is associated with the field of the Newtonian attractive force

$$(22a) \quad \mathbf{F} = -\text{grad } \Phi = -A \text{ grad } \frac{1}{r}.$$

The hydrodynamical meaning of Φ is again the velocity potential of a source or sink at O .

In general, no stream function Ψ can be associated with the velocity potential in the three-dimensional case. Only in the case of an axial symmetric flow is it possible to construct a stream function.⁶ For this purpose cylindrical coordinates ρ, φ, z are introduced, z being the axis of symmetry. If the problem is axial-symmetric, Φ will not depend on φ but only on ρ and z . The potential equation (1), the mathematical equivalent of incompressibility, reads then (see problem I, 3)

$$(23) \quad \frac{\partial^2 \Phi}{\partial \rho^2} + \frac{1}{\rho} \frac{\partial \Phi}{\partial \rho} + \frac{\partial^2 \Phi}{\partial z^2} = 0.$$

It may also be written in the form

$$(23a) \quad \frac{\partial}{\partial \rho} \rho \frac{\partial \Phi}{\partial \rho} + \frac{\partial}{\partial z} \rho \frac{\partial \Phi}{\partial z} = 0.$$

From this form we can conclude that there exists a function $\Psi = \Psi(\rho, z)$ such that

$$\frac{\partial^2 \Psi}{\partial \rho \partial z} = \frac{\partial}{\partial \rho} \rho \frac{\partial \Phi}{\partial \rho} = - \frac{\partial}{\partial z} \rho \frac{\partial \Phi}{\partial z}.$$

If we now put in particular

$$(24) \quad \frac{\partial \Psi}{\partial z} = \rho \frac{\partial \Phi}{\partial \rho}, \quad \frac{\partial \Psi}{\partial \rho} = - \rho \frac{\partial \Phi}{\partial z},$$

we obtain by cross multiplication

$$\rho \left(\frac{\partial \Phi}{\partial \rho} \frac{\partial \Psi}{\partial \rho} + \frac{\partial \Phi}{\partial z} \frac{\partial \Psi}{\partial z} \right) = 0.$$

This implies that in any meridian plane $\varphi = \text{const}$ the curves $\Phi = \text{const}$ and $\Psi = \text{const}$ are mutually orthogonal. In other words, in such a plane the lines $\Psi = \text{const}$ coincide with the direction $\text{grad } \Phi$ and are *stream lines*. The function Ψ may therefore be considered as a stream function. From (24) and $\mathbf{v} = -\text{grad } \Phi$, one obtains the velocity components in the form

$$(25) \quad v_\rho = - \frac{1}{\rho} \frac{\partial \Psi}{\partial z}, \quad v_z = \frac{1}{\rho} \frac{\partial \Psi}{\partial \rho}.$$

It is impossible, however, to combine Φ and Ψ to form a complex function $\Phi + i\Psi$ of the variable $\rho + iz$ as in the two-dimensional case. If this could be done, then the relations (24) should coincide with the Cauchy-Rie-

⁶Stokes, Trans. Cambridge Phil. Soc. Vol. 7, 1842, p. 439.

mann Eqs. (5), which is not the case because of the factor ρ in (24). Also, Φ and Ψ would have to satisfy the equation $\partial^2 u / \partial \rho^2 + \partial^2 u / \partial z^2 = 0$, but actually Φ satisfies Eq. (23) and Ψ the equation obtained from $\text{curl } \mathbf{v} = 0$ by (25):

$$(26) \quad \frac{\partial^2 \Psi}{\partial \rho^2} - \frac{1}{\rho} \frac{\partial \Psi}{\partial \rho} + \frac{\partial^2 \Psi}{\partial z^2} = 0.$$

The powerful tool of the theory of complex functions cannot be used in three-dimensional potential theory.⁷

20. A Fundamental Theorem of Vector Analysis

The theorem which we wish to prove here is this: *A continuous vector field \mathbf{V} , defined everywhere in space and vanishing at infinity together with its first derivatives, can be represented as the sum of an irrotational field \mathbf{V}_1 and a solenoidal field \mathbf{V}_2 :*

$$(1) \quad \mathbf{V} = \mathbf{V}_1 + \mathbf{V}_2,$$

where

$$(1a) \quad \text{curl } \mathbf{V}_1 = 0, \text{ div } \mathbf{V}_2 = 0.$$

Our decomposition charges all sources and sinks of the given field \mathbf{V} to the component field \mathbf{V}_1 and all vortices to the component field \mathbf{V}_2 so that:

$$(1b) \quad \text{div } \mathbf{V}_1 = \text{div } \mathbf{V}, \quad \text{curl } \mathbf{V}_2 = \text{curl } \mathbf{V}.$$

The representation (1) is *unique except for a vectorial constant*.

This fundamental theorem was proved in its essentials by Stokes⁸ in

⁷The great mathematician David Hilbert (1862-1943) sharply characterized the futility of all attempts in this direction by the following remark: time is one-dimensional, space is three-dimensional, however the number, that is, the perfect complex number, has two dimensions.

⁸In his big paper: On the dynamical theory of diffraction, Trans. Cambridge Phil. Soc. Vol. 9, p. 1, reprinted in Math. and Phys. Papers, Vol. II, Cambridge, 1883, p. 243 and particularly p. 254 ff. Stokes does not yet give an explicit definition of the vector potential \mathbf{A} . Instead, \mathbf{V}_2 is calculated by the following formula obtained through a combination of our equations (5) and (9)

$$4\pi \mathbf{V}_2 = \int \frac{\text{curl curl } \mathbf{V}}{r} d\tau.$$

For a rigorous proof see: O. Blumenthal, Ueber die Zerlegung unendlicher Vektorfelder, (Mathem. Annalen 61, 235, 1905). His only restriction is that \mathbf{V} and its first derivatives vanish at infinity while no additional assumption is made about how quickly they vanish. It turns out that the component fields \mathbf{V}_1 and \mathbf{V}_2 need not vanish themselves, they may even become in a restricted way infinite. In the following we shall make the somewhat vague assumption that \mathbf{V} vanishes "sufficiently strongly" at infinity.

1849. In a more complete form, it is the basis of Helmholtz's paper on vortex motion of 1858, where it is also proved (implicitly however, and, of course, without the use of vector notation). This theorem penetrates deeper into the integration methods of mathematical physics than anything we have done so far; it is of great importance in hydrodynamics, but even more so in electro-magnetic theory. We shall prove it in three steps.

1. *Calculation of V_1 .* The irrotational vector V_1 can be derived from a scalar potential Φ in the form

$$(2) \quad V_1 = -\text{grad } \Phi + \text{const.}$$

The potential Φ satisfies the differential equation

$$\text{div grad } \Phi = \nabla^2 \Phi = -\text{div } V_1,$$

which because of our condition (1b) may also be written as

$$(3) \quad \nabla^2 \Phi = -\text{div } V.$$

The constant added in (2) for the sake of generality means nothing for the determination of Φ . From the *inhomogeneous potential equation* (3) the right member of which is a known function, Φ is determined by Green's theorem in the form

$$(4) \quad 4\pi\Phi = \int \frac{\text{div } V}{r} d\tau.$$

(see 1a below). Here $r = r_{PQ}$ is the distance of the field point P , at which Φ is to be determined, from the "source" point Q which designates the place of the volume element $d\tau$, that is to say, the coordinates of Q are the integration variables. If Φ is known, V_1 is also known from (2) except for a constant.

2. *Calculation of V_2 .* One introduces a *vector potential* A by putting

$$(5) \quad V_2 = \text{curl } A + \text{const}$$

and adds as a further condition

$$(6) \quad \text{div } A = 0.$$

Note: if A fulfills (5), $A + \text{grad } \lambda$, with λ being an arbitrary point function, does the same; hence an additional condition like (6) may be stipulated.

Because of (5)

$$\text{curl curl } A = \text{curl } V_2,$$

which, according to (1b), may be written

$$(7) \quad \text{curl curl } A = \text{curl } V.$$

Also here the additive constant in (5) is immaterial. To (7) we now apply the vector rule (3.10a) valid for Cartesian components:

$$\nabla^2 \mathbf{A} = \text{grad div } \mathbf{A} - \text{curl curl } \mathbf{A}.$$

Because of (6) this reduces to $\nabla^2 \mathbf{A} = -\text{curl curl } \mathbf{A}$, hence (7) is equivalent to

$$(8) \quad \nabla^2 \mathbf{A} = -\text{curl } \mathbf{V}.$$

The components of \mathbf{A} then satisfy, like Φ , inhomogeneous potential equations that can be integrated by the following formula, analogous to (4):

$$(9) \quad 4\pi \mathbf{A} = \int \frac{\text{curl } \mathbf{V}}{r} d\tau.$$

We shall prove in 2a that this representation of \mathbf{A} satisfies by itself the condition (6). When \mathbf{A} is known, \mathbf{V}_2 is obtained by (5) except for a constant.

3. *Uniqueness of the resolution* $\mathbf{V} = \mathbf{V}_1 + \mathbf{V}_2$. Suppose there were another resolution $\mathbf{V}'_1, \mathbf{V}'_2$ beside $\mathbf{V}_1, \mathbf{V}_2$. The irrotational vector $\mathbf{V}'_1 - \mathbf{V}_1$ would then at the same time be solenoidal, since we should have according to (1b)

$$\text{div} (\mathbf{V}'_1 - \mathbf{V}_1) = 0.$$

In the same way we conclude that the solenoidal vector $\mathbf{V}'_2 - \mathbf{V}_2$ should at the same time be irrotational since, again by (1b),

$$\text{curl} (\mathbf{V}'_2 - \mathbf{V}_2) = 0.$$

The calculation of the potentials Φ and \mathbf{A} for the vectors $\mathbf{V}'_1 - \mathbf{V}_1$ and $\mathbf{V}'_2 - \mathbf{V}_2$ carried out as in (4) and (9) would yield $\Phi = 0, \mathbf{A} = 0$. Hence, by (2) and (5), we have

$$\mathbf{V}'_1 - \mathbf{V}_1 = \text{const}, \quad \mathbf{V}'_2 - \mathbf{V}_2 = \text{const}.$$

Thus the resolution is indeed *unique* except for a vectorial constant. For more details see Blumenthal, loc. cit.

1a. *The calculation of Φ and \mathbf{A} by Green's theorem.* Let us put in Green's theorem (3.15)

$$U = \Phi, \quad V = \frac{1}{r}$$

and apply it to a large sphere with radius R and center O . We know from (19.22) that $\nabla^2(1/r) = 0$ except for the singular point $r = 0$ which has to be excluded from the integration by a small spherical surface with

radius ρ . First we calculate the surface integral over the ρ -sphere which appears on the right side of (3.15). Let Ω denote the solid angle, that is, $d\Omega$ be the surface element of the unit sphere. The surface element of the ρ -sphere is $d\sigma = \rho^2 d\Omega$. Since dn is the outward normal seen from the region of integration, we have

$$dn = -d\rho, \quad \frac{\partial U}{\partial n} = -\frac{\partial \Phi}{\partial \rho}, \quad \frac{\partial V}{\partial n} = -\frac{d}{d\rho} \frac{1}{\rho} = +\frac{1}{\rho^2}.$$

That part of the right member of (3.15) which refers to the ρ -sphere becomes therefore

$$(10) \quad \Phi \int d\Omega + \int \frac{\partial \Phi}{\partial \rho} \rho d\Omega.$$

The second integral in (10) vanishes for $\rho \rightarrow 0$, and the first equals 4π . (Note that the factor Φ tends to the value of Φ at $\rho = 0$).

We now consider the surface integral over the R -sphere. The same consideration as before leads to the following expression for this integral

$$(10a) \quad - \int \Phi d\Omega - \int \frac{\partial \Phi}{\partial R} R d\Omega.$$

But this time both integrals vanish provided Φ goes to zero with $R \rightarrow \infty$ and $\partial \Phi / \partial R$ vanishes more strongly than $1/R$. This is what we want to enforce by requiring that V should vanish "sufficiently strongly" at infinity. The sum of the surface integrals over both spheres becomes then $4\pi\Phi$.

On the other hand, the first member of (3.15) is, because of (3) and $\nabla^2(1/r) = 0$,

$$\int \frac{\text{div } \mathbf{V}}{r} d\tau.$$

This finishes the proof of Eq. (4); the proof of (9) follows exactly the same lines.

2a. Proof that $\text{div } \mathbf{A} = 0$. We take the divergence of either side of equation (8)

$$\text{div } \nabla^2 \mathbf{A} = -\text{div } \text{curl } \mathbf{V} = 0.$$

Since the operators div and ∇^2 are commutative, one concludes that $u = \text{div } \mathbf{A}$ satisfies the homogeneous equation $\nabla^2 u = 0$. We carry out the integration as before under 1a) and notice that the surface integral over the R -sphere has again the limit zero, while the volume integral that appears in Green's representation of u is now identically zero. This shows that the additional condition (6) for $\text{div } \mathbf{A}$ is actually fulfilled.

3a. *More about the uniqueness.* When the vector field \mathbf{V} is not defined everywhere in space, but only inside a boundary surface Σ , additional surface integrals over Σ appear in place of the vanishing surface integrals over the surface of the infinitely large R -sphere. In the calculation of Φ , for instance, we have instead of (10a)

$$(12) \quad \int_{\Sigma} \Phi \frac{\partial}{\partial n} \frac{1}{r} d\Sigma - \int_{\Sigma} \frac{1}{r} \frac{\partial \Phi}{\partial n} d\Sigma.$$

This invalidates the representation (4) as well as our uniqueness proof, and the same is true for the representation (9) and the transformation (11). In the case of a finite domain it is indeed necessary to prescribe suitable boundary conditions on the surface Σ , in order to give a definite meaning to the resolution "irrotational-solenoidal".

Note that in the case of an infinitely extended vector field that is everywhere defined the constants in (2) and (5) must cancel each other, since the sum $\mathbf{V} = \mathbf{V}_1 + \mathbf{V}_2$ is supposed to vanish at infinity, according to our assumption at the beginning of this article.

Our uniqueness theorem has a well known counterpart in two dimensions: a function $f(x + iy)$ that is everywhere regular in the complex plane including the point ∞ is necessarily a constant (Liouville's theorem). Both real and imaginary parts of such a function represent a two dimensional potential that is irrotational and solenoidal at the same time; both parts must therefore be constants, making f a complex constant.

4. *Representation of a velocity field with given vortices.* For the sake of simplicity we assume first the entire space filled with a moving fluid and identify the vector \mathbf{V} with the fluid velocity \mathbf{v} . According to the condition of incompressibility, $\text{div } \mathbf{v} = 0$; hence by (4) $\mathbf{V}_1 = 0$, and $\mathbf{V} = \mathbf{v} = \mathbf{V}_2$ (the additive constant has been omitted). Upon introducing the vortex vector $\boldsymbol{\omega}$ which, for the present, we assume continuously distributed in space, we have by (9) and (5)

$$(13) \quad 2\pi\mathbf{A} = \int \frac{\boldsymbol{\omega}}{r} d\tau, \quad \mathbf{v} = \text{curl } \mathbf{A}.$$

The velocity \mathbf{v} can be represented by a superposition of the contributions of the individual vortex elements $\boldsymbol{\omega} d\tau$. Consider now the vortex tube (cf. p. 136) associated with a certain vortex element $\boldsymbol{\omega} d\tau$, a segment of which having the length $|\Delta s|$ and cross-section Δq is shown in Fig. 28. If the vortex strength $\mu = \boldsymbol{\omega} \Delta q$ [see (18.15)] is introduced, the contribution \mathbf{A}' of our vortex element to the vector potential \mathbf{A} is given by

$$(14) \quad 2\pi\mathbf{A}' = \frac{\mu}{r} \Delta s.$$

The corresponding contribution \mathbf{v}' to the velocity of the flow is then

$$(15) \quad \mathbf{v}' = \text{curl } \mathbf{A}' = \frac{1}{2\pi} \text{curl} \left(\frac{\mu}{r} \Delta \mathbf{s} \right).$$

Here the vector $\mu \Delta \mathbf{s}/r$ has the direction of $\Delta \mathbf{s}$ which, according to the definition of the vortex tube is identical with the direction ω . The operation curl to which this vector is subjected refers to the coordinates of the field point P for which \mathbf{v}' is to be computed. It is now convenient to introduce

FIG. 28. The contribution of the element $\Delta \mathbf{s}$ of a vortex tube to the vector potential \mathbf{A} and the flow vector \mathbf{v} .

an auxiliary coordinate system, taking $\Delta \mathbf{s}$ as the z -axis of a Cartesian system with origin O at the volume element of the vortex tube under consideration.⁹ With $A' = A'_z$, $A'_x = A'_y = 0$, we obtain from (15)

$$(16) \quad 2\pi v'_x = 2\pi \frac{\partial A'_z}{\partial y} = -\frac{\mu}{r^3} \Delta s \frac{y}{r},$$

$$2\pi v'_y = -2\pi \frac{\partial A'_z}{\partial x} = +\frac{\mu}{r^3} \Delta s \frac{x}{r}, \quad v'_z = 0.$$

These three equations can be written in condensed form:

$$(17) \quad 2\pi \mathbf{v}' = \frac{\mu}{r^3} \Delta \mathbf{s} \times \mathbf{r}.$$

The direction of \mathbf{v}' is orthogonal to $\Delta \mathbf{s}$ as well as to the position vector $\mathbf{r} = \mathbf{OP}$; its magnitude is given by

$$(18) \quad 2\pi |\mathbf{v}'| = \frac{\mu}{r^3} |\Delta \mathbf{s}| \sin \vartheta,$$

where ϑ is the angle between $\Delta \mathbf{s}$ and \mathbf{r} . The orientation of \mathbf{v}' follows from the right hand rule for vector products.

The motion at the field point P due to the vortex element $\mu \Delta \mathbf{s}$ is de-

⁹Instead of that we could also use the general formula $\text{curl } f\mathbf{a} = f \text{curl } \mathbf{a} + (\text{grad } f) \times \mathbf{a}$, which gives (17) if one puts $\mathbf{a} = \Delta \mathbf{s} = \text{const}$ and $f = \mu/r$.

terminated by the law (17). The total velocity at P is the vectorial sum of the elemental velocities \mathbf{v}' :

$$(19) \quad \mathbf{v} = \sum \mathbf{v}'.$$

5. *The electro-magnetic interpretation of solenoidal fields.* We now compare (18) with the well known classical law of Biot-Savart

$$(20) \quad |d\mathbf{F}| = \frac{i ds}{r^2} \sin \vartheta,$$

where i is the current intensity in the element ds of the conductor and $d\mathbf{F}$ the force acting on the magnetic unit pole at the field point P ; ϑ and r have the same meaning as in Fig. 28; also the oriented direction of $d\mathbf{F}$ coincides with the oriented direction of \mathbf{v}' , given by the vector product rule.

This amounts to a perfect analogy between hydrodynamics and electrodynamics, which, according to a remark of Helmholtz, has helped greatly in the development of either science.

The current intensity i corresponds to the vortex strength μ , the current density \mathbf{J} to the vortex vector $\boldsymbol{\omega}$. The Biot-Savart force $d\mathbf{F}$ acting between an individual current element and the unit pole is the analogue of our elemental velocity $2\pi\mathbf{v}'$, the magnetic field strength (that is the force on the unit pole due to the total system of currents) corresponds (except for the factor 2π) to the total velocity vector $\mathbf{v} = \sum \mathbf{v}'$. As a system of electric currents is surrounded by magnetic field lines, so a system of vortex tubes is surrounded by stream lines. In electrodynamics we speak of the field \mathbf{F} as *induced* by the current density \mathbf{J} ; it is convenient to use the same expression in hydrodynamics and to speak of the velocity \mathbf{v} as *induced* by the vorticity $\boldsymbol{\omega}$.

This analogy corresponds to the correlation b) on p. 110 that coordinates the flow \mathbf{v} to the magnetic field strength and the rotation (previously $\boldsymbol{\xi}$ and now $\boldsymbol{\omega}$) to the electric field strength.

In the electromagnetic case all these things become particularly simple if one considers *linear conductors*, that is, wires of sufficiently small cross-section. Their counterparts in hydrodynamics are the *vortex filaments* introduced on p. 141 which will be treated in the following article.

6. *Boundary value problems in the finite space.* The determination of the velocity distribution in the case of the continuous flow of an infinitely extended incompressible fluid has been represented under 4) as a *summation problem*, provided the flow vector vanishes at infinity. The vector potential \mathbf{A} is found by integration over the distributed vorticity which is considered as given. The scalar potential is here immaterial since it

was possible to assume the flow vector to be free of sources and sinks throughout the space. This is different when the flow is restricted to a finite domain, where we have to consider boundary conditions for the pressure (e.g. $p = 0$ at a free surface) and for the velocity (e.g. $v_n = 0$ at a rigid wall). If sources are present in the flow, they must be excluded from the domain of validity of Euler's equations and the excluding surfaces must be considered as boundary surfaces of the fluid. The simple integral representation of A is no longer sufficient and a scalar potential Φ appears in addition, as earlier in 3a. As a consequence of the boundary conditions we face now a *boundary value problem* which can no longer be solved by a simple superposition of sources and vortices, but calls for the application of special mathematical methods suitable for the given boundary conditions (e.g. conformal mapping in the two-dimensional case).

21. Straight and Parallel Vortex Filaments

In this article we consider the following two-dimensional problem: Given a number of straight vortex filaments normal to the x, y -plane. What can be said about their mutual interaction in the course of time? With such a question we enter the domain of vortex dynamics while we have so far only dealt with the kinematic aspect of vortex theory (for instance in our analysis of the induced velocity field). The basis of vortex dynamics is found in Helmholtz's conservation theorem of 18 where we learned about the convective character of the vorticity. Hence, if we know the velocity imparted to the particles of an individual vortex filament by the other vortex filaments, we are also informed about the velocity with which that vortex filament moves along and about its contingent change of shape. Dynamics and kinematics of vortex filaments are thus directly connected. In the two-dimensional case to which we restrict ourselves in this article, it is understood that the vortex filament remains straight.

1. The Single Vortex Filament

As already learned in (19.7), the velocity field of the single vortex is given by

$$(1) \quad \Phi + i\Psi = iA \log(x + iy),$$

$$(1a) \quad \pm v = v_\varphi = -\text{grad}_\perp \Phi = \frac{A}{r} = \frac{\mu}{\pi r}.$$

The stream lines are circles about the origin; the vortex proper, that is to say the point O , does not take part in the motion.

This is the place to examine the connection between the field due to a simple vortex and the Biot-Savart law of the last article. To do this we must leave the complex plane and introduce the z -coordinate along the vortex filament, which reaches from $-\infty$ to $+\infty$. Let $x, y, 0$ and $0, 0, z$ be the coordinates of the field point and of the "source" point that supplies the integration variable as before. The line element, previously $|\Delta s|$, is now dz , its distance from the field point, previously called r , is now $R = \sqrt{x^2 + y^2 + z^2} = \sqrt{r^2 + z^2}$ where the new r stands for $\sqrt{x^2 + y^2}$ as in (1a). From (20.17) and (20.19) we obtain after evaluation of the vector product

$$(2) \quad v_x + iv_y = \sum (v'_x + iv'_y) = \frac{\mu}{2\pi} (-y + ix) \int_{-\infty}^{+\infty} \frac{dz}{(r^2 + z^2)^{3/2}},$$

while v_z is obviously zero. To evaluate the improper integral in (2) we start with the well known formula

$$\int_0^a \frac{dz}{\sqrt{r^2 + z^2}} = \log(a + \sqrt{r^2 + a^2}) - \log r$$

and obtain by differentiation under the integral sign with respect to r

$$-r \int_0^a \frac{dz}{(r^2 + z^2)^{3/2}} = \frac{r}{\sqrt{r^2 + a^2}} \frac{1}{a + \sqrt{r^2 + a^2}} - \frac{1}{r}.$$

If $a \rightarrow \infty$, the first term to the right vanishes, and we have

$$\int_{-\infty}^{+\infty} \frac{dz}{(r^2 + z^2)^{3/2}} = 2 \int_0^{\infty} \frac{dz}{(r^2 + z^2)^{3/2}} = \frac{2}{r^2}.$$

Thus Eq. (2) yields

$$(2a) \quad v_x + iv_y = \frac{\mu}{\pi} \frac{-y + ix}{r^2}, \quad \pm |\mathbf{v}| = v_\varphi = \frac{\mu}{\pi r}$$

in agreement with (1a) in sense and direction.

On denoting by \mathbf{u} a vector in $\pm z$ -direction* of length $|\mu|$ and by \mathbf{r} the position vector in the x, y -plane, Eq. (2a) can be written as

$$(2b) \quad \mathbf{v} = \frac{1}{\pi r^2} \mathbf{u} \times \mathbf{r}$$

The components v_x and v_y calculated from (2b) are, in fact, identical with the values resulting from (2a). Eq. (2b) differs from the three-dimensional formula for \mathbf{v}' in (20.17) in the missing factor 2 and in the denominator of the right member which is now r^2 instead of r^3 . The difference is caused by the preceding integration with respect to z .

*Depending on the sign of μ .

2. Two Vortex Filaments of Equal Strength and Opposite or Equal Sense

The case of two opposite vortex filaments was dealt with in Eq. (19.12) et seq. From (19.14) or directly from Fig. 29a the following result is obtained: The velocity v_1 imparted to the filament F_1 by F_2 is equal and parallel to the velocity v_2 imparted to F_2 by F_1 :

$$(3) \quad v_1 = v_2 = \frac{\mu}{2\pi c} = v \quad (2c = \text{distance } F_1F_2).$$

On the other hand, the velocity v_0 at the center M of the segment F_1F_2 , subject to the common action of F_1 and F_2 equals

$$(3a) \quad v_0 = \frac{\mu}{\pi c} + \frac{\mu}{\pi c} = 4v.$$

Thus we see: both vortex filaments proceed with common velocity v ; the fluid between them moves in the same direction in which F_1 and F_2 move, but with

FIG. 29a. Two equally strong vortices of opposite orientation: the plane of symmetry can be replaced by a rigid surface of separation (wall).

FIG. 29b. Two equally strong vortices of the same orientation move on a circle in diametrical position.

larger velocity. Fluid particles in line with F_1 and F_2 but not between them move in the opposite direction; their velocity becomes very large in the immediate neighborhood of F_1 and F_2 .

Not only at M , but at all points M' , M'' of the bisectrix of F_1F_2 the resultant velocity due to both filaments is parallel to the bisectrix. One may therefore replace it by a rigid wall since the flow along the bisectrix is just the one required by the boundary condition along a rigid wall. Hence an isolated vortex filament, originally at rest, starts to move if a wall is brought toward it; it travels parallel to the wall, the faster the closer the wall. The vortex is, as it were, pushed forward by its virtual image that is obtained by reflexion in the wall. More about that will be learned in the more complicated case of Fig. 31.

The case of *two vortex filaments of equal orientation* is also represented by (19.12), when the sign of the second term to the right is reversed. According to (3) F_2 induces at F_1 a velocity v that is opposite to the velocity which F_1 induces at F_2 . While F_1 travels downward on a circle with radius c , F_2 travels upward by the same amount. The diameter F_1F_2 turns about the center M which is constant in space. Both vortices travel therefore on the same circle, the one being diametrically opposite to the other.

3. A Theorem Concerning the "Center of Mass" of Two or More Vortices

When the strengths μ_1 and μ_2 of the two vortex filaments are different, the vortex points F_1 , F_2 still travel on concentric circles, but the radii are different. *The common center is the center of mass of μ_1 and μ_2* , when we think of μ_1 and μ_2 in terms of masses carried by the points F_1 and F_2 . The center of mass is, of course, on the line through F_1 and F_2 , *inside* the segment F_1F_2 if μ_1 and μ_2 have the *same* orientation (Fig. 30a), and

FIG. 30a (left), b (right). Two vortices move in circles about their "centroid." The centroid does (a), or does not (b), separate the vortices depending on whether the orientations of the vortices are equal or opposite.

outside if the orientation is *opposite* (Fig. 30b). In the latter case one of the masses must be counted negative. Figures 30a,b have been drawn under the assumption $\mu_2 > \mu_1$ and $|\mu_2| > \mu_1$, respectively.

The common center S of the circular paths described by F_1 and F_2 is found by connecting the end point of the velocity vector v_1 with the end point of v_2 (see Fig. 30a). This line intersects the line F_1F_2 in S . Since v_1 is due to F_2 and v_2 to F_1 , one has

$$(4) \quad v_1 = \frac{\mu_2}{2\pi c}, \quad v_2 = \frac{\mu_1}{2\pi c}.$$

For the position of the intersection point S we have $\overline{SF_1}/v_1 = \overline{SF_2}/v_2$, which yields because of (4)

$$(5) \quad \mu_1 \overline{SF_1} = \mu_2 \overline{SF_2}.$$

Hence S is indeed the centroid of the masses μ_1 and μ_2 .

The same construction is carried out in Fig. 30b for the case of opposite vortices. If here $|\mu_2| = \mu_1$, the point S is shifted to infinity: both circles degenerate into parallel lines and the first case of 2. is reobtained. The second case of 2. obviously corresponds to $\mu_1 = \mu_2$, so that the two circles of Fig. 30a coincide.

It should be realized that the point S so constructed is by no means at rest if considered as a point of the fluid. Actually the velocity at S in the case of Fig. 30a is given by

$$v_s = \frac{\mu_1}{\pi \overline{SF_1}} - \frac{\mu_2}{\pi \overline{SF_2}} = \frac{\mu_1}{\pi \overline{SF_1}} \left(1 - \frac{\mu_2}{\mu_1} \frac{\overline{SF_1}}{\overline{SF_2}} \right).$$

The expression in parentheses is because of (5)

$$1 - \frac{\mu_2}{\mu_1} \neq 0.$$

The statement that S does not move means only that the geometrical center of the circular paths of the vortices F_1 and F_2 is at rest and does not say anything about the motion of a fluid particle that happens to be at S . The term *center of mass at rest* will be used in this sense also in the remainder of this section.

Let us now consider a system of a number of vortex filaments $F_1, F_2, \dots, F_i, \dots, F_k$. The velocity induced by F_i at an arbitrary field point P can be written by means of (2b) as

$$(6) \quad \mathbf{v} = \frac{1}{\pi} \frac{\boldsymbol{\mu}_i \times (\mathbf{r} - \mathbf{r}_i)}{|\mathbf{r} - \mathbf{r}_i|^2}$$

where $\mathbf{r} - \mathbf{r}_i$ is the relative position vector of P with respect to F_i . Let P now coincide with F_k and sum over all i with the exception of $i = k$ since F_k is not affected by its own induction. Thus

$$(7) \quad \mathbf{v}_k = \frac{1}{\pi} \sum_i' \frac{\boldsymbol{\mu}_i \times (\mathbf{r}_k - \mathbf{r}_i)}{|\mathbf{r}_k - \mathbf{r}_i|^2}$$

is obtained where the apostrophe at the summation sign means the exclusion of the value k from the possible i -values. We introduce now

$$\mathbf{r}_{ik} = \mathbf{r}_k - \mathbf{r}_i, \quad r_{ik} = |\mathbf{r}_k - \mathbf{r}_i|$$

(7a)

$$\mathbf{e}_{ik} = \frac{\mathbf{r}_k - \mathbf{r}_i}{r_{ik}} = -\mathbf{e}_{ki}$$

where \mathbf{e}_{ik} is a unit vector in the x,y -plane. We shall further need a unit vector \mathbf{e} normal to the x,y -plane to indicate the direction of the vector \mathbf{y} : $\mathbf{y}_i = \mu_i \mathbf{e}$. With these notations, Eq. (7) transforms into

$$(7b) \quad \mathbf{v}_k = \frac{1}{\pi} \sum_i' \mu_i \frac{\mathbf{e} \times \mathbf{e}_{ik}}{r_{ik}}.$$

Now we form

$$(8) \quad \sum \mu_k \mathbf{v}_k = \frac{1}{\pi} \sum_k \sum_i' \mu_i \mu_k \frac{\mathbf{e} \times \mathbf{e}_{ik}}{r_{ik}}.$$

In the double sum to the right, \mathbf{e}_{ik} and therefore $\mathbf{e} \times \mathbf{e}_{ik}$ is antisymmetric in i and k while the products $\mu_i \mu_k$ and the distances r_{ik} are, of course, symmetric. Hence the terms cancel in pairs, and we have the result

$$(9) \quad \sum \mu_k \mathbf{v}_k = 0,$$

which implies that the velocity \mathbf{v}_s of the centroid of our vortex system (but only in the sense pointed out above) vanishes

$$(10) \quad \mathbf{v}_s = \frac{\sum \mu_k \mathbf{v}_k}{\sum \mu_k} = 0.$$

4. The Law of Areas for a System of Vortex Filaments

In a certain sense, there exists also an analogue to the law of areas in general mechanics; as we shall see, the *total angular momentum of the system of vortices is constant*, in the absence of external forces.

We define the momentum of a single vortex filament by $\mu_k \mathbf{v}_k$ and the moment of momentum or angular momentum of the system of vortices relative to an arbitrary origin O by

$$\mathbf{M} = \sum_k \mu_k \mathbf{r}_k \times \mathbf{v}_k.$$

Substituting from (7b) we obtain

$$(11) \quad \mathbf{M} = \frac{1}{\pi} \sum_k \sum_i' \frac{\mu_i \mu_k}{r_{ik}} \mathbf{r}_k \times (\mathbf{e} \times \mathbf{e}_{ik}).$$

On interchanging i and k and considering the antisymmetric character of the \mathbf{e}_{ik} we obtain

$$(11a) \quad \mathbf{M} = -\frac{1}{\pi} \sum_k \sum_i' \frac{\mu_i \mu_k}{r_{ik}} \mathbf{r}_i \times (\mathbf{e} \times \mathbf{e}_{ik}).$$

We add now Eqs. (11) and (11a) and find by applying the definition of \mathbf{e}_{ik} in (7a) the following form of \mathbf{M} :

$$(11b) \quad \mathbf{M} = \frac{1}{2\pi} \sum_k \sum_i' \mu_i \mu_k \mathbf{e}_{ik} \times (\mathbf{e} \times \mathbf{e}_{ik}).$$

According to a well known vector identity

$$(12) \quad \mathbf{e}_{ik} \times (\mathbf{e} \times \mathbf{e}_{ik}) = \mathbf{e}(\mathbf{e}_{ik} \cdot \mathbf{e}_{ik}) - \mathbf{e}_{ik}(\mathbf{e} \cdot \mathbf{e}_{ik}),$$

but the first term to the right equals \mathbf{e} and the second is zero (\mathbf{e}_{ik} is a unit vector, so is \mathbf{e} , and they are normal to each other). Thus it is seen that the right member of (11b) depends only on the vortex strengths μ_i and has the constant direction \mathbf{e} ; it is therefore a constant vector

$$(13) \quad \mathbf{M} = \frac{\mathbf{e}}{2\pi} \sum_i \sum_k' \mu_i \mu_k = \text{const.}$$

5. General Remarks on the Dynamics of Vortices

The dynamics of vortices which we have studied here is indeed a very peculiar one and deviates decisively from the dynamics of mass points.

To begin with, Newton's first law is altered. The isolated vortex (which is therefore not subjected to "forces") *remains in a state of rest*. A uniform rectilinear motion can only be acquired by association with a second vortex of equal strength but opposite sense of rotation or under the action of a wall at rest. Thus the relativity principle of classical mechanics according to which the state of rest and of uniform motion are equivalent is no longer valid. The reason is, of course, that the fluid to which the vortex belongs plays the role of a preferred frame of reference.

The modification of the second law is even more remarkable. The external action originating in a second vortex does not determine the *acceleration* but the *velocity*. The content of the law of motion of the mass center is shifted accordingly: not the *acceleration*, but the *velocity* of the mass center vanishes. As far as the *law of areas* is concerned the angular momentum of the vortex system is constant as in the case of a mechanical system in the absence of external forces, but the constant is entirely determined by the vortex strengths according to Eq. (13), in contradistinction to the mechanics of masses where this constant is a constant of integration that depends on initial conditions which may be chosen freely.

6. Atmospheric Vortices

At first thought it seems impossible to realize infinitely long vortex filaments experimentally. But, as Helmholtz noticed, in a fluid layer bounded by two parallel planes normal to the vortex filaments, the same vortex motions can be produced as in a fluid of infinite "thickness".

Such a fluid layer is realized to a certain extent by our atmosphere if one disregards the curvature of the earth. In fact, water spouts and tornadoes can be considered as vortex filaments on a tremendous scale

(filament diameter 5-500m), whereas atmospheric cyclones and anti-cyclones, the horizontal dimensions of which may well extend over 1000 km, being many times larger than their vertical extensions (10-15 km), combine the properties of vortices with those of waves.

For applications in meteorology the classical theory of vortices has to be modified in two points. The normal state of the atmosphere is not a state of rest but of uniform rotation; for an observer connected with the surface of the earth the fluid in which the vortex motion takes place is not free of external forces as we have assumed so far, but under the action of the Coriolis force. In addition to this dynamical correction there is also a thermodynamical one which is due to the compressibility of the air: since the density of the air is connected with the air pressure by an equation of state $\rho = F(p, T, \dots)$ which contains not only the pressure, but also the temperature T and possibly other variables such as humidity, the expression curl $(1/\rho \text{ grad } p)$ does in general not vanish. That means the presence of processes which can generate or destroy vorticity.

Those are the two extensions of the classical vortex theory that are considered in the meteorological literature when more general vortex theorems are formulated. (V. Bjerknes,¹⁰ H. Ertel¹¹).

22. Circular Vortex Rings

Closed vortices, in particular those of circular shape, differ from the straight vortices of the preceding section in that they occur or can be easily made to occur on a small scale. As smoke rings, they are well known to smokers, but they may also be seen above chimney tops. For the purpose of demonstration the following device will serve well: A circular hole is made in the front wall of a cardboard box, the rear wall is removed and a piece of somewhat elastic cloth is stretched over that end. Into the box is put a dish of hydrochloric acid and another of ammonium hydroxide; thus a dense smoke of ammonium chloride is produced. Smoke is ejected through the hole by a sharp tap against the rear wall and curls up in the form of a circular vortex as it passes the edge of the aperture. Fig. 31a illustrates this process. The vortex ring thus created moves straight forward for a distance of several yards with considerable speed.

According to the fundamental theorem of vortex theory (cf. p. 132) the vortex adheres to the fluid, that is, the air particles are carried along with the vortex. This becomes apparent when a candle is put in the way of the vortex: The flame is blown out by the "whirlwind" with a soft whistle.—Decreasing the aperture in the box wall makes for a *smaller*

¹⁰V. Bjerknes, *Meteorolog. Z.* 1900, pp. 97 and 145, also 1902, p. 96.

¹¹H. Ertel, *Physikal. Z.* 1942, p. 526, also *Meteorol. Z.* 1942, pp. 277 and 385.

radius of the vortex ring and at the same time for *larger* speed. When the circular aperture is replaced by a rectangular one the vortex, rectangular when it emerges, develops regular pulsations that indicate a tendency toward the circular shape; the latter is the *stable* one, while the rectangular shape is *unstable*.—The circular vortex increases its radius when approaching a wall parallel to the plane of the ring (Fig. 32).

FIG. 31. a. Formation of a vortex ring when an air current is ejected through a hole. b. The vortex ring approaches a plane wall.

FIG. 32. The vortex ring widens when it approaches a wall parallel to its plane; its translatory velocity decreases.

The following experiment, not easily performed with our device, presents little difficulty to a smoker practiced in the art of blowing rings: A small ring is made to follow a bigger one. Moving with greater speed, it catches up with the bigger vortex ring and slips through it. Thereupon the smaller ring grows larger while the bigger one contracts. It has by now become the quicker of the two and will pass through the other, and, theoretically, the game should repeat over and over again. For this experiment, vortices in a liquid are more suitable than smoke rings. One uses colored liquid which is dropped upon the surface of a water reservoir from a pipette. When a drop strikes the surface, it pulls apart in the shape of a ring which penetrates into the water and expands at the same time. The next drop, or rather the vortex ring which it becomes, is initially smaller and overtakes the larger ring, etc. This arrangement permits one to observe the passing-through phenomenon several times in succession.

Turning now to the interpretation of these experiments, we start with the discussion of some aspects of the problem that can be dealt with by elementary means. This is the case if no account is taken of the inter-

action of the vortex ring with itself. The vortices, therefore, will for the present be considered as *infinitely thin* filaments.

Eq. (20.17), the equivalent of the Biot-Savart law, serves as a starting point and gives the velocity contribution \mathbf{v}' induced by a single vortex element $\mu\Delta s$ at given field point. For the midpoint M of the vortex ring in particular, all contributions become equal in amount and direction since in this case (20.17) becomes

$$v' = \frac{\mu\Delta s}{2\pi a^2}$$

where a denotes the radius of the ring. By summation over all Δs the velocity v_M at the midpoint is obtained:

$$(1) \quad v_M = \frac{\mu}{2\pi a^2} \sum \Delta s = \frac{\mu}{a}$$

Thus the velocity at M is seen to increase with decreasing a . As we observed before and shall prove later, the translatory velocity of the vortex ring increases also with decreasing a .

We take now as field point an arbitrary point A on the axis of symmetry of the ring, denote its distance from the center M by z (the distance from any point of the ring being $r = \sqrt{a^2 + z^2}$), and consider the components of \mathbf{v}' parallel and normal to the axis. The normal components due to any two diametrically opposite vortex elements will cancel each other. The axial component of \mathbf{v}' is $v'a/r$. By summation over all Δs , Eq. (20.17) leads to

$$(2) \quad v_A = \frac{\mu}{2\pi r^3} \frac{a}{r} \sum r \Delta s = \frac{\mu a^2}{r^3} = \mu \frac{a^2}{(a^2 + z^2)^{3/2}}.$$

Hence the velocity decreases along the axis on either side of M and goes to zero as z grows indefinitely.

For a field point in general position the summations that lead from \mathbf{v}' to \mathbf{v} are no longer quite so elementary, but require integrations of elliptic type. The same is true, as is well known, for the mathematically analogous calculation of the magnetic field induced by a circular current loop.

On the other hand, it is now possible to interpret some of the phenomena described in a *qualitative* way.

Fig. 31a indicates schematically the formation of a vortex as the air flows through the aperture, Fig. 31b illustrates the conditions that prevail when the vortex ring meets a wall parallel to its own plane. At the wall, the boundary condition is $v_n = 0$. It can be satisfied by employing the *method of images*, a procedure of general usefulness in problems of this character. To the physically real vortex on the left side of the wall one

adds a *virtual* vortex on the right side, in this way extending to infinity the hydrodynamic field that, physically, is bounded by the wall. An air particle W adjacent to the wall receives the velocity contribution \mathbf{v}'_1 from the real vortex μ_1 and \mathbf{v}'_2 from the virtual vortex μ_2 ; according to Eq. (20.17), \mathbf{v}'_1 is perpendicular to the plane subtended by the vector \mathbf{r}_1 and the axis of the vortex element μ_1 . Evidently, \mathbf{v}'_1 and \mathbf{v}'_2 add up to a motion *parallel* to the wall, thus *satisfying the condition* $v_n = 0$. This, obviously, is true not only for the two pairs of vortex elements in the plane of the diagram, but for any pair of elements in image position.

We now wish to find out about the influence exerted by the image vortex upon the real vortex,¹² e.g. upon the upper vortex element μ_1 in Fig. 31b. The strongest action is to be expected from the closest neighbor, that is, the upper element μ_2 . Again according to (20.17), this action consists in an induced velocity directed *vertically upward*, indicated in the diagram by a vertical arrow at the upper left element. All the other elements μ_2 will partly aid in this action or partly, but in a smaller degree, counteract it (e.g. the lower element μ_2). The same argument applied to the lower element μ_1 leads to the vertical downward arrow at the place of that element. In the diagram the influence of the real vortex upon its image is also indicated.

We see then that the real vortex is *enlarged* when it approaches the wall because of the hydrodynamic action of the image vortex. The same is true for the image vortex. As the radius of the ring grows, so the forward motion directed to the wall attenuates, since the translatory motion of the vortex ring is essentially in inverse proportion to the radius. (This has been mentioned before but has not been proved.) Hence the vortex growing ever larger and weaker has evanesced to infinity before it reaches the wall.

Using the same qualitative methods we can also understand the mutual slipping through of a pair of vortices (Fig. 33a, b, c, d). In Fig. 33a the radii and speeds of the two vortices are equal. Having been generated one after the other by the same device, their sense of rotation is the same, in contrast to Fig. 31a in which the senses of rotation were opposite. This time, the interaction of the two vortices consists in the enlargement of the more advanced vortex and, simultaneously, in the diminution of the rear vortex as indicated by the vertical arrows in Fig. 33a. In Fig. 33b and c the vortices are shown before and after passing which becomes possible on account of the greater speed of the rear vortex (cf. the horizontal arrows in Fig. 33b). In Fig. 33c, the interaction of the vortex pair at

¹²Speaking physically, the influence is, of course, all due to the wall, but we have just convinced ourselves that this influence is correctly described by the assumption of a virtual image vortex.

this stage is again indicated by vertical arrows: The more advanced vortex grows, the rear vortex contracts, hence the first is decelerated, the second accelerated. The result is Fig. 33d, a repetition of Fig. 33a: The game is ready to start anew.

But these qualitative methods are no longer sufficient for problems that involve the *interaction of the vortex with itself*. The translatory motion

FIG. 33. The mutual threading of two vortex rings.

of a circular vortex is of that kind. Now the cross section of the vortex ring must be assumed finite, e.g. as a circle of radius c very small in comparison with the ring radius a . Within the circular cross section one might perhaps try a finite (e.g. constant) rotation ω ; the vortex strength μ that so far has been used only for *filamentous* vortices is now connected with ω by

$$\mu = \pi c^2 \omega.$$

The most convenient approach is through the stream function Ψ (19.24); within the vortex cross section the differential equation for Ψ is not Eq. (19.26) but the inhomogeneous equation

$$\frac{\partial^2 \Psi}{\partial \rho^2} - \frac{1}{\rho} \frac{\partial \Psi}{\partial \rho} + \frac{\partial^2 \Psi}{\partial z^2} = 2\omega.$$

The representation of Ψ (valid outside the cross section) by complete elliptical integrals of the first and second kind has already been given by Helmholtz. It serves as basis for the computation of the translatory velocity v_T , a computation that is mathematically involved and at the same time physically unsatisfactory. It will be omitted here. The result is¹³

$$(3) \quad v_T = \frac{\mu}{2\pi a} \left(\log \frac{8a}{c} - \frac{1}{4} \right).$$

¹³For a critical review of literature see A. E. H. Love, *Encykl. d. Mathem. Wiss.* IV. 3. p. 118

The term written here as $\frac{1}{2}$ is uncertain; it depends on the assumed ω -distribution over the cross-section. Our previous statement, repeatedly used in the discussion of the experiments, that v_T increases with decreasing a and decreases with increasing a is confirmed by Eq. 3, but the physically undetermined quantity a/c makes the result appear rather unrealistic. A comparison between (3) and (1) shows that v_T may be larger or smaller than v_M , depending on the choice of a/c .

Similar difficulties and a result formally quite analogous to (3) occur in the computation of the inductance of a wire (cf. vol. III), but in the electrical problem the radius c of the wire is of course physically determined.

How could we remove this uncertainty in the case of the circular vortex? There is hardly any other way but to investigate more completely the process of vortex formation at the edge of the circular aperture. This should result, if not in a definite radius c , then at least in a definite ω -distribution over the cross section (of course, ω should decrease radially). However, such an investigation could hardly be carried out and would certainly not be worth the labor; hence we have to leave the attractive and successful theory of vortex rings incomplete in an essential point.

A more direct grasp of the translatory motion of the vortex may be achieved by comparison with the motion of the straight vortex pair in 21, Fig. 29a. A vortex pair may be obtained from a vortex ring by restricting one's attention to two diametrically opposite ring elements. Lengthening of these two elements makes up, in a certain way, for the disregard of the other elements and finally leads to a pair of parallel straight filaments. To be sure, the similarity of the two vortex arrangements is only superficial, but their translatory motions are remarkably analogous. If we replace in Eq. (21.3) the letter c , which denotes half the distance of the vortex pair, by the ring radius a , the translatory velocity of the vortex pair becomes

$$v = \frac{\mu}{2\pi a}.$$

This is indeed the first factor on the right side of our Eq. 3 for v_T . The direction of v was perpendicular to the plane of the vortex pair; our v_T is perpendicular to the plane of the ring, as it should be.

A peculiar vortex motion may be observed in rowing. At the places where the oar breaks the surface of the water just previous to being lifted, small depressions of the surface appear—we could call them “dimples”—that run along on the surface. They are the endpoints of a vortex arc that has been escorting the submerged contour of the oar while it was pulled through the water. The dimple-like shape has its cause in the combined

action of centrifugal force and gravity. The rotating water surface must be normal to the resultant force in the same way as it is normal to gravity if no rotation is present. Now, while the surface form of a mass of water rotating with constant ω is the well known paraboloid, in our case ω diminishes quickly in radial direction and vanishes at a finite distance from the vortex center; the depression is thus restricted to the immediate neighborhood of the end of the vortex filament. The running along of a pair of dimples is illustrative of the translatory motion v_r of the vortex arc connecting the two dimples underneath the water surface.

Since it has become certain through optical investigations (Zeeman effect) that the solar matter in the sun spots is engaged in vigorous vortex motion, one would conclude that, there too, a vortex filament has emerged to the surface, coming out of the interior of the sun; and one would assume that to each sun spot there belongs a companion spot with converse sense of rotation, the two being connected by a vortex filament of roughly semi-circular shape that passes through the interior of the sun. On the other hand, one should be aware of the fact that the solar matter is not a perfect inviscid fluid. Thus it appears rather a bold step to apply our ideas about vortex motion literally to the interpretation of solar phenomena.

THEORY OF WAVES

Ever since waves were studied, water waves have served the natural scientist as a model for wave theory in general, although they are much more complicated than acoustical or optical waves. As *surface waves* they are bound to the common surface of two media, while the ordinary acoustic and optical waves are *three dimensional waves*.

There is this fundamental difference between vortices and waves: vortices pull the matter along in their own motion while in a wave the average locomotion of an individual fluid particle vanishes; it is not *matter* that travels but *energy* and *phase*.

We shall discuss in this chapter waves with different symmetry characteristics, such as *plane waves*, *circular waves*, *ship waves*, and *Mach waves*, starting out with the simplest type, the *plane progressive waves*. According to the nature of the restoring force we distinguish *gravity waves* and *capillary waves*. Gravity waves are the large, conspicuous waves which one usually has in mind in talking of water waves.

23. Plane Gravity Waves in Deep Water

We assume the wave as a completely periodic phenomenon and express the time dependence as on p. 98 in the form $e^{-i\omega t}$; waves of a more general time dependence can be obtained by superposition of partial waves having different circular frequencies (cf. 26).

We further assume that the wave motion is generated *out of the state of rest*, say, by a gust, a mechanical disturbance or the like (in problem VI, 3 we shall investigate under what circumstances an air current that grazes along a horizontal water surface can produce a wave motion). Since the fluid can be considered as *inviscid*, and since we shall consider in this and in the following article only the *potential field* of gravity, it follows from the conservation law of 18 that the motion possesses a *velocity potential*. This can depend in the case of a *plane wave* only on *two* spatial coordinates x and y , where x is the direction in which the wave progresses and y the depth coordinate. The problem is independent of the third spatial coordinate z which is horizontal and orthogonal to the direction of propagation. Φ is thus a two-dimensional potential as far as the space coordinates are concerned, and, according to 19, has the form $f(x \pm iy)$ in an *incompressible fluid*.

Let y be counted positive downward; since we wish to obtain a train of waves advancing in the positive x -direction, the x -dependence of f must be of a *trigonometrical* form, or, of the form of an imaginary exponential when written in this more convenient way. This leads to the following possibilities

$$(1) \quad \Phi = f(x + iy) e^{-i\omega t} = A e^{i(kx - \omega t)} e^{-ky},$$

or

$$(1a) \quad \Phi = f(x - iy) e^{-i\omega t} = B e^{i(kx - \omega t)} e^{+ky}.$$

Here, k is again the wave number, and there is

$$(2) \quad k = \frac{2\pi}{\lambda}, \quad \omega = \frac{2\pi}{\tau},$$

where λ is the wave length and τ the period.

We first assume the water *infinitely deep*, that is, the y -coordinate of the ground $y = h$ should be very large compared to λ .

At the ground,

$$(2a) \quad ky = 2\pi \frac{h}{\lambda} \rightarrow \infty.$$

This shows that the potential (1a) is not usable since it would yield infinite velocity amplitudes at the ground, but the potential (1) satisfies all conditions that have been imposed so far.

The representation (1) contains three parameters, A , ω , and k . A determines the amplitude of the wave for $y = 0$; both A and the (circular) frequency ω depend on the particular form of the excitation. While these two quantities can be chosen freely, the wave number k must be determined in its ratio to ω , for, according to (2), the ratio

$$(3) \quad \frac{\omega}{k} = \frac{\lambda}{\tau} = V,$$

is the *velocity of propagation* of the waves.

For the determination of k we must utilize the *condition for the free surface*:

$$(4) \quad p = 0,$$

(the atmospheric pressure is taken as zero). Eq. (4) follows from (12.19) if capillarity is neglected; it introduces a dynamic element into our theory while our argument so far has been wholly of a kinematic nature.

The pressure p and the potential Φ are connected by Euler's equations, which we shall use in the integrated form of Bernoulli's equation. Since

our problem involves a velocity potential variable in time, we have to take Bernoulli's equation in the form (11.15). We shall, however, neglect the quadratic term $(\nabla\Phi)^2$, since we consider the amplitude factor A as a *small quantity* (the usual procedure in mechanics of small oscillations). The abridged form of Bernoulli's equation is then

$$(5) \quad -\frac{\partial\Phi}{\partial t} + \frac{1}{\rho}(p + U) = \text{const.}$$

As explained on p. 89, the constant in (5) is independent of the space coordinates, but in general dependent on time. The only function of time which in our case does not upset the periodicity and the uniform advancement of the wave is

$$\text{const} = F(t) = 0.$$

Under these circumstances (5) assumes the simple form

$$(5a) \quad \frac{\partial\Phi}{\partial t} = \frac{U}{\rho}.$$

Here U is the gravity potential per unit of volume taken at the surface. Since y is counted positive downward, we have in general

$$(5b) \quad U = -\rho gy.$$

Let the equation of the surface profile be $y = \eta$, where η is a function of x and t . A positive η means a depression, a negative η an elevation, of the surface. From (5a) we have

$$(6) \quad \frac{\partial\Phi}{\partial t} = -g\eta.$$

The function η must have again the form of a progressive wave, like the one we have set up for the velocity potential Φ . Thus

$$(7) \quad \eta = a e^{i(kx - \omega t)}.$$

The constant a introduced here is in general complex since it includes amplitude *and* phase of the surface function; also, a has the character of a small quantity like A . If we substitute (7) and (1) in (6), we obtain after cancellation of the common exponential factor

$$(8) \quad i\omega A e^{-k\eta} = ga.$$

We now expand $e^{-k\eta}$ in powers of $k\eta$ and neglect the products $A\eta$, $A\eta^2$, etc. as small quantities of higher order; Eq. (8) then simplifies to

$$(9) \quad i\omega A = ga.$$

This is a relation between A and a , but it is not the relation between k and ω we require. The latter is obtained by introducing a further *kinematic* condition: We stipulate that the motion of the surface must coincide at any time with the motion of those fluid particles that happen to be at the surface at this time. That such a condition must be satisfied is rather obvious; we specify, however, that the components of the two motions taken in the normal direction n of the surface should be equal, since a motion of the fluid particles in the tangential plane does not change the shape of the surface, hence is immaterial for our problem. On denoting the velocity of the surface with V and the particle velocity with v as usual, our condition reads

$$(10) \quad V_n = v_n.$$

The component v_n , expressed by the velocity potential Φ , is

$$v_n = -\frac{\partial \Phi}{\partial n}.$$

However, if A is sufficiently small (the wave sufficiently flat), we can replace within a "cosine error", that is, with disregard of terms of second order

$$(10a) \quad \frac{\partial \Phi}{\partial n} \quad \text{by} \quad \frac{\partial \Phi}{\partial y}.$$

V is treated correspondingly: we replace

$$(10b) \quad V_n \quad \text{by} \quad \frac{\partial \eta}{\partial t},$$

that is by the "sinking speed" of the surface. With these simplifications, condition (10) reads

$$(11) \quad \frac{\partial \eta}{\partial t} = -\frac{\partial \Phi}{\partial y}.$$

Substituting for η and Φ from (7) and (1), we obtain, again after cancellation of the exponential on both sides,

$$(12) \quad -i\omega a = kA.$$

Now, the comparison of (9) and (12) yields at once

$$(13) \quad \frac{A}{a} = \frac{g}{i\omega} = -\frac{i\omega}{k}.$$

Our conclusions from (13) are:

1. There is a phase difference of $\pi/2$ between the a -wave and the A -

wave. If A is chosen a real quantity, which is permissible, a becomes purely imaginary; or, employing real representation, we can write for Φ in accordance with (1)

$$(14) \quad \Phi = A \cos(kx - \omega t)e^{-ky},$$

and Eq. (7) becomes now [cf. (13)]

$$(14a) \quad \eta = -\frac{\omega}{g} A \sin(kx - \omega t)$$

or

$$(14b) \quad \eta = -\frac{k}{\omega} A \sin(kx - \omega t).$$

2. The relation between k and ω is given by Eq. (13):

$$(15) \quad \omega^2 = gk.$$

Introducing here the velocity of propagation, we obtain [cf. (3)]

$$(16) \quad V^2 = \frac{\omega^2}{k^2} = \frac{g}{k} = \frac{g\lambda}{2\pi}, \quad V = \sqrt{\frac{g\lambda}{2\pi}}.$$

*The velocity of propagation depends on the wave length; long waves travel faster than smaller ones.*¹

When the propagation velocity of a wave depends on the wave length as in Eq. (16), we speak of dispersion, using an expression borrowed from

FIG. 34. The phase velocity V as a function of the wave length λ . The diagram gives the dispersion of gravity waves for $\lambda \ll h$ (segment a), $\lambda \gg h$ (segment b), $\lambda \approx h$ (segment c); h = depth of the water.

optics. The dispersion in a medium is *normal* when longer (red) waves have larger velocities (smaller index of refraction) than shorter (violet) waves. The behavior of *gravity waves in deep water thus corresponds to the case of normal dispersion in optics.*

¹We should like to recommend to readers who are irritated by the complex representation of periodic phenomena, to carry out the preceding calculation once more with real quantities and to convince themselves that they obtain again Eq. (16) although in a somewhat more cumbersome way. One would have to replace (1) by (14) and (7) by $\eta = |a| \cos(kx - \omega t + \alpha)$, where α is the phase difference between φ and η that is to be determined.

Fig. 34 should make this clearer. V is represented by the upper half of an ordinary parabola which has the V -axis as a tangent at $\lambda = 0$. Only the middle part a of the parabola has been drawn as a solid line, this being the region for which our assumptions are actually valid. For, if the wave length λ keeps increasing, it finally becomes of the same order of magnitude as the depth of the water h , and our assumption (2a) is no longer valid. This case will be taken up in the next article. On the other hand, if one goes to very small values of λ , gravity is no longer the decisive dynamic parameter, but *surface tension* takes the lead; this brings about a fundamental change of the dispersion law (see 25).

24. Plane Gravity Waves in Shallow and Moderately Deep Water

If we now assume the depth h as finite, the second form of the potential (23.1a) need no longer be rejected, but is as good as the form (23.1); hence a linear combination of (1) and (1a) may be taken for the velocity potential Φ :

$$(1) \quad \Phi = e^{i(kx - \omega t)} \{Ae^{-ky} + Be^{+ky}\}.$$

The new boundary condition at the bottom is: $v_y = 0$, or, $\partial\Phi/\partial y = 0$ for $y = 0$. This is, by (1), equivalent to

$$-Ae^{-kh} + Be^{+kh} = 0,$$

a condition for A and B which is more conveniently handled, if we introduce a constant C defined by

$$\frac{1}{2} C = Ae^{-kh} = Be^{+kh}$$

so that

$$(1a) \quad A = \frac{1}{2} Ce^{+kh}, \quad B = \frac{1}{2} Ce^{-kh}.$$

Then the potential Φ assumes the form

$$\begin{aligned} \Phi &= e^{i(kx - \omega t)} \frac{C}{2} \{e^{k(h-y)} + e^{-k(h-y)}\} \\ (2) \quad &= e^{i(kx - \omega t)} C \cdot \cosh k(h - y). \end{aligned}$$

The expression (23.7) for the surface depression remains unchanged; we rewrite it here:

$$(3) \quad \eta = ce^{i(kx - \omega t)}.$$

Likewise, the dynamic and kinematic surface conditions (23.6) and (23.11) remain valid. They give for $y = 0$, because of (2) and (3),

$$(4) \quad i\omega C \cosh kh = gc,$$

$$(5) \quad -i\omega c = Ck \sinh kh.$$

We first discuss the case of *shallow* water, that is,

$$kh \ll 1, \quad \cosh kh = 1, \quad \sinh kh = kh.$$

Eqs. (4) and (5) yield in this case

$$i\omega C = gc, \quad -i\omega c = Ck^2 h,$$

or

$$(6) \quad \frac{C}{c} = \frac{g}{i\omega} = -\frac{i\omega}{k^2 h}.$$

The formula for the velocity of propagation is now

$$(7) \quad V^2 = \frac{\omega^2}{k^2} = gh, \quad V = \sqrt{gh}.$$

(One is reminded of the definition of the velocity head $h = v^2/2g$ on p. 45, but it is merely a formal analogy, due to dimensional reasons.)

In shallow water the velocity of propagation is independent of the wave length; there is no dispersion.

On the basis of Eq. (7) we can now complete Fig. 34 for large λ values. The curve should approach a horizontal asymptote for $\lambda > h$ in the distance \sqrt{gh} from the λ -axis, as indicated by the branch *b* of this line.

When λ and h are of the same order of magnitude (*moderately deep* water), Eqs. (4) and (5) still govern the behavior of the wave. In this case, they supply directly

$$(8) \quad \frac{C}{c} = \frac{g}{i\omega \cosh kh} = -\frac{i\omega}{k \sinh kh},$$

from which we infer

$$(9) \quad \tanh kh = \frac{\omega^2}{gk}.$$

On introducing $x = kh$ and $d = \omega^2 h/g$, we obtain

$$(9a) \quad \tanh x = \frac{d}{x}.$$

The solution of this transcendental equation can be obtained graphically: We plot the equilateral hyperbola d/x and the curve $\tanh x$ above x as

abscissa (the latter is a monotonic increasing function with a horizontal asymptote at the distance 1 from the x -axis). There is then only one intersection point of the two curves, and its abscissa $x = x_0$ is the root of Eq. (9a); the required value of k is x_0/h . The *velocity of propagation in moderately deep water* is therefore

$$(10) \quad V = \frac{\omega}{k} = \frac{\omega h}{x_0}.$$

We have obtained an implicit representation of the dispersion law which should be supplemented by a chart or table of the solutions of Eq. (9a) in function of the parameter d . We also see in what way Fig. 34 is to be completed: the gap between segment a ($h \gg \lambda$) and segment b ($h \ll \lambda$) is bridged by segment c ($h \cong \lambda$) corresponding to Eq. (10). Since this

FIG. 35. Graphical solution of the transcendental Eq. (9a).

part of the curve increases, too, one sees that the *dispersion is normal* throughout.

The transition from a to c can also be read from the following formula which is a direct consequence of (9)

$$(10a) \quad V^2 = \frac{\omega^2}{k^2} = \frac{g\lambda}{2\pi} \tanh \frac{2\pi h}{\lambda}.$$

One obtains from (10a)

$$\text{for } h \gg \lambda: \quad V^2 \rightarrow \frac{g\lambda}{2\pi}, \quad \text{Eq. (23.16),}$$

$$\text{for } h \ll \lambda: \quad V^2 \rightarrow gh, \quad \text{Eq. (24.7).}$$

A remark on *surf formation* may be inserted here which is of a purely qualitative nature and includes perhaps an over-interpretation of our equations. Surf is bound to a region of very small h and, consequently, small $kh = x$ so that $\tanh x \cong x$. The transcendental Eq. (9a) becomes then algebraic: $x = d/x$. The root is

$$x_0 = \sqrt{d} = \omega \sqrt{\frac{h}{g}},$$

the velocity of propagation according to (10) is therefore

$$(11) \quad V = \sqrt{gh},$$

which is our formula (7) for shallow water. Now, our analysis is only valid for water of *uniform* depth, but we may try to apply it to the case of decreasing depth in the vicinity of the shore (cf. Fig. 36). Besides, our results apply only to *small amplitudes* since the amplitude squares have been omitted; nevertheless, we use them now for finite amplitudes, assuming *two* values for h , viz., h_c characterizing the crest and h_r characterizing the trough of a wave (cf. Fig. 36), and obtain from (11)

$$(11a) \quad \frac{V_c}{V_r} = \sqrt{\frac{h_c}{h_r}} > 1.$$

Hence the velocity of propagation of the crest is larger than that of the trough, which would modify the shape of the wave as indicated in Fig. 36

FIG. 36. Surf formation.

by the crest to the right. This offers an explanation of the surf phenomenon on the basis of our equations, although it is doubtful whether the conclusions are legitimate.

We turn to the very attractive problem of the path of an individual particle in wave motion which shall be discussed under the assumption of moderately deep water. Let x, y be the particle coordinates in water at rest and x', y' the same in water disturbed by the wave motion. The displacement from the rest position is then

$$(12) \quad \xi = x' - x, \quad \eta = y' - y;$$

where η no longer denotes the surface disturbance as before, but the disturbance at an arbitrarily specified depth y , (similarly ξ). The particle velocity according to (2) is

$$(13) \quad \begin{aligned} v_x = \dot{\xi} &= -\frac{\partial \Phi}{\partial x} = -ike^{(kx - \omega t)} C \cosh k(h - y), \\ v_y = \dot{\eta} &= -\frac{\partial \Phi}{\partial y} = ke^{(kx - \omega t)} C \sinh k(h - y). \end{aligned}$$

It will be noticed that Φ is here differentiated with respect to x, y , while it should be differentiated with respect to the variable coordinates x', y' ; also, we should write in (13) x', y' or $x + \xi, y + \eta$ instead of x, y . The difference, however, would be of second order in the quantities C, ξ and η and may therefore be neglected.

Integrating (13) with respect to t , which amounts to a division by $-i\omega$, we obtain

$$(14) \quad \xi = \frac{k}{\omega} e^{i(kx - \omega t)} C \cosh k(h - y),$$

$$\eta = i \frac{k}{\omega} e^{i(kx - \omega t)} C \sinh k(h - y).$$

where the constants of integration must be taken as zero because of the periodicity of the displacement. We introduce the notations (they will justify themselves presently)

$$(15) \quad a = \frac{kC}{\omega} \cosh k(h - y), \quad b = \frac{kC}{\omega} \sinh k(h - y)$$

and write the *real part* of (14), using these abbreviations:

$$(16) \quad \xi = a \cos(kx - \omega t), \quad \eta = -b \sin(kx - \omega t).$$

To find the equation of the particle path we have to eliminate t from (16). By squaring ξ and η we obtain

$$(17) \quad \frac{\xi^2}{a^2} + \frac{\eta^2}{b^2} = 1,$$

which is the equation of an ellipse. The reason why we had to change back to the real representation becomes now apparent: the complex writing preserves its physical significance only in linear operations!

The ratio of the minor to the major axis follows from (15) as

$$(17a) \quad \frac{b}{a} = \tanh k(h - y) = \begin{cases} 0 & \text{for } y = h, \text{ bottom} \\ \tanh kh & \text{for } y = 0, \text{ surface.} \end{cases}$$

The excentricity of the ellipses is the same at any depth:

$$(17b) \quad e = \sqrt{a^2 - b^2} = \frac{kC}{\omega}.$$

Fig. 37a represents the position and shape of the ellipses in the general case, Fig. 37b in the case of deep water, Fig. 37c in the case of shallow

FIG. 37. The path curves of water particles (a) in moderately deep water, (b) in deep water, (c) in shallow water.

water. The ellipses of Fig. 37a are *confocal* if they are coaxially superimposed upon each other. In the limiting case $kh \rightarrow \infty$ we have by (17a)

$$\frac{b}{a} = \tanh(\infty) = 1.$$

The ellipses thus become *circles* as in Fig. 37b. The radii are determined by computing a or b from (15) and the first equation (1a):

$$\begin{aligned} a &= \frac{kC}{\omega} \cosh k(h - y) = \frac{k}{\omega} A e^{-kh} (e^{k(h-y)} + e^{-k(h-y)}) \\ &= \frac{k}{\omega} A (e^{-ky} + e^{-k(2h-y)}) \rightarrow \frac{k}{\omega} A e^{-ky}, \\ b &= \frac{kC}{\omega} \sinh k(h - y) = \frac{k}{\omega} A e^{-kh} (e^{k(h-y)} - e^{-k(h-y)}) \\ &= \frac{k}{\omega} A (e^{-ky} - e^{-k(2h-y)}) \rightarrow \frac{k}{\omega} A e^{-ky}. \end{aligned}$$

The radii of the circles are seen to decrease very quickly with increasing depth. In the other limiting case where kh and, *a fortiori*, $k(h - y)$ go to zero we obtain from (17a)

$$\frac{b}{a} = \tanh 0 = 0.$$

The ellipses degenerate into horizontal *straight segments* (cf. Fig. 37c); in shallow water there is, so to speak, no space left for a vertical displacement. The amplitude of the horizontal oscillation, e , is independent of the depth y [cf. (17b)].

The stream lines of the velocity field are no less interesting than the

path curves of the particles. Since in the present case of plane waves we have a two-dimensional velocity field, the stream function Ψ is obtained by (19.5) from the following equations

$$\frac{\partial \Psi}{\partial x} = -\frac{\partial \Phi}{\partial y}, \quad \frac{\partial \Psi}{\partial y} = \frac{\partial \Phi}{\partial x}.$$

On substituting the general² expression for Φ from (2), we obtain

$$\frac{\partial \Psi}{\partial x} = ke^{i(kx - \omega t)} C \sinh k(h - y),$$

$$\frac{\partial \Psi}{\partial y} = ike^{i(kx - \omega t)} C \cosh k(h - y).$$

The first or second of these expressions is now integrated over x or y respectively and the integration constant set equal to zero as before; this leads to

$$\Psi = -ie^{i(kx - \omega t)} C \sinh k(h - y).$$

To find the stream lines we have to consider this equation at a specified instant t . Let us then take the real part for $t = 0$:

$$(18) \quad \Psi = C \sin kx \cdot \sinh k(h - y).$$

For comparison, we write down the surface depression η according to (3), express c by C through (6), and take again the real part at $t = 0$:

$$(19) \quad \eta = -\frac{\omega}{g} C \sin kx.$$

A glance at (18) shows: the streamline $\Psi = 0$ requires $y = h$: the bottom is therefore a part of the streamline, which is fairly obvious; but for $kx = 0, \pm\pi, \pm 2\pi$, we have again $\Psi = 0$, whatever y is. At the same abscissas, η vanishes likewise, as is seen from (19). Hence the flow pattern is divided into rectangular domains which contain the stream lines. Furthermore we conclude from (18) that $\partial \Psi / \partial x = 0$ if $\cos kx = 0$, whatever y is. This happens at the abscissas $kx = \pi/2, 3\pi/2, \dots$, for which η has a maximum or a minimum; at these points all streamlines are horizontal.—Altogether this is sufficient information to form an idea of the general pattern of the streamlines (cf. Fig. 38).

The patterns of Fig. 38 and 37a are convincingly verified by actual photographs of path curves and streamlines. For the purpose of photography the fluid is kept in a narrow glass container with parallel walls, and small light absorbing particles such as metal filings mixed in; one

²In the case of shallow water the stream lines are obviously horizontal.

photographs across the container and obtains the *streamlines* by a *short exposure*. In viewing the photographs the eye involuntarily connects the line elements traced by the dark particles and recognizes the continuous arcs of the stream lines, and also their position relative to the fluid surface which appears moderately sharp in the picture. With a *longer exposure*, e.g., as long as a half period, and a less dense interspersation of metal particles, the *path curves* can well be distinguished as elliptical arcs, but the surface does not show up distinctly. This second picture gives also evidence

FIG. 38. The streamlines of gravity waves in water of finite depth.

of the propagation of the phase, if one compares the starting points (or end points) of the arcs left and right in the photograph.

The particles remain essentially at their places; this, at least, is true if the amplitude is sufficiently small, as assumed in our calculation, but is no longer quite correct for a finite amplitude. Therefore it is only the phase that travels with the velocity V which we have computed; phase velocity would thus be a more accurate designation for V .

25. Plane Capillary Waves and Combined Capillary-Gravity Waves

In the following discussion we shall first disregard gravity entirely, taking only the *surface tension* T into account. The surface is no longer free of forces, but under the action of the normal pressure N caused by T . Accordingly, the condition for the hydrodynamic pressure at the surface is not $p = 0$ as in (23.4), but, in the case of a plane wave, according to (17.10)

$$(1) \quad p = T \frac{\partial^2 \eta}{\partial x^2}.$$

(Note that u of (17.10) must be replaced by the *surface elevation* $-\eta$.) The value of p given by (1) is to be introduced in Bernoulli's equation (23.5) together with $U = 0$ (gravity is disregarded for the time being). Hence we obtain

$$(2) \quad \frac{\partial \Phi}{\partial t} = \frac{T}{\rho} \frac{\partial^2 \eta}{\partial x^2}.$$

FIG. 39a. A photograph of the streamlines (short exposure).

FIG. 39b. A photograph of the path curves (longer exposure).

The kinematic considerations at the beginning of 23 have dealt with the character of a plane wave in general and are consequently still valid. We therefore can take over the expressions (23.1) for Φ and (23.7) for η . Eq. (2) becomes after cancellation of the exponential and omission of second order terms

$$(3) \quad i\omega A = \frac{T}{\rho} k^3 a.$$

Also the kinematic condition (23.11) is in force; it gives, as in (23.12), a second equation

$$(4) \quad -i\omega a = kA.$$

From (3) and (4) we have

$$(5) \quad \frac{A}{a} = \frac{T}{\rho} \frac{k^3}{i\omega} = -\frac{i\omega}{k}$$

and, therefore, the following relation between ω and k

$$(6) \quad \omega^2 = \frac{T}{\rho} k^3.$$

The velocity of the capillary waves is

$$(7) \quad V^2 = \frac{\omega^2}{k^2} = \frac{T}{\rho} k, \quad V = \sqrt{\frac{T}{\rho} \frac{2\pi}{\lambda}}.$$

This then is a case of *anomalous dispersion* since V increases with *decreasing* λ , contrary to the gravity waves which show *normal* dispersion at all finite wave lengths. In Fig. 40, we have plotted V as a function of

FIG. 40. Superposition of the phase velocities of capillary and gravity waves as functions of λ .

λ , obtaining the descending segment 1 (broken line). For comparison we have added the characteristic of the gravity waves from Fig. 34 as branch 2 (broken line). Let the intersection point which exists under all circumstances have the abscissa $\lambda = \lambda_0$. For $\lambda < \lambda_0$ the curve 1 is above curve 2, since the propulsive force of the capillary waves depends on the curvature of the surface profile which, for a given amplitude, is the larger the smaller the wave length. (This is also the reason why in Fig. 34 the segment α was not continued beyond a certain lower limit.) For $\lambda > \lambda_0$ the curve 2 is above 1. The unimportance of capillarity for large wave lengths which expresses itself in the small V -values justifies our use of the velocity potential for *deep water* throughout the present article. Even at a moderate

depth h the quotient h/λ is large for capillary waves, and so is *a fortiori* hk .

It is now easy to treat the general case of *combined action of capillarity and gravity*. We have only to introduce in Bernoulli's equation (23.5) the value p from (1) and the value for the gravity potential from (23.5b) $U = -\rho g \eta$. In place of (3) we obtain

$$(8) \quad i\omega A = \left(\frac{T}{\rho} k^3 + g \right) a.$$

From (4) and (8) follows now, instead of (5),

$$(9) \quad \frac{A}{a} = \frac{1}{i\omega} \left(\frac{T}{\rho} k^3 + g \right) = -\frac{i\omega}{k},$$

and therefore, instead of (6) and (7),

$$(10) \quad \omega^2 = \frac{T}{\rho} k^3 + gk,$$

$$(11) \quad V^2 = \frac{\omega^2}{k^2} = \frac{T}{\rho} k + \frac{g}{k} = V_1^2 + V_2^2.$$

Here V_1 is the velocity of the capillary wave according to (7), and V_2 is the velocity of the gravity wave according to (23.16); the velocity of the combination wave is found by a *quadratic superposition* formula.

Let us first compute from (11) the minimum of V as a function of λ . We obtain

$$2V \frac{dV}{d\lambda} = \frac{d}{dk} \left(\frac{T}{\rho} k + \frac{g}{k} \right) \frac{dk}{d\lambda} = 0,$$

and therefore

$$(12) \quad \frac{T}{\rho} = \frac{g}{k^2}, \quad \lambda_{\min} = \frac{2\pi}{k} = 2\pi \sqrt{\frac{T}{\rho g}}.$$

But λ_{\min} is at the same time the abscissa of the intersection point of the branches 1 and 2, which has been denoted by λ_0 in Fig. 40. In fact, one obtains from (7) and (23.16) the following equation for λ_0

$$\sqrt{\frac{T}{\rho} \frac{2\pi}{\lambda_0}} = \sqrt{\frac{g\lambda_0}{2\pi}},$$

hence $\lambda_0 = \lambda_{\min}$. The corresponding value of V_{\min} is found as

$$(13) \quad V_{\min}^2 = 2V_1^2 = 2V_2^2 = 2\sqrt{\frac{Tg}{\rho}}.$$

The general value (11) of V^2 can be put in the elegant form

$$(14) \quad \frac{V^2}{V_{\min}^2} = \frac{1}{2} \left(\frac{\lambda_{\min}}{\lambda} + \frac{\lambda}{\lambda_{\min}} \right),$$

which is easily verified.

We finally turn to the *numerical* values which in the present problem are not without interest. The constant of surface tension between water and air³ is

$$T = 72 \frac{\text{dynes}}{\text{cm}} = 72 \frac{\text{gr}}{\text{sec}^2}.$$

From (12) and (13) one obtains with $\rho = 1$, $g = 981$:

$$\lambda_{\min} = 2\pi \sqrt{\frac{72}{981}} = 1.73 \text{ cm}, \quad V_{\min} = \sqrt{2 \sqrt{72 \times 981}} = 23.2 \frac{\text{cm}}{\text{sec}}.$$

Water waves with a velocity of less than 23 cm/sec do not exist; waves of larger and of smaller wave length than $\lambda_{\min} = 1.73$ cm travel with greater velocity than 23 cm/sec. Lord Kelvin proposed for waves $\lambda < \lambda_{\min}$ the name "ripples"; one sometimes observes big gravity waves the faces of which are covered with fine capillary ripples.

26. The Concept of Group Velocity

At the end of 24 the term phase velocity was proposed in place of velocity of propagation V and it was pointed out that the *phase* of the wave advances with the velocity V . The phase is given in our representation [(23.1), (23.7), (24.1), etc.] by the exponent $i(kx - \omega t)$; if it is kept constant, that is, if one looks for the locus of equal phase as time proceeds, one obtains the condition

$$(1) \quad k dx - \omega dt = 0, \quad \text{therefore} \quad \frac{dx}{dt} = \frac{\omega}{k} = V.$$

For waves of a given invariable frequency (or, borrowing an expression from optics, for *monochromatic* waves), this is the only velocity that can come into consideration.

That is no longer true if waves of different frequency are superposed on each other. We speak then of a *group of waves*, particularly in the case where the frequencies are closely together. (Today one prefers, particularly in wave mechanics, the term "wave packet", an expression,

³Note that the most accurate method to determine T consists in the measurement of λ of standing capillary waves excited by a tuning fork. Elevation measurements in capillary tubes tend to be inaccurate because of impurities along the walls of the tube.

which is perhaps not quite so elegant as appropriate.) The wave group progresses with the *group velocity* U which, in general, is different from the phase velocity V . It is convenient to write the expression for U in the following way that will be justified later:

$$(2) \quad U = \frac{d\omega}{dk}.$$

If the waves proceed *without dispersion*, that is, if V is independent of the wave length λ (or of the wave number k) one obtains from (1) $d\omega = Vdk$ and therefore

$$(2a) \quad U = V.$$

Group and phase velocity coincide only for wave processes free of dispersion.

In general, however, we have

$$d\omega = V dk + k \frac{dV}{dk} dk,$$

or, by (2),

$$(2b) \quad U = V + k \frac{dV}{dk} = V - \lambda \frac{dV}{d\lambda}.$$

For normal dispersion ($dV/d\lambda > 0$), the group velocity is smaller than the phase velocity, for anomalous dispersion ($dV/d\lambda < 0$) the converse statement holds.

For gravity waves in deep water we have by (23.17)

$$V = \sqrt{\frac{g\lambda}{2\pi}}, \quad \frac{dV}{d\lambda} = \frac{1}{2\lambda} V,$$

and by (2b)

$$(2c) \quad U = V - \frac{1}{2} V < V.$$

On the other hand, for pure capillary waves (25.7) yields

$$V = \sqrt{\frac{T}{\rho} \frac{2\pi}{\lambda}}, \quad \frac{dV}{d\lambda} = -\frac{1}{2\lambda} V,$$

hence

$$(2d) \quad U = V + \frac{1}{2} V > V.$$

For the combined capillary-gravity waves we have according to Fig. 40 for $\lambda < \lambda_{\min}$ anomalous dispersion, therefore $U > V$; for $\lambda > \lambda_{\min}$ the

dispersion is normal and $U < V$. For $\lambda = \lambda_{\text{min}}$, $U = V$, corresponding to the horizontal tangent in Fig. 40 and to the vanishing factor $dV/d\lambda$ in (26).

The possibility of U and V having opposite signs has also been discussed.⁴

The concept of group velocity is originally a hydrodynamical one (Stokes 1876), but has proved of fundamental importance in optics (Lord Rayleigh). In wave mechanics phase velocity has formal significance while the group velocity is the important physical quantity, viz. the velocity of the particle represented by the wave packet (L. de Broglie 1924).

Let us first reproduce here the usual elementary derivation of formula (2), following Stokes. We superpose two waves that advance in positive x -direction, having the same amplitude, but slightly different frequency, hence slightly different wave number:

$$(3) \quad \eta = a\{\sin(k_1x - \omega_1t) + \sin(k_2x - \omega_2t)\}.$$

The wave group so produced has the character of a *beat*: at points where the difference of two phases is equal to $2n\pi$, there is reinforcement; when the phase difference is $(2n+1)\pi$ there is neutralization. This can be seen if (3) is written in the following form

$$(3a) \quad \eta = 2a \cos\left(\frac{k_1 - k_2}{2}x - \frac{\omega_1 - \omega_2}{2}t\right) \sin\left(\frac{k_1 + k_2}{2}x - \frac{\omega_1 + \omega_2}{2}t\right).$$

The cosine term vanishes or equals ± 1 , depending on whether the phase difference of the two partial waves is an uneven or even multiple of π . Introducing

$$\frac{k_1 + k_2}{2} = k_0, \quad \frac{\omega_1 + \omega_2}{2} = \omega_0, \quad k_1 - k_2 = \Delta k, \quad \omega_1 - \omega_2 = \Delta \omega$$

we write for (3a)

$$(3b) \quad \eta = C \sin(k_0x - \omega_0t), \quad C = 2a \cos \frac{1}{2}(\Delta kx - \Delta \omega t).$$

The introduction of the "amplitude-factor" C for the cosine factor should suggest that it is a *slowly variable* quantity. We call it the group amplitude. The phase velocity of the compound wave as it follows from the sine factor in (3b) is

$$V = \frac{\omega_0}{k_0}$$

⁴Cf. Sir Arthur Schuster, *Theory of Optics*, London, 1924, p. 330.

and thus not sensibly different from the phase velocities of the component waves

$$V_1 = \frac{\omega_1}{k_1} \quad \text{and} \quad V_2 = \frac{\omega_2}{k_2}.$$

On the other hand, the velocity of propagation of the "amplitude" C is found by setting

$$\Delta kx - \Delta \omega t = \text{const},$$

which yields when differentiated

$$(3c) \quad \Delta k \, dx - \Delta \omega \, dt = 0, \quad \frac{dx}{dt} = \frac{\Delta \omega}{\Delta k}.$$

In the limit $\Delta k \rightarrow 0$ we therefore obtain our formula (2).

We can go beyond the very special assumption (3) when we consider an arbitrary group of waves whose frequencies are spread over a small frequency band. Since it is now convenient to return to complex representation, we put η in the form

$$(4) \quad \eta = \int_{k_0-\epsilon}^{k_0+\epsilon} a(k) e^{i(kx - \omega t)} dk.$$

The amplitude of the partial wave is now $a(k)dk$ and the small band width of the whole group 2ϵ , if measured in wave number units, so as to be concentrated about the central wave number k_0 . We rewrite the exponent in (4) accordingly:

$$kx - \omega t = k_0 x - \omega_0 t + (k - k_0)x - (\omega - \omega_0)t.$$

If this is done, (4) assumes the form

$$(4a) \quad \eta = C e^{i(k_0 x - \omega_0 t)}, \quad C = \int_{k_0-\epsilon}^{k_0+\epsilon} a(k) e^{i[(k-k_0)x - (\omega-\omega_0)t]} dk.$$

To find the velocity of propagation of the amplitude C in this more general case, we have to set the exponential in C , which alone contains x and t , constant. This yields for the whole wave group the sensibly constant value

$$\frac{dx}{dt} = \frac{\omega - \omega_0}{k - k_0} = \frac{\Delta \omega}{\Delta k}$$

in agreement with Eq. (2), if Δk is sufficiently small.

It should be noticed that the more general formula (4) as well as the expression (3) constitute a superposition of infinitely long wave trains, but do not represent an isolated hill or a few crests and troughs. To express an isolated wave group (a wave packet) by analytical means would require

the use of Fourier integrals; the integration in (4) would have to be carried out over all wave numbers from $-\infty$ to $+\infty$ instead of over the narrow range 2ϵ .

A wave packet can proceed *without change of shape* only if there is no dispersion. In the general case the group dissolves on account of the dispersion since its partial waves do not keep together; this tendency is of particular importance for the particle concept of wave mechanics. The conservation of the packet in the absence of dispersion follows directly from d'Alembert's solution (13.11), at least in the case of a sufficiently small amplitude, when this solution applies to dispersion-free hydrodynamics as well as to acoustics. An arbitrary initial disturbance $\eta = F(x)$ is then given by $\eta = F(x - Vt)$ at any later time if the initial velocity $\partial\eta/\partial t$ has been suitably chosen. This means that the wave can advance *without change of shape*.

In Fig. 41a and b a simple construction of the group velocity is shown that uses Eq. (2b) and the relation $\tan \alpha = \pm dV/d\lambda$.

FIG. 41. Construction of the group velocity for a given phase velocity when the dispersion curve is given; (a) normal, (b) anomalous dispersion.

Reynolds⁵ and, simultaneously, Lord Rayleigh⁶ have pointed out the relation between the group velocity and the *transport of energy* and thus enhanced the physical understanding of the concept of group velocity. In their theory the ratio of group velocity U to phase velocity V appears as the ratio of the energy flow S through a specified cross-section of the wave during the time τ to the energy E contained in the fluid region ahead of this cross-section per length $V\tau$:

$$(5) \quad \frac{U}{V} = \frac{S}{E}.$$

⁵Reynolds, O., Papers on math. and phys. Subj., Cambridge 1901, Vol. I, p. 198, from Nature 46 (1877) 343.

⁶Lord Rayleigh, Scientific papers, Cambridge 1901, Vol. I, p. 322 and Theory of sound, Vol. I, appendix from Proc. London Math. Soc. 9, 21.

It is convenient for what follows, to identify the time τ with the period of oscillation, so that $V\tau$ is equal to the wave length λ . The energy E is more accurately defined as the energy *surplus* of the oscillating fluid over the fluid at rest.

Let us examine these relations for deep water waves of sufficiently small amplitude. Since we are concerned with energy, that is with a quadratic function of the rates of displacement, we cannot use the complex representation. Taking the real equations (23.14) and (23.14b)

$$\begin{aligned}\Phi &= A \cos(kx - \omega t)e^{-ky}, \\ \eta &= -\frac{k}{\omega} A \sin(kx - \omega t),\end{aligned}\tag{6}$$

we can obtain the potential energy of gravity contained between the undisturbed surface $y = 0$ and the wave surface $y = \eta$ at a specified time t , per length λ in x -direction and per width 1 in z -direction:

$$\begin{aligned}E_{\text{pot}} &= g\rho \int_0^\lambda dx \int_0^\eta y dy \\ &= g\rho \frac{k^2}{\omega^2} \frac{A^2}{2} \int_0^\lambda \sin^2(kx - \omega t) dx = g\rho \frac{k^2}{\omega^2} \frac{A^2}{4} \lambda.\end{aligned}\tag{7}$$

Using the dispersion formula (23.15), we rewrite this result:

$$E_{\text{pot}} = \frac{\rho}{4} k A^2 \lambda = \frac{\rho}{2} \pi A^2.\tag{7a}$$

This is at the same time the difference between the potential energy of the oscillating fluid and the fluid at rest for the *entire* depth which reaches from $y = \eta$ to $y = \infty$ for the moving fluid and from $y = 0$ to $y = \infty$ for the fluid at rest.

The kinetic energy contained in this region has the same magnitude, as is always the case for small oscillations; this will be discussed in detail in problem V, 1. The total energy, or more accurately, the energy excess over the fluid at rest becomes therefore

$$E = E_{\text{kin}} + E_{\text{pot}} = \rho\pi A^2.\tag{8}$$

In order to determine the energy flow S through the cross-section at $x = \lambda$, which may be replaced by the cross-section $x = 0$, we have to know the pressure p at this cross-section. This is found from Bernoulli's equations (23.5) and (23.5b) as

$$p = \rho \frac{\partial \Phi}{\partial t} + \rho g y + \text{const.}\tag{9}$$

Since p acts normal to the plane $x = 0$, its product with the x -component of the velocity, multiplied with $dy dt$ expresses the work dW done at the surface element $dy \cdot 1$ during dt :

$$(9a) \quad dW = pv_x dy dt = -p \frac{\partial \Phi}{\partial x} dy dt.$$

The work performed at the cross-section $x = 0$ during the time τ represents the energy flow through this cross-section in this time. It is by (9a) and (9)

$$(10) \quad S = - \int_0^\tau dt \int_{-\infty}^{\infty} dy p \frac{\partial \Phi}{\partial x} = - \int_0^\tau dt \int_{-\infty}^{\infty} dy \left(\rho \frac{\partial \Phi}{\partial t} + \dots \right) \frac{\partial \Phi}{\partial x}.$$

The terms $\rho gy + \text{const}$ not written out in (10) have the periodic factor $\partial \Phi / \partial x$. Since they are independent of t , their contributions cancel when integrated over the period τ . Substitution from (6) gives

$$S = \rho \omega k A^2 \int_0^\tau dt \sin^2 \omega t \int_{-\infty}^{\infty} e^{-2ky} dy$$

or, after integration,

$$(11) \quad S = \frac{\rho}{2} \pi A^2 e^{-2ky} = \frac{\rho}{2} \pi A^2.$$

Here, e^{-2ky} has been replaced by 1 which means omission of terms of higher order than A^2 .

Comparing (11) and (8), one obtains

$$(12) \quad \frac{S}{E} = \frac{1}{2}.$$

This is indeed the value of the ratio U/V for deep water waves obtained in (2c). We have thus confirmed in this simplest case the general energetic definition (5) of the group velocity. It also holds in the considerably more complicated case of moderately deep water where Eqs. (2b) and (24.10a) lead to

$$(13) \quad \frac{U}{V} = \frac{1}{2} \left(1 + \frac{2kh}{\sinh 2kh} \right).$$

Let us now have a look at this result from a more qualitative point of view; we again consider the wave train of length λ ending at $x = 0$. If no dispersion were present, the entire energy content of the wave would flow through the cross-section during the period τ ; in other words, we should have $S = E$ and $U = V$. Actually, only a part of this energy is transported in the case of normal dispersion (half of it with deep water

waves), whereas the other part remains in the oscillating fluid ahead of the cross-section. This makes the case of anomalous dispersion appear rather peculiar since more energy passes through the cross-section than is present in the λ -train ahead of it; the energy remaining in the train would be negative. To maintain the wave motion in such a case requires expending more energy than travels with the wave; in the first case less excitation energy is required for the same amount of energy transported. *Energy transport is thus easier in a medium of normal dispersion and more difficult in a medium of anomalous dispersion.*

27. Circular Waves

The waves that are produced when a stone is thrown into water form a series of concentric circular crests and troughs; their amplitudes are not constant, nor are the distances between the crests. What one observes is a sharp decrease of the amplitude and an increase of the distance between two subsequent crests, which seems to follow a peculiar law. This problem that appears so simple requires for its solution a considerable mathematical apparatus: we not only need Bessel functions and Fourier integrals, but we should have to use the method of steepest descent if we were to treat it in full accuracy. A systematic treatment of these devices will be given in Vol. VI. At this point we shall limit ourselves to such explanations as are directly required here.

For our analysis we shall replace the stone that hits the water surface by a "standard disturbance": at $r = 0$ a cylindrical piston of radius r_0 is immersed in the water to a distance a from the surface and suddenly withdrawn at the time $t = 0$. If we again denote the surface depression by η , the initial state is given by

$$(1) \quad \begin{aligned} \eta &= a, & r < r_0. \\ \eta &= 0, & r > r_0. \end{aligned}$$

In preparation for the problem of a single disturbance we first consider the much simpler case of a periodic excitation.

1. The Periodic Case. Introduction of Bessel Functions

The excitation we have in mind works in a similar way as the device that produces waves in a swimming pool: a straight board subjected to a periodic motion excites plane progressive gravity waves advancing normal to the board. We have investigated waves of this type in 23 for deep water and wish now to transfer our previous results to the present circular symmetric problem.

Introducing cylindrical polar coordinates r, φ, y (y positive downward), we write the condition of incompressibility for the velocity potential Φ (cf. problem I, 3) in the form

$$(2) \quad \frac{\partial^2 \Phi}{\partial r^2} + \frac{1}{r} \frac{\partial \Phi}{\partial r} + \frac{1}{r^2} \frac{\partial^2 \Phi}{\partial \varphi^2} + \frac{\partial^2 \Phi}{\partial y^2} = 0.$$

If we at first assume circular symmetry, Φ does not depend on φ and can be written as follows

$$(3) \quad \Phi = A f(r) e^{-k y} e^{-i \omega t}.$$

Now the following differential equation results for $f(r)$:

$$(4) \quad \frac{d^2 f}{dr^2} + \frac{1}{r} \frac{df}{dr} + k^2 f = 0.$$

We substitute $kr = \rho$ and obtain

$$(4a) \quad \frac{d^2 f}{d\rho^2} + \frac{1}{\rho} \frac{df}{d\rho} + f = 0.$$

Let $J_0(\rho)$ be the solution of this equation which is regular at $\rho = 0$ and assumes there the value 1. The power series expansion of this function can be easily found from (4a) by the method of undetermined coefficients:

$$(5) \quad J_0(\rho) = 1 - \left(\frac{\rho}{2}\right)^2 + \frac{1}{2!^2} \left(\frac{\rho}{2}\right)^4 - \frac{1}{3!^2} \left(\frac{\rho}{2}\right)^6 + \dots$$

If, on the other hand, Φ is not independent of φ , then we replace $f(r)$ by $f_n(r) e^{i n \varphi}$ and obtain instead of (4) and (4a)

$$(6) \quad \frac{d^2 f_n}{dr^2} + \frac{1}{r} \frac{df_n}{dr} + \left(k^2 - \frac{n^2}{r^2}\right) f_n = 0$$

and

$$(6a) \quad \frac{d^2 f_n}{d\rho^2} + \frac{1}{\rho} \frac{df_n}{d\rho} + \left(1 - \frac{n^2}{\rho^2}\right) f_n = 0.$$

Let $J_n(\rho)$ denote that solution of (6a) which is regular at $\rho = 0$ and admits the following expansion,

$$(7) \quad J_n(\rho) = \frac{1}{n!} \left(\frac{\rho}{2}\right)^n - \frac{1}{1!(n+1)!} \left(\frac{\rho}{2}\right)^{n+2} + \frac{1}{2!(n+2)!} \left(\frac{\rho}{2}\right)^{n+4} - \dots$$

which may be considered as a generalization of (5). The functions J_n are known as *Bessel Functions of n^{th} order*; they are entire transcendental functions.

The following relation between J_1 and J_0

$$(8) \quad J_1(\rho) = -\frac{d}{d\rho} J_0(\rho),$$

can be immediately verified from (5) and (7).

On writing Eq. (4a) in the form

$$\frac{d}{d\rho} \left(\rho \frac{dJ_0}{d\rho} \right) + \rho J_0(\rho) = 0,$$

where $J_0(\rho)$ has been written for f , one has because of (8),

$$\rho J_0(\rho) = \frac{d}{d\rho} (\rho J_1(\rho)).$$

This relation, integrated to an arbitrary upper limit, yields the following formula

$$(8a) \quad \int_0^{\rho_0} \rho J_0(\rho) d\rho = \rho_0 J_1(\rho_0).$$

We shall also need the integral representation

$$(9) \quad J_0(\rho) = \frac{1}{2\pi} \int_{-\pi}^{+\pi} e^{i\rho \cos \alpha} d\alpha.$$

It is not difficult to verify that this expression satisfies Eq. (4a) and has the value 1 for $\rho = 0$, wherefore it must be identical with (5). The same result can also be obtained, though less directly by series expansion of the exponential function in (9). Obviously, (9) can also be written in the form

$$(9a) \quad J_0(\rho) = \frac{1}{\pi} \int_0^{\pi} e^{i\rho \cos \alpha} d\alpha.$$

We now substitute $f = J_0(kr)$ in the formula for the potential (3) and obtain

$$(10) \quad \Phi = A J_0(kr) e^{-ky} e^{-i\omega t}.$$

This formula satisfies the condition for deep water: $\Phi \rightarrow 0$ for $y \rightarrow \infty$, but it should also satisfy the conditions (23.6) and (23.11) for the surface $y = 0$. The analytical form of the surface depression is assumed in correspondence to the form of Eq. (10)

$$(10a) \quad \eta = a J_0(kr) e^{-i\omega t}.$$

Our expression for Φ and η leads, by exactly the same steps as in Eqs. (23.9), (23.12) and (23.13), after cancellation of $J_0(kr) e^{-i\omega t}$, to

$$(11) \quad \frac{A}{a} = \frac{g}{i\omega} = -\frac{i\omega}{k}.$$

Thus we reobtain the dispersion law (23.15)

$$(11a) \quad \omega = \sqrt{gk}$$

and the final expression for the potential becomes

$$(12) \quad \Phi = \frac{ag}{i\omega} J_0(kr) e^{-ky - i\omega t}.$$

2. Single Disturbance. The Fourier-Bessel Integral

The content of the Fourier integral theorem is this: an arbitrary function $F(x)$ (provided it is not "too irregular") can be represented by superposition of trigonometric functions $\sin kx$ or by the equivalent exponential functions e^{ikx} in the form

$$(13) \quad F(x) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} dk e^{ikx} \int_{-\infty}^{+\infty} d\xi F(\xi) e^{-i k \xi}, \quad -\infty < x < +\infty.$$

This theorem has an analogue in the following representation of F by Bessel functions

$$(13a) \quad F(r) = \int_0^{\infty} k dk J_0(kr) \int_0^{\infty} \xi d\xi F(\xi) J_0(k\xi), \quad 0 < r < +\infty.$$

Both theorems will be proved in Vol. VI, where (13a) will be obtained as a consequence of (13).

We now apply (13a) to the initial state (1). Our function $F(r)$ is then given by

$$F(r) = \eta = \begin{cases} a & \text{for } 0 < r < r_0, \\ 0 & \text{for } r_0 < r < \infty. \end{cases}$$

Its representation according to (13a) is

$$(14) \quad \eta_{t=0} = a \int_0^{\infty} k dk J_0(kr) \int_0^{r_0} \xi d\xi J_0(k\xi).$$

For the evaluation of the inner integral Eq. (8a) is used, which gives, with $k\xi = \rho$ and $k r_0 = \rho_0$,

$$\int_0^{r_0} \xi d\xi J_0(k\xi) = \frac{1}{k^2} \int_0^{\rho_0} \rho d\rho J_0(\rho) = \frac{r_0}{k} J_1(kr_0).$$

Instead of the double integral (14) we have got

$$(14a) \quad \eta_{t=0} = ar_0 \int_0^\infty J_0(kr) J_1(kr_0) dk.$$

Now we can show that η and Φ at any later instant $t > 0$ have the following forms:

$$(15) \quad \eta = ar_0 \int_0^\infty J_0(kr) J_1(kr_0) \exp(-i \sqrt{gk} t) dk,$$

$$(16) \quad \Phi = -iagr_0 \int_0^\infty J_0(kr) J_1(kr_0) \exp(-ky - i \sqrt{gk} t) dk / \sqrt{gk}.$$

For a proof, we observe first that (15) takes the value of (14a) if $t = 0$. Now, the expressions (15) and (16) are obtained by applying the same "operator"

$$r_0 \int_0^\infty J_1(kr_0) dk \dots$$

to the periodic solutions (10a) and (12), with due regard to the dispersion law (11a). Since (10a) and (12) satisfy the differential equation of our problem and the boundary conditions for $y = 0$ and $y = \infty$, the same must be true for our expressions (15) and (16). Furthermore (15) and (16) satisfy the initial condition for $t = 0$ and are thus the required solutions.

3. Integration with Respect to k . The Method of the Stationary Phase

The quantities of physical interest in circular waves are all connected with the surface function η to which we therefore limit the following discussion. To evaluate η we first replace J_0 in (15) by its integral representation (9a) and reverse the order of integration, obtaining the double integral

$$(17) \quad \eta = \frac{ar_0}{\pi} \int_0^\pi d\alpha \int_0^\infty dk J_1(kr_0) \exp(ikr \cos \alpha - i \sqrt{gk} t).$$

We denote the inner integral by K , put $2\tau = t \sqrt{gr_0}/r$ and introduce a new integration variable by $p = \sqrt{kr_0}$; with these notations we have

$$(18) \quad K = \frac{2}{r_0} \int_0^\infty p dp J_1(p^2) \exp[i(p^2 \cos \alpha - 2p\tau)r/r_0].$$

Here r/r_0 is a very large number, the exponential is, therefore, a rapidly varying function of p . In general, the positive and negative oscillations of

the integrand will cancel except at those places where the factor of ir/r_0 is *slowly* variable. If we abbreviate this factor by

$$(19) \quad f(p) = p^2 \cos \alpha - 2pr,$$

this will happen when

$$(19a) \quad f'(p) = 0, \quad p = p_0 = \frac{\tau}{\cos \alpha}.$$

This observation leads to a method of estimating the value of the integral known as the *method of the stationary phase*. Since the "phase" of the quickly oscillating exponential function becomes stationary at p_0 , one limits the range of integration to the neighborhood of this value and thus achieves the integration by elementary means. It was particularly Lord Kelvin who applied this method expertly to many problems of hydrodynamics and optics. The mathematically exact form of this device⁷ is called the *method of steepest descent* which we mentioned before.

Eq. (19) can be written in the form

$$f(p) = \cos \alpha \{ (p - p_0)^2 - p_0^2 \}$$

The integral (18) then becomes

$$(20) \quad K = \frac{2}{r_0} \exp(-ip_0^2 \cos \alpha \cdot r/r_0) \int_{p_0-\epsilon}^{p_0+\epsilon} J_1(p^2) p \exp[i \cos \alpha (p - p_0)^2 r/r_0] dp.$$

where the range of integration is now an ϵ -neighborhood of p_0 . The factors $J_1(p^2)$ and p in the integrand are *slowly variable* compared with the exponential function and may be replaced by $J_1(p_0^2)$ and p_0 . We finally substitute in (20)

$$(20a) \quad s = q(p - p_0), \quad q^2 = \frac{\tau}{r_0} \cos \alpha$$

and obtain

$$(21) \quad K = (2/r_0) \exp(-ip_0^2 \cos \alpha \cdot r/r_0) J_1(p_0^2) \frac{p_0}{q} \int_{-\epsilon q}^{+\epsilon q} e^{is^2} ds.$$

As to the position of the critical value $p = p_0$, (19a) gives, since τ is positive,

$$\begin{aligned} p_0 > 0 & \quad \text{for} \quad 0 < \alpha < \frac{\pi}{2}, \\ p_0 < 0 & \quad \text{for} \quad \frac{\pi}{2} < \alpha < \pi. \end{aligned}$$

⁷The problem of the circular waves has been treated according to that method in the Munich thesis of H. Widenbauer, Z. angew. Mathem. u. Mech. 14, 321 (1939). Our Fig. 42 has been taken from this paper.

In the first case p_0 and, consequently, the value $s = 0$ fall in the range of integration $0 < k < \infty$; not so in the second case. Thus the representation (21) is valid only for $\alpha < \pi/2$. Otherwise we have

$$(21a) \quad K = 0; \quad \frac{\pi}{2} < \alpha < \pi,$$

which means complete extinction by "interference".

The final evaluation of (21) is achieved by means of the well known formula

$$(22) \quad \int_{-\infty}^{+\infty} e^{-t^2} dt = \sqrt{\pi}.$$

On replacing t by

$$t = e^{-i(\pi/4)} s, \quad t^2 = -is^2, \quad dt = e^{-i(\pi/4)} ds,$$

we are led^{*} to

$$(22a) \quad \int_{-\infty}^{+\infty} e^{t^2} ds = e^{i(\pi/4)} \sqrt{\pi}.$$

The left member is our integral in (21) whose limits become $\pm \infty$ if r/r_0 is made to approach infinity at constant ϵ and $\cos \alpha \neq 0$. If we introduce the result (22a) in (21) we obtain

$$(23) \quad K = (2 \sqrt{\pi/r_0}) \exp(-ip_0^2 \cos \alpha \cdot r/r_0 + i\pi/4) J_1(p_0^2) \frac{p_0}{q}.$$

Now the value of p_0 following from (17a) and (19a),

$$p_0 = \sqrt{\frac{gr_0 t^2}{4r^2}} \frac{1}{\cos \alpha},$$

is very small, provided

$$(24) \quad \frac{gr_0 t^2}{4r^2} \ll 1$$

(but we must exclude a small finite neighborhood of $\alpha = \pi/2$). The Bessel function J_1 is, for small p_0 , sufficiently well approximated by the first term of (7):

$$J_1(p_0^2) = \frac{p_0^2}{2}, \quad p_0 J_1(p_0^2) = \frac{p_0^3}{2} = \frac{1}{2} \left(\frac{gr_0 t^2}{4r^2} \right)^{3/2} \frac{1}{\cos^3 \alpha}.$$

^{*}It will be noticed that the original path of the integration in (22a) is the bisectrix of the 1st and 3d quadrant in the complex s -plane which forms also the limit of convergence of the integral; this path may be replaced by the real axis and two circular arcs; the contributions of the latter vanish if $R \rightarrow \infty$.

Taking the value of q from (20a) we obtain finally for K

$$(25) \quad K = \sqrt{\frac{\pi}{\cos^7 \alpha}} \frac{r_0}{r^{\frac{7}{2}}} \left(\frac{gt^2}{4r} \right)^{3/2} \exp(-igt^2/4r \cos \alpha + i\pi/4).$$

4. Integration with Respect to α . Discussion of a Limiting Case

We return now to (17), where we may restrict the integration interval to $0 < \alpha < \pi/2$ because of (21a). On introducing the volume displaced by the initial impulse, $V_0 = \pi r_0^2 a$, (17) is transformed into

$$(26) \quad \eta = \frac{V_0}{r^2} \left(\frac{gt^2}{4\pi r} \right)^{3/2} \int_0^{\pi/2} \frac{d\alpha}{\cos^{7/2} \alpha} \exp(-igt^2/4r \cos \alpha + i\pi/4).$$

We shall finally have to make $r_0 \rightarrow 0$. In order to obtain a finite effect in the limit, V_0 must be kept constant, that is to say, the depth of immersion a must approach ∞ in a definite way. We shall come back to this eventually.

The representation of η by (26) depends essentially on the variable

$$(27) \quad u = \frac{gt^2}{4r}.$$

Our aim is to determine the asymptotic behavior of η if $u \rightarrow \infty$. Now for large u the exponent in (26) becomes once more a rapidly varying function of α , so that the method of the stationary phase can again be applied. Similarly as before, we denote the factor of u in the exponent of (26) by $f(\alpha)$ and have

$$f(\alpha) = \frac{1}{\cos \alpha}, \quad f'(\alpha) = \frac{\sin \alpha}{\cos^2 \alpha}.$$

The critical α -value is thus

$$\alpha = \alpha_0 = 0, \quad f(\alpha_0) = 1, \quad f(\alpha) = 1 + \frac{\alpha^2}{2}, \quad \frac{1}{\cos^{7/2} \alpha_0} = 1,$$

and consequently

$$(28) \quad \eta = \frac{V_0}{r^2} \left(\frac{u}{\pi} \right)^{3/2} \exp(-iu + i\pi/4) \int_0^\epsilon \exp(-iu\alpha^2/2) d\alpha.$$

We need the value of the integral in (28) for large u . Keeping ϵ constant, we apply the same argument that led us from (21) to (23). This time the integral in (28) transforms as follows:

$$\int_0^\epsilon \exp(-iu\alpha^2/2) d\alpha = \sqrt{\frac{2}{u}} \int_0^\infty \exp(-is^2) ds = \sqrt{\frac{\pi}{2u}} \exp(-i\pi/4).$$

By substitution in (28) we finally obtain

$$(29) \quad \eta = \frac{V_0}{\sqrt{2\pi r^3}} u e^{-iu}.$$

The dimensions in this equation are easily checked: u is a number according to (27), V_0/r^3 is a length and so is η .

Our method seems to break down at the upper limit $\pi/2$ of the integral in (26) because of the denominator $\cos \alpha$, but according to (21a) this is at the same time the lower limit at which K vanishes. Thus one is probably right to assume that a special investigation of the behavior of (26) at the upper limit is unnecessary.

The real part of (29) is the surface equation in which we are interested; we have

$$\eta = \frac{V_0}{\sqrt{2\pi r^3}} u \cos u.$$

η becomes infinite for $r = 0$, which is quite understandable since the depth of immersion a has become infinite in the limiting process $r_0 \rightarrow 0$ for fixed V_0 . The amplitudes of the crests decrease according to u/r^3 or r^{-3} , the crests follow each other at the distance

$$\Delta r = \frac{8\pi r^2}{g t^3},$$

as is easily seen, if the phases of neighboring crests $u = 2\pi n$, $u = 2\pi(n+1)$ are compared for constant t . Hence the wave length is no longer a constant as in our previous examples of wave motion, but increases at

FIG. 42. Shape of the water surface t seconds after the ring waves were excited; t must satisfy the condition $u \gg 1$.

constant t with r^2 and decreases at constant r with t^3 . Fig. 42 is a diagram of the surface profile η . Its appearance agrees well with that of a water surface disturbed by the fall of a small object like a stone or a rain drop.

Our problem was set as a prize problem by the academy of Paris in 1816 and solved by Cauchy. About this and a later paper of Poisson cf. the report of H. Burkhardt.*

28. Ship Waves (*Kelvin's Limit Angle and Mach's Angle*)

The wave pattern that is left behind by a ship at sea consists of a system of waves that envelopes the hull lengthwise and is interwoven with a system of cross waves. The two systems advance with the boat so as to be stationary relative to it. The beauty of the pattern is most impressive when viewed from an airplane or from the top of a high cliff, but the same phenomenon on a more modest scale develops behind a duck swimming in a pond.

In our analysis the object that produces the waves will be considered as a point. The problem can then be formulated in the following way: The instantaneous location of the boat is the origin of a system of circular waves; this origin is in uniform rectilinear motion, its velocity being the speed of the boat v . Our task is to find *the result of the superposition of the successive circular waves*. That it will be stationary relative to the boat is evident, but the detail structure of the wave pattern is surprising enough and can only be unraveled by a careful analysis.

With a view to Fig. 43, let O be the location of the boat at the time $t = 0$, and Q its location t seconds earlier so that $QO = vt$. We wish to find the ordinate of the water surface η at the field point P . It is to be compounded of all ordinates η_i that were produced at earlier instants t by means of the formula

$$(1) \quad \eta = \beta \int_{-\infty}^0 \eta_i dt.$$

The factor β in (1) must have the dimension of a reciprocal time; we put it equal to v/l . For the length l there is hardly any choice other than the cube root of the initial displacement V_0 in Eq. (27.29). Thus we obtain from (1) and (27.29)

$$(2) \quad \eta = C \int_{-\infty}^0 \frac{1}{r_i^2} u_i \exp(-iu_i) dt, \quad C = \frac{V_0^{2/3} v}{\sqrt{2\pi}}$$

where r_i is the distance QP in Fig. 43, that is, the distance between the field point P and the location of the source of disturbance, t seconds ago.

Now let P have the polar coordinates r and ϑ relative to the pole O ; r and ϑ are therefore independent of t . According to Fig. 43 we obtain

*Jahresbericht der deutschen Math. Ver. Vol. X, p. 429 (1908).

$$(3) \quad r_i^2 = r^2 + v^2 t^2 + 2rvt \cos \vartheta,$$

where t is negative. As in (27.27) we put

$$(4) \quad u_i = \frac{g}{4r_i} \frac{t^3}{r_i} = f(t).$$

The representation (27.29) which we have applied in (2) was computed under the assumption $u \gg 1$. With this condition, $f(t)$ becomes again a rapidly varying function so that the method of stationary phase can be applied. We then have to find the roots of the equation $f'(t) = 0$. From (4) and (3) we obtain

$$(5) \quad \frac{4}{g} f'(t) = \frac{2t}{r_i} - \frac{t^2}{r_i^3} (v^2 t + rv \cos \vartheta) = \frac{t}{r_i^3} (v^2 t^2 + 3rvt \cos \vartheta + 2r^2).$$

Hence the roots of $f'(t) = 0$ are

$$t = -\frac{3}{2} \frac{r}{v} \cos \vartheta \pm \sqrt{\frac{9}{4} \frac{r^2}{v^3} \cos^2 \vartheta - 2 \frac{r^2}{v^3}}.$$

If ϑ is an acute angle, the roots t_1 and t_2 are both negative

$$(6) \quad \begin{aligned} t_1 &= -\frac{3}{2} \frac{r}{v} \left(\cos \vartheta - \sqrt{\cos^2 \vartheta - \frac{8}{9}} \right), \\ t_2 &= -\frac{3}{2} \frac{r}{v} \left(\cos \vartheta + \sqrt{\cos^2 \vartheta - \frac{8}{9}} \right). \end{aligned}$$

Now, in order to fall in our integration interval $-\infty < t < 0$, the roots not only have to be negative, they must also be real. This implies

$$\cos^2 \vartheta > \frac{8}{9}, \quad |\vartheta| < \vartheta_0,$$

where ϑ_0 denotes the limiting angle

$$(7) \quad \cos^2 \vartheta_0 = \frac{8}{9} \quad \text{or} \quad \operatorname{tg} \vartheta_0 = \frac{1}{\sqrt{8}}, \quad \vartheta_0 = 19^\circ 28'.$$

This angle was first determined by Lord Kelvin. For $|\vartheta| > \vartheta_0$ there is no such t -value as would make the phase stationary, that is to say, *the whole wave pattern is bounded on either side by a straight line forming the angle ϑ_0 with the direction of motion of the boat*. This is shown in Fig. 44 which is taken from Lamb's¹⁰ *Hydrodynamics*.

The interference pattern itself can be understood on the basis of the integral (2) which essentially reduces to the two contributions of the neigh-

¹⁰H. Lamb, *Hydrodynamics*, Cambridge, 5th edition, p. 409 ff.

borhoods of t_1 and t_2 . These contributions contain the phase factors $\exp[-if(t_1)]$ and $\exp[-if(t_2)]$. By putting $f(t_1)$ and $f(t_2)$ constant, one obtains the two systems of curves, the lengthwise and transverse waves mentioned before. In Fig. 44 the successive crests of the two systems have been drawn. We shall discuss these curves by giving the field point P a

FIG. 43 (left). Illustrating the generation of ship waves. O is the present position of the ship, $Q, Q' \dots$ are previous positions of the ship, $P, P' \dots$ are specified positions of the field point.

FIG. 44 (right). Lengthwise and transverse ship waves.

variety of positions, having in mind that the disturbance at P at the time $t = 0$ is essentially caused by two annular waves that issued from the source in the positions Q' and Q'' at the times t_1 and t_2 respectively.

Let us start with a field point position $P = P'$ on the limiting line $\vartheta = \vartheta_0$. The two values t_1 and t_2 in (6) coincide. The common source position associated with this case is the point Q' in Fig. 43. Its distance from O is by (6)

$$OQ' = -vt'_1 = -vt'_2 = \frac{3}{2} r' \cos \vartheta_0,$$

where r' is the distance of P' from O . The direction of the curves of uniform phase $f(t_1) = f(t_2) = \text{const}$ in P' is given by a circular arc element with center Q' and radius $Q'P'$. Both curves of constant phase pass through P' in the same forward direction. Considered as one curve they form a *cusp* at P' .

If now ϑ is decreased and r so chosen that $f(t_2)$ remains constant the source position associated with t_2 moves to the *left* from Q' (see Fig. 43) since $-vt_2$ increases according to (6). When ϑ reaches the value zero, Q' reaches the position Q'' , so that

$$OQ'' = -vt_2 = \frac{3}{2} r \left(1 + \frac{1}{3}\right) = 2r.$$

Here r is the distance between O and the field point P_2'' at which the transverse wave intersects the course of the boat. The direction of the phase curve is obviously perpendicular to the course; it coincides with the circular element of radius $Q_2''P_2'' = r$ about the center Q_2'' . This gives a general idea of the shape of the phase curves $f(t_2) = \text{const.}$

If, on the other hand, we choose the r -values for decreasing ϑ so that $f(t_1)$ remains constant, $-vt_1$ decreases [see (6)] and the point Q' in Fig. 43 moves *right* to the new position Q_1 . The slope of the lengthwise wave through P' becomes flatter, as is shown by the circular arc about Q_1 with radius Q_1P_1 . The distance OQ_1'' becomes for very small ϑ

$$-vt_1 = \frac{3}{2}r \left(1 - \frac{\vartheta^2}{2} - \sqrt{\frac{1}{9} - \frac{\vartheta^2}{2}} \right) = r \left(1 + \frac{3}{8}\vartheta^2 \right)$$

so that Q_1'' nearly coincides with the field point P_1'' when both are close to O . The lengthwise waves should become tangential to the direction of travel at O if our method were still valid in the neighborhood of O . This, however, is not the case: Our method of stationary phase breaks down for a short running time t . Nevertheless the general shape of the lengthwise waves has thus been clarified.

The phase curves $f(t_1) = \text{const.}$, $f(t_2) = \text{const.}$ are essentially identical with the actual wave pattern observed. Along either curve the contribution of the integral whose phase is *not* constant shows up as a secondary ripple, at least at some distance from O . For a comprehensive analytical representation of both families of curves see Lamb loc. cit. and L. Hopf in his Munich thesis quoted on p. 120; there the evaluation is carried out by complex integration.

Looking back at our result it appears strange that there should exist a limiting angle ϑ_0 independent of the traveling speed v . This seems to disagree with the well known photographs of projectiles moving with supersonic speed, first obtained by the Austrian philosopher and physicist Ernst Mach (1838-1916) with the so-called schlieren method. The projectile in Mach's beautiful theory is shrunk to a moving point, just as the steam boat before, from which compression waves originate continually. At the time of observation the wave that has originated t seconds ago has now spread over a spherical surface of radius $r = ct$ where c is the sound velocity. In the meantime the projectile has traveled a distance $x = vt$. The spherical shells so produced have an enveloping circular cone, the *Mach cone*. Half its apex angle is called the *Mach angle* and given by

$$\sin \vartheta_0 = \frac{r}{x} = \frac{c}{v}.$$

The Mach angle is approaching zero with increasing v , in contrast to the limiting angle $\vartheta_0 = 19^\circ 18'$ in the case of the ship waves.

The reason for this different behavior is found in the *dispersion*. The sound waves travel at fixed velocity c without dispersion. The deep water

FIG. 45. A projectile moves with supersonic velocity between two parallel walls, the Mach cone is reflected at the walls.

FIG. 45a. The projectile has pierced a thin wooden wall. The wood splinters also produce Mach cones of varying apex angles, according to their velocities.

waves follow the dispersion law $V = \sqrt{g/k}$. With the velocity thus depending on the wave length, there exist waves which at any given speed of the boat run along with the boat, while in the Mach phenomenon all waves are overtaken by the projectile. Thus the fact that ϑ_0 is independent of v becomes understandable.

We could substantiate this interpretation if we treated the *ship waves in shallow water*, in the sense of 24. According to (24.7) there is no dis-

FIG. 45b. The projectile passes a cylinder with circular slots. The spherical waves originating at the openings are tangential to the Mach cone of the projectile.

persion in this case, and Mach's purely geometrical argument may be applied. If $v > V$ the limiting angle should go to zero with increasing v . This problem, however, in which we would have to assume a flat disturbance (a flat-bottomed boat) seems to us rather artificial. However, the classical investigations of annular waves on which the theory of ship waves is based (Euler 1759, Laplace 1776, Lagrange 1787) assumed shallow water.

We close this chapter with some of the less well known pictures of the Mach phenomenon which were taken in the ballistic laboratory of

C. Cranz. Fig. 45 shows a projectile flying between two walls: the Mach cones suffer regular reflection at the walls, also, on this and the other photographs a tail of eddies is shed from the rear end of the projectile. Fig. 45a shows a shot through a thin wooden wall which is located at the left border of the picture: the projectile itself which has somewhat deviated from its path after piercing the wall and the numerous splinters flying along show their Mach cones. Note that the splinters possess Mach cones with larger apex angles than the projectile in accordance with their smaller velocities which, however, are still larger than the sound velocity c . Fig. 45b is very instructive: the projectile was shot through a cylinder furnished with circular slots and is just emerging from the other end. Spherical waves come from the slots whose envelopes fit the Mach cone of the projectile accurately. Here we see a direct experimental realization of the mental picture we have of the formation of the Mach cone as the envelop of individual spherical waves. At the same time the photograph is a beautiful visualization of *Huygen's principle*, which likewise operates with envelopes of spherical waves.

FLOW WITH GIVEN BOUNDARIES

29. Flow Past a Plate

In this and the following articles we restrict ourselves to two-dimensional flow and may, therefore, make use of the powerful tool of the theory of complex functions.

We take up again our discussion of elliptical coordinates ξ, η in 19. The connection with Cartesian coordinates x, y is given by Eq. (19.15)

$$(1) \quad x + iy = c \cosh (\xi + i\eta).$$

Here c is half the focal distance (cf. Fig. 27) and, at the same time, half the length of the projection of our plate in the x, y -plane; the plate is supposed to be infinite in $\pm z$ -direction.

In elliptic coordinates the front and back sides of the plate are simultaneously given by

$$\xi = 0, \quad -\pi < \eta < +\pi,$$

corresponding to the infinitely narrow ellipse of Fig. 27. For these values the right member of Eq. (1) is real, hence $y = 0$ and $-c < x < c$.

On the other hand, for

$$\eta = \pm \frac{\pi}{2}, \quad 0 < \xi < \infty$$

the right member of (1) becomes a positive or negative purely imaginary number, hence $x = 0$ and $y \gtrless 0$, as can also be seen from Fig. 27.

Consider now the analytic function

$$(2) \quad \Phi + i\Psi = \text{const} \sinh (\xi + i\eta)$$

already anticipated in (19.20). Let the constant in (2) be equal to iqc , where q is a real quantity having the dimension of a velocity:

$$(2a) \quad \text{const} = iqc; \quad q, c > 0.$$

Now, $\Phi + i\Psi$ is not only an analytic function of $\xi + i\eta$, but through (1) an analytic function of $x + iy$ likewise. Consequently Φ and Ψ may be interpreted as *velocity potential* and *streamfunction* (19) provided they satisfy such boundary conditions in the x, y -plane as are required by the

problem under consideration. The values of Φ and Ψ along certain lines of the x, y -plane have been listed in the following table, the auxiliary variables ξ and η playing the role of parameters:

ξ, η -plane	x, y -plane	values of Φ, Ψ
$\xi = 0$	$x = c \cos \eta, \quad y = 0$	$\Psi = 0, \quad \Phi = -qc \sin \eta$
$\eta = -\frac{\pi}{2}$	$x = 0, \quad y = -c \sinh \xi < 0$	$\Psi = 0, \quad \Phi = qc \cosh \xi > 0$
$\eta = +\frac{\pi}{2}$	$x = 0, \quad y = +c \sinh \xi > 0$	$\Psi = 0, \quad \Phi = -qc \cosh \xi < 0$
$\xi \rightarrow \infty$	$x^2 + y^2 = \frac{c^2}{4} e^{2\xi} \rightarrow \infty$	$\Psi = +qx, \quad \Phi = -qy$

The first three lines of this table are explained in our previous remarks, if one takes into account that the right member of (2) becomes real for $\xi = 0$ as well as for $\eta = \pm\pi/2$ because of (2a). As regards the last line, the effect of the limit $\xi \rightarrow \infty$ on x, y , etc. can be easily seen if one separates real and imaginary parts in (1) and (2). One obtains for large ξ

$$(3) \quad \begin{aligned} x &= \frac{c}{2} e^{\xi} \cos \eta, & y &= \frac{c}{2} e^{\xi} \sin \eta, \\ \Phi &= -\frac{qc}{2} e^{\xi} \sin \eta, & \Psi &= \frac{qc}{2} e^{\xi} \cos \eta, \end{aligned}$$

in agreement with the last line of the table.

According to the Φ and Ψ values in the last line, the flow field in the neighborhood of the point infinity of the x, y -plane is uniform, viz.

$$(3a) \quad v_y = -\frac{\partial \Phi}{\partial y} = q, \quad v_x = -\frac{\partial \Phi}{\partial x} = 0.$$

The first three lines of the table contribute the following additional information about the flow: the streamline $\Psi = 0$ coincides with the negative y -axis (line 2) and with the positive y -axis (line 3). According to line 1, a singularity appears at $y = 0$.

In its total extension, $\Psi = 0$ may be described as follows: the branch $\eta = -\pi/2$ corresponding to the negative y -axis splits into two branches at $y = 0$ (center of the front side of the plate). They follow the surface of the plate and are obtained according to the first line, when η passes from $-\pi/2$ to $\pi/2$ either by adding or subtracting π ($-3\pi/2$ being equivalent to $\pi/2$). The two branches join at the center of the back side and, from

there on, $\Psi = 0$ coincides with the positive y -axis.¹ This streamline together with the known flow pattern at infinity forms a frame for the family of streamlines $\Psi = \text{const}$, that makes the diagram of Fig. 46 acceptable.

The point or, rather, the points O on the front and back side of the plate are of particular interest. They are called *points of bifurcation* with

FIG. 46. Plate at right angle to flow. The theoretical flow pattern downstream is a mirror image of the upstream pattern.

reference to the division of the streamline $\Psi = 0$, or *branch points* with reference to the mapping function. Physically speaking, they are *stagnation points* since the velocity of flow vanishes there ($v_x = v_y = 0$). According to Bernoulli's theorem they are points of *maximum pressure*: From (11.9) we have for steady flow and in the absence of external forces ($U = \text{const}$)

$$(4) \quad p = \text{const} - \frac{\rho}{2} v^2.$$

If we put the pressure at infinity equal to zero, so that p is the "hydrodynamic" pressure due to the acceleration of the fluid in the presence of the plate, then $\text{const} = \rho/2 q^2$ [q is the flow velocity at infinity according to (3a)] and

$$(4a) \quad p = \frac{\rho}{2} (q^2 - v^2).$$

This shows immediately that p_{max} is larger than any other possible p -value.

The pressure distribution along the plate is found from our formulas as follows: From

$$\Phi = -qc \sin \eta, \quad x = c \cos \eta,$$

¹If the ξ, η -strip in Fig. 27a which is in one-to-one correspondence with the x, y -plane is shifted downward by $\pi/2$, the streamline $\Psi = 0$ is represented by an H -shaped figure, the upper and lower horizontal of which correspond to the same ray $y > 0, x = 0$.

we find
$$v = - \frac{\partial \Phi}{\partial \eta} \frac{d\eta}{dx} = q \frac{\cos \eta}{\sin \eta},$$

and by (4a)
$$p = \frac{\rho}{2} q^2 \left(1 - \frac{\cos^2 \eta}{\sin^2 \eta} \right).$$

Here the front side is given by $-\pi < \eta < 0$ and the back side by $0 < \eta < \pi/2$ and $-3\pi/2 < \eta < -\pi$, or simply, $0 < \eta < \pi$. The pressure becomes then

$$p = -\infty, \quad \text{for } \eta = \begin{cases} 0, & x = +c \\ \pm\pi, & x = -c \end{cases} \text{ at the edges of the plate}$$

$$p = 0, \quad \text{for } \eta = \begin{cases} \pm \frac{\pi}{4}, & x = +\frac{c}{\sqrt{2}} \\ \pm \frac{3\pi}{4}, & x = -\frac{c}{\sqrt{2}} \end{cases} \text{ at a distance } 0.29c \text{ from} \\ \text{either edge toward the center}$$

and, as we have found before $p = p_{\max} = \rho q^2/2$ for $\eta = \pm\pi/2$, $x = 0$, center of plate.

This pressure distribution is impossible in a perfect fluid because of the occurrence of a negative pressure (which at the edges becomes even infinite); the fluid would separate under a negative pressure.²

A second consequence which is no less paradoxical, is this: The resultant pressure force exerted by the stream upon the plate is zero, (the resultant moment vanishes, too) since the pressure at any surface element on the front side is canceled by the corresponding pressure on the back side. In other words, *if the fluid is transformed to rest at infinity* (by superposition of the constant velocity field $\Phi = qy$), *so that the plate moves through the fluid with uniform velocity* q no work would have to be expended in such a process. Once the plate together with the surrounding fluid has been set in motion, it will keep on moving with constant velocity.

This paradoxical assertion in a generalized form, in which it applies to rigid bodies of arbitrary shape, is attributed to d'Alembert or Euler.³

²Here the emphasis lies on the fact that the pressure becomes *arbitrarily* strongly negative; if it were only negative, but would stay bounded, we could make good for that by choosing the pressure at ∞ sufficiently positive.

³In the introduction to his book, *Hydrodynamik*, Leipzig, Akademische Verlagsgesellschaft 1927, C. W. Oseen quotes Spinoza as an even earlier authority. One could say, in a sense, that Oseen's book has as its aim the analysis of the paradox. For instructive detail observations in two dimension see G. Hamel, *Z. angew. Math. u. Mech.* 15 (1935) 52

FIG. 47a. The vertical plate in real flow. Stagnation point at the upstream center of the plate.

FIG. 47b. The oblique plate in real flow. The stagnation point is shifted toward the upstream edge of the plate.

Kirchhoff, Lord Kelvin and, later, Minkowski* investigated the general conditions for a steady motion like the one in our example from the point of view of abstract hydrodynamics. It was found that the direction of the momentum would have to coincide with the axis of the moment of momentum to make the motion possible. In the case under consideration, however, the occurrence of arbitrary large negative pressures makes the motion physically impossible.

Let us now compare Fig. 46 with the photograph of a real flow past a plate in Fig. 47a.⁴ The two Figs. 46 and 47a are in very good agreement upstream of the plate but have nothing in common downstream. In the picture of the real flow eddies occur behind the plate that are generated in the process of passing the edges of the plate and move downstream with the fluid. We shall investigate this phenomenon in 30 and 32.

For the present, however, we wish to maintain our theoretical viewpoint incomplete though it is, and investigate the flow past an *oblique plate*. We rotate the x, y -system with respect to the ξ, η -system by the angle $\gamma < \pi/2$ and change Eqs. (1) and (2) into

$$(5) \quad x + iy = ce^{i\gamma} \cosh (\xi + i\eta),$$

$$(6) \quad \Phi + i\Psi = iqc \sinh (\xi + i\eta + i\gamma).$$

The table of p. 208 is now replaced by:

ξ, η -plane	x, y -plane	values of Φ, Ψ
$\xi = 0$	$\begin{cases} x = c \cos \eta \cos \gamma \\ y = c \cos \eta \sin \gamma \end{cases}$	$\Psi = 0, \quad \Phi = -qc \sin (\eta + \gamma)$
$\eta = \mp \frac{\pi}{2}$	$\begin{cases} x = \pm c \sinh \xi \sin \gamma \\ y = \mp c \sinh \xi \cos \gamma \end{cases}$	$\begin{cases} \Psi = \pm qc \sinh \xi \sin \gamma \\ \Phi = \pm qc \cosh \xi \cos \gamma \end{cases}$
$\xi \rightarrow \infty$	$x^2 + y^2 = \frac{c^2}{4} e^{2\xi} \rightarrow \infty$	$\Psi = qx, \quad \Phi = -qy$

*Preuss. Akad. Ber., 1888, 1095.

⁴Figs. 39a, b and 47a, b are reproductions of photographs taken by the firm of Ahlborn in Hamburg.

According to the table, the front and back sides of the plate represented by $\xi = 0$, $-\pi < \eta < 0$, and $0 < \eta < \pi$ are still the streamline $\Psi = 0$. In the neighborhood of the point infinity of the x, y -plane, that is for $\xi \rightarrow \infty$, we have a uniform field of flow with constant velocity q as before; the streamlines in this region are the lines $x = \text{const}$, but the lines $\eta = \mp\pi/2$ are no longer streamlines. Geometrically, they represent a pair of rays that coincide with the two halves of the bisectrix of the plate; the center column of our table gives for these lines the equation $y = -x \cot \gamma$. Altogether, there are no rectilinear streamlines in the finite domain.

In order to analyze the flow pattern we first determine the *stagnation points*. They are the branch points of the function that maps the $\Phi + i\Psi$ -plane on the $x + iy$ -plane. Now, the general condition for a branch point is:

$$(7) \quad \frac{d(\Phi + i\Psi)}{d(x + iy)} = 0.$$

The differential quotient is calculated from (5) and (6) as follows:

$$(7a) \quad \frac{d(\Phi + i\Psi)}{d(\xi + i\eta)} \bigg/ \frac{d(x + iy)}{d(\xi + i\eta)} = \frac{iq \cosh(\xi + i\eta + i\gamma)}{e^{i\gamma} \sinh(\xi + i\eta)}.$$

Condition (7) leads therefore to

$$(7b) \quad \cosh(\xi + i\eta + i\gamma) = 0,$$

or, on separating into real and imaginary parts, to

$$(7c) \quad \cosh \xi \cos(\eta + \gamma) = 0, \quad \sinh \xi \sin(\eta + \gamma) = 0.$$

Since $\cosh \xi$ is never zero, and $\sinh \xi$ vanishes only for $\xi = 0$, the solution of (7c) is

$$(8) \quad \eta = \pm \frac{\pi}{2} - \gamma, \quad \xi = 0.$$

Thus there are again two stagnation points one of which is in the front, the other in the back of the plate:

$$(8a) \quad \xi = 0, \quad \eta = -\frac{\pi}{2} - \gamma \quad \text{and} \quad \xi = 0, \quad \eta = +\frac{\pi}{2} - \gamma.$$

They are not in the center of the plate, but shifted up and down by the same amount $|x + iy| = c \sin \gamma$, as follows from (5). In Fig. 48 they have been denoted by O_1 and O_2 . At these points we have again $v_x = v_y = 0$ and the pressure is, according to Bernoulli's equation (4a), a maximum: $p_{\text{stagn}} = p_{\text{max}} = \rho q^2/2$. From our derivation it follows that the stagnation points are points of bifurcation as before. The streamline that

meets the plate at O_1 and divides there into two branches is normal to the plate, and so is the stream line issuing from O_2 .

FIG. 48. Flow past an oblique plate. The theoretical flow pattern downstream is obtained by rotating the upstream pattern about the center of the plate by 180° .

The differential quotient computed in (7a) yields quite generally the velocity of flow in the complex form

$$(9) \quad \frac{d(\Phi + i\Psi)}{d(x + iy)} = -v_x + iv_y.$$

This is a direct consequence of the form of $f'(z)$ in (19.4a) together with the Cauchy-Riemann equations (19.5). If we take the absolute value in (9) and substitute (7a), we obtain

$$(10) \quad |v| = q \left| \frac{\cosh(\xi + i\eta + i\gamma)}{\sinh(\xi + i\eta)} \right|.$$

In particular for $\xi = 0$, that is, on the plate itself, we have on either side

$$(10a) \quad |v| = q \left| \frac{\cos(\eta + \gamma)}{\sin \eta} \right|.$$

The pressure distribution is found from (10a) by substitution in Bernoulli's equation (4a):

$$(11) \quad p = \frac{\rho}{2} q^2 \left(1 - \frac{\cos^2(\eta + \gamma)}{\sin^2 \eta} \right).$$

This leads again to

$$p = -\infty \quad \text{for} \quad \eta = \begin{cases} 0 \\ \pm\pi \end{cases},$$

that is at the edges of the plate, and the point where the pressure vanishes is found from $p = 0$ as

$$(12) \quad \cos^2(\eta + \gamma) = \sin^2 \eta$$

which can be written $\cos(\eta + \gamma) = \pm \cos(\pi/2 - \eta)$, and therefore

$$\text{either} \quad \eta + \gamma = \frac{\pi}{2} - \eta, \quad \eta = \eta_1 = \frac{\pi}{4} - \frac{\gamma}{2},$$

$$\text{or} \quad \eta + \gamma = -\frac{\pi}{2} - \eta, \quad \eta = \eta_2 = -\frac{\pi}{4} - \frac{\gamma}{2}.$$

The value η_1 is positive, the corresponding point lies therefore on the backside; the converse is true for η_2 . The zone of negative pressure is on the back side between $\eta = 0$ and $\eta = \eta_1$, on the front side between $\eta = -\pi$ and $\eta = \eta_2$. Since arbitrarily large negative pressures are not permissible, our solution in the case of the oblique plate has as little physical reality as in the special case of a normal plate.

The comparison of Fig. 48 with the photograph of a real flow in 47b illustrates what we mean. Ahead of the plate the two stream patterns are rather similar, in particular, there is a stagnation point in front which has the expected position. The downstream flow, however, is entirely different. Instead of an antisymmetric repetition of the upstream pattern we meet again the characteristic eddies in alternating positions.

In this article we have only dealt with the *steady* flow past a plate. A plate problem occurs also in acoustics, when a light circular disk is suspended in the *non-steady* field of a sound beam. This so-called Rayleigh disk plays a significant part in the measurement of sound intensities; the analytic methods discussed so far and developed in the following are of importance for the theory of this instrument, as Lord Rayleigh⁵ has shown; for this reason our statement about the unrealistic character of the obtained solutions should be restricted to the case of steady flow.

30. The Problem of the Wake; Surfaces of Discontinuity

"There is nothing in the nature of a liquid that should prevent two adjacent fluid layers from sliding past each other with finite relative velocity, provided we consider the fluidity as perfect, that is, exclude all friction. Our assertion is certainly true for those properties of the liquid which are considered in the hydrodynamic equations, viz. the conservation of mass in each volume element and the equality of the pressure in all directions; these two factors do not preclude the possibility of a finite difference of the tangential velocities on either side of a surface in the interior of the fluid. The components of the velocity normal to the surface and the pressure, however, must be equal on both sides of such a surface".⁶

⁵Lamb, *Hydrodynamics*, Cambridge, 5th ed., Chap. IV, Art. 77.

⁶Helmholtz, *Preuss. Akad. Ber.*, 1868.

Helmholtz further points out that a sharp edged obstacle always produces discontinuity surfaces in the flow and that in this way the negative pressures that would otherwise be present are avoided. He also observes that the discontinuity surface which originally is conceived as a geometrical surface curls up under the influence of friction and takes the form of a sequence of eddies (Helmholtz speaks of vortex filaments). All this will be discussed in 32; for the present we maintain the assumption of a perfect inviscid fluid.

With this in mind we again take up the two-dimensional problem of the plate, assuming the plate normal to the flow for the sake of simplicity, as at the beginning of 29. Two lines of discontinuity—if we now use two-dimensional terminology—issue from the end points of the segment that represents our plate. They are symmetric to the y -axis, but of unknown shape (cf. Fig. 49, where the edges of the plate are denoted by A and B).

FIG. 49. Helmholtz flow past a vertical plate AB . The wake is delimited by the discontinuity lines A' and B' that originate at the edges of the plate.

The wake is enclosed between the two discontinuity lines and the plate, and we imagine the state of the wake to be dead water in the literal sense: its velocity is assumed as zero, and the pressure is everywhere constant, say, equal to p_0 . According to Helmholtz, we then have also for the fluid that flows along the discontinuity lines the following boundary conditions for the pressure and the normal component of the flow:

$$(1) \quad p = p_0, \quad v_n = 0.$$

The tangential component v_t follows now from Bernoulli's equation (29.4a) which yields because of (1)

$$(2) \quad |\mathbf{v}|^2 = v_t^2 = q^2 - \frac{2}{\rho} p_0.$$

The tangential component is thus constant along the lines of discontinuity. Infinite velocities and negative pressures no longer occur.

Kirchhoff⁷ worked out Helmholtz's idea in detail and applied it among other things to the plate problem. He considers in addition to the two complex variables

⁷G. Kirchhoff, Crelles Journ. 70 (1860) and Vorlesungen über Mechanik, Chap. XXII.

$$z = x + iy \quad \text{and} \quad f = \Phi + i\Psi$$

a third variable

$$(3) \quad \zeta = \frac{1}{-v_x + iv_y}$$

connected with z and f by the relation

$$(4) \quad \zeta = \frac{dz}{df}$$

as in (29.9), and introduces the assumption that *the wake reaches to infinity* (we have tried to indicate that in Fig. 49). The pressure p_0 then equals the pressure at infinity which we defined as zero in (29.4a), so that now p_0 in Eq. (2) must also be put equal to zero. From (2) we obtain

$$(5) \quad |-v_x + iv_y| = v_x = q$$

all along the lines of discontinuity. Consequently we have for ζ the boundary condition

$$(5a) \quad |\zeta| = \frac{1}{q}.$$

We wish to emphasize, however, that the assumption of discontinuity lines reaching to infinity is too restricted. Indications for this will be found at the end of this article.

Let us now look for the image of the discontinuity line, which separates the moving fluid from the wake in the plane of the complex variable ζ (cf. Fig. 50).

FIG. 50. Mapping of the z -plane on the ζ -plane.

Starting with the point infinity of the z -plane, we have there

$$v_y = q, \quad v_x = 0, \quad \text{and by (3)} \quad \zeta = -\frac{i}{q}.$$

The image point U in the ζ -plane is therefore on the negative imaginary axis. The images of the two discontinuity lines must pass through the point U , in agreement with (5a). We draw now a semi-circle of radius $1/q$ and center zero; it passes through U and terminates at the real axis in the points $\zeta = \pm 1/q$, which are the images of the points A and B in Fig. 49 (edges of the plate). All along the plate one has $v_y = 0$ and therefore ζ real; this holds also at the edges.

We finally consider the stagnation point O in Fig. 49. There

$$v_x = v_y = 0, \quad \text{and by (3)} \quad \zeta = \infty.$$

The image of O is the point ∞ of the ζ -plane. This determines completely the mapping of the two halves of the plate: Since ζ is real along the plate, as was just pointed out, one half of the plate maps on the segment OA , the other on the segment OB of the real axis in Fig. 50.

In describing the circuit $UAOB$ in Fig. 49, the region of the "live" flow⁸ remains to the left, and the region of the dead water to the right. Accordingly, the marked region in Fig. 50 to the left of the image circuit corresponds to the region of flow, the unmarked region to the wake. Yet that does not determine the analytic solution of our mapping problem since the shape of the lines of discontinuity is still unknown.

This part of the problem calls for a discussion of the mapping of the z -plane on the f -plane, the characteristic points of which are listed in the following table. As before we assign the equation $\Psi = 0$ to the "symmetric" stream line which separates at the stagnation point, whereupon the entire boundary of the dead water becomes real in the f -plane. The zero level of the velocity potential Φ is now assigned to the stagnation point O ; this makes Φ negative along OA and along OB . We denote the unknown value of Φ at A and B by f_0 . (Note that f_0 is at the same time the value of f at A and B since $\Psi = 0$; Φ must decrease from O to A or from O to B , hence is negative along OA and OB .) f_0 is negative and given by

$$(6) \quad f_0 = - \int_0^{+\infty} v_x dx = - \int_0^{-\infty} v_x dx.$$

We have thus found a correspondence between the total boundary of the wake and the negative real axis of the f -plane, but it is not a one-to-one

FIG. 51. Mapping of the z -plane on the f -plane.

correspondence, since, for instance, the plate front AOB is mapped on the double segment $f_0 - O - f_0$, cf. Fig. 51. This can be helped by making a cut along the negative real axis. The two borders of the cut form the image of the wake boundary, while the positive real axis has already been

⁸If we had used the reciprocal variable $\zeta' = 1/\zeta$, instead of ζ , the region of flow would map on the *interior* of the semi-circle and the circuit $UAOB$ on the closed boundary of the semi-circle. We have retained Kirchhoff's original definition of ζ in (3) to make a comparison with the original paper easier, although the map of the flow in the plane ζ' , being simply the *hodograph* of the flow, has a stronger physical appeal.

in one-to-one correspondence with the stream line $\Psi = 0$. The marking of Fig. 51 indicates that the cut f -plane is the image of the flow field in Fig. 49. The wake is mapped on a second sheet of the f -plane connected with the sheet of Fig. 51 across the branch cut (the two sheets form one Riemann surface).

	z	ζ	f	angular change
A	$+c$	$-\frac{1}{q}$	$f_0 < 0$	$\frac{1}{2}$
B	$-c$	$+\frac{1}{q}$	$f_0 < 0$	$\frac{1}{2}$
O	0	$\pm \infty$	0	$\frac{1}{2}$
U	∞	$-\frac{i}{q}$	∞	

Let us now try to find the analytical form of the mapping of the ζ -plane on the f -plane, omitting the z -plane and comparing the Figs. 50 and 51. (It will be noticed that this is feasible without knowing the discontinuity lines, since the plane of the physical flow matters no longer.) If the mapping were everywhere conformal, it would be given by a bilinear relation between ζ and f . There are, however, points where the conformality breaks down, though not in the interior of the marked regions of the two figures, but on the boundary; they have been indicated in the last column of our table. The number $\frac{1}{2}$ going with A and B means that the angle π occurring at the boundary points A and B in the f -plane appears as the angle $\pi/2$ in the ζ -plane; the number $\frac{1}{2}$ going with O should likewise tell us that the angle 2π at O in the f -plane appears in the ζ -plane as π . From this we infer that the relation between ζ and f must contain

$$f \text{ in the form } \sqrt{f}, \quad \zeta \text{ in the form } \left(\zeta \pm \frac{1}{q}\right)^2.$$

We therefore consider the following bilinear relation of these quantities

$$\frac{\left(\zeta + \frac{1}{q}\right)^2}{\left(\zeta - \frac{1}{q}\right)^2} = \frac{\sqrt{f_0} - \sqrt{f}}{\sqrt{f_0} + \sqrt{f}}$$

or, written more conveniently,

$$(7) \quad \frac{(q\zeta + 1)^2}{(q\zeta - 1)^2} = \frac{1 - \sqrt{\frac{f}{f_0}}}{1 + \sqrt{\frac{f}{f_0}}}.$$

This function fulfills the requirements of the table as can be shown by expanding (7) in power series at the points A , B , O . We shall come back to this in the next article in a more systematic way.

Let us now compute ζ explicitly. Eq. (7) can be rearranged in the form

$$(7a) \quad (q\zeta)^2 + 2\sqrt{\frac{f_0}{f}} q\zeta + 1 = 0;$$

the roots of this equation are

$$(8) \quad \zeta = -\frac{1}{q} \left(\sqrt{\frac{f_0}{f}} \pm \sqrt{\frac{f_0}{f} - 1} \right).$$

The salient point in this analysis is now that it is possible to eliminate the auxiliary variable ζ by (4) and to obtain a *differential equation between the two original variables z and f* , viz.

$$(9) \quad \frac{dz}{df} = -\frac{1}{q} \left(\sqrt{\frac{f_0}{f}} \pm \sqrt{\frac{f_0}{f} - 1} \right).$$

Its integration determines the mapping function.

It is convenient for this purpose to introduce the parameter α by

$$(10) \quad \begin{aligned} \sqrt{\frac{f}{f_0}} &= \sin \alpha, & df &= 2f_0 \sin \alpha \cos \alpha d\alpha. \\ \sqrt{\frac{f_0}{f}} &= \frac{1}{\sin \alpha}, & \sqrt{\frac{f_0}{f} - 1} &= \frac{\cos \alpha}{\sin \alpha}. \end{aligned}$$

Choosing the upper sign in (9), we obtain

$$dz = -\frac{2f_0}{q} (\cos \alpha + \cos^2 \alpha) d\alpha$$

which gives integrated

$$(11) \quad z = -\frac{2f_0}{q} \left\{ \sin \alpha + \frac{1}{2} (\sin \alpha \cos \alpha + \alpha) \right\}.$$

In this integration the constant must be set equal to zero, since $f = 0$ for $\alpha = 0$ according to (10), and z is supposed to be zero if $f = 0$ according to our table.

For $\alpha = \pi/2$, f equals f_0 by (10); according to our table this characterizes the edge of the plate A , or $z = c$. Thus we have

$$(12) \quad c = -\frac{2f_0}{q} \left(1 + \frac{\pi}{4}\right), \quad \frac{f_0}{q} = \frac{-2c}{\pi + 4}$$

which determines the hitherto unknown quantity f_0 . We substitute this value in (11) and obtain by separation of real and imaginary parts the following parametric representation of the plate:

$$(13) \quad \begin{aligned} x &= \frac{4c}{\pi + 4} \left\{ \sin \alpha + \frac{1}{2} (\sin \alpha \cos \alpha + \alpha) \right\}, \\ y &= 0, \end{aligned}$$

traced by the point x, y when α varies according to

$$(13a) \quad -\frac{\pi}{2} < \alpha < +\frac{\pi}{2}.$$

Now we allow α to take complex values, starting from $\pi/2$:

$$(13b) \quad \alpha = \frac{\pi}{2} - i\beta, \quad 0 < \beta < \infty.$$

Then one has

$$(13c) \quad \sin \alpha = \cosh \beta, \quad \cos \alpha = +i \sinh \beta.$$

If α changes according to (13b), f remains real by (10) and (12), hence (13b) represents the continuation of the stream line $\Psi = 0$ beyond the end point A , that is to say, the lower branch of the discontinuity line in Fig. 49. Its parametric representation is obtained from (11) by separation of the real and imaginary part in the following form:

$$(14) \quad \begin{aligned} x &= \frac{4c}{\pi + 4} \left(\cosh \beta + \frac{\pi}{4} \right), \\ y &= \frac{2c}{\pi + 4} (\cosh \beta \sinh \beta - \beta). \end{aligned}$$

This is a transcendental curve; its numerical determination makes no difficulty. For large β -values it can be approximated by a parabola.

Eqs. (10), (11) and (12) contain the general solution of our flow problem. When α takes arbitrary complex values we obtain

$$(15) \quad f = \Phi + i\Psi = -\frac{2qc}{\pi + 4} \sin^2 \alpha,$$

$$(16) \quad z = x + iy = \frac{4c}{\pi + 4} \left\{ \sin \alpha + \frac{1}{2} (\sin \alpha \cos \alpha + \alpha) \right\}.$$

An explicit representation of Φ and Ψ in terms of x and y such as would be obtained by elimination of the parameter α is neither feasible nor necessary.

To check our results we may compare the value of f_0 in (12) with its original definition in (6). According to (6) we ought to have

$$(17) \quad f_0 = - \int_0^{\epsilon} v_x dx = \int_0^{\epsilon} \frac{\partial \Phi}{\partial x} dx = \Phi_{\epsilon} - \Phi_0.$$

By (15) we have the Φ -values

$$\begin{aligned} \Phi_{\epsilon} &= - \frac{2c\eta}{\pi + 4} & \text{for } \alpha &= \frac{\pi}{2}, \\ \Phi_0 &= 0 & \text{for } \alpha &= 0. \end{aligned}$$

Thus (17) and (12) are in agreement.

Contrary to 29, the results of which led us to the d'Alembert-Euler paradox, our present theory gives a reasonable value for the *total pressure* P acting on the plate per unit of length under the influence of the streaming fluid.

From Bernoulli's theorem (29.4a) we have

$$(18) \quad P = \int_{-\epsilon}^{+\epsilon} p dx = \frac{\rho}{2} q^2 \int_{-\epsilon}^{+\epsilon} \left(1 - \frac{v^2}{q^2} \right) dx.$$

Along the front of the plate v equals v_x , hence $v^2 = 1/\zeta^2$ by (3), and (18) takes the form

$$(19) \quad P = \frac{\rho}{2} q^2 \int_{-\epsilon}^{+\epsilon} \left(1 - \frac{1}{q^2 \zeta^2} \right) dx.$$

This integral can be evaluated in the following elegant manner: along the plate, dx equals $d\zeta$; thus we obtain from (4)

$$(19a) \quad dx = \zeta df, \quad P = \frac{\rho}{2} q \int \left(q\zeta - \frac{1}{q\zeta} \right) df.$$

From (8), where we choose again the upper sign, we have

$$- q\zeta = \sqrt{\frac{f_0}{f}} + \sqrt{\frac{f_0}{f} - 1}.$$

The reciprocal value of this expression may be written

$$- \frac{1}{q\zeta} = \sqrt{\frac{f}{f_0}} - \sqrt{\frac{f}{f_0} - 1},$$

so that

$$q\xi - \frac{1}{q\xi} = -2\sqrt{\frac{f_0}{f}} - 1,$$

a result that could have been read from the quadratic equation (7a). Upon introducing the last expression in (19a), we obtain

$$(20) \quad P = -2\rho q \int_0^{f_0} \sqrt{\frac{f_0}{f}} - 1 \, df.$$

As regards the limits of the integral and the factor 2, note that the pressure distribution is symmetric with respect to the center, and therefore the contributions of the upper and the lower half equal.

If we now introduce the parameter α from (10) we obtain

$$(21) \quad P = -4\rho f_0 q \int_0^{\pi/2} \cos^2 \alpha \, d\alpha = -\rho f_0 q \pi$$

and, on substitution of f_0 from (12),

$$(22) \quad \frac{P}{2c} = \frac{\pi}{\pi + 4} \rho q^2 = 0.88 \frac{\rho}{2} q^2.$$

The pressure per unit of surface is thus proportional to the square of the flow velocity at infinity in agreement with the general hydraulic experience (cf., e.g., p. 80); we could formulate our result also in this way: the pressure is proportional to the kinetic energy per unit of volume of the undisturbed flow, or, in other words, proportional to the stagnation pressure at 0. The numerical coefficient, however, does not agree too well with the results of careful measurements. In the case of the infinitely long plate the actual coefficient is about 2.0 according to Prandtl (*Strömungslehre*, p. 165)⁹ instead of our value 0.88. The reason is—also according to Prandtl¹⁰—that the real wake does not reach to infinity and the two separate regions of the flow join at some distance behind the plate. Besides, the pressure downstream of the plate is smaller than the pressure of the undisturbed flow because of the eddies present in the wake. This leads to a “suction” on the back side that adds to the pressure on the front side.

The last remarks throw a good deal of doubt on the basic assumption of Kirchhoff's wake theory which has been widely accepted in literature. An essential feature of the theory is the assumption $p_0 = 0$ introduced in connection with Eq. (2). It is identical with the hypothesis of an infinitely extended wake as explained on p. 217. Attempts at a general treatment

⁹Cf. also Hunsaker and Rightmire, *op. cit.*, p. 198.

¹⁰See C. Schmieden, *Z. für Luftfahrtforschung* 17, (1940) 37 and M. Kolscher, *ibid.* p. 154.

of the problem which drop this assumption (see, e.g., footnote p. 223) are too complicated to be presented in this book.

Let us finally have a look at the interesting question of stability; suppose the plate is not kept rigidly fixed, but is allowed to revolve about an axis through its center, what will be its position relative to the flow? If the preferred orientation were parallel to the flow, the total pressure P would vanish. The experiment shows, however, that the plate orients itself normal to the flow.

A complete investigation of this question would require knowledge of the flow pattern and of the discontinuity surfaces also in the case of the oblique plate. We can do without that if we trust the stream pattern in Fig. 48 as far as the qualitative position of the stagnation point on the front side of the plate is concerned which, in Fig. 47b, is confirmed by the experiment. We take it then that the stagnation point travels toward the leading edge of the plate whenever the plate turns from the normal to an oblique position. The pressure maximum then travels in the same direction. When the plate, as in Fig. 48, is turned counterclockwise out of the normal position, the pressure produces a clockwise moment which tends to restore the normal position. *This is therefore the stable position of the plate.* The same argument applied to the *parallel position* shows that *it is unstable.*

A weather vane likewise, would not turn into the wind but normal to it, if its axis were centrally located (actually the rear face is much larger than the front face). In fact, the Rayleigh disk (cf. p. 215) which is centrally suspended places itself normal to the sound beam.

31. The Problem of the Free Jet Solved by Conformal Mapping

It might appear that the mapping function given in (30.7) is the result of a lucky guess rather than of rigorous deduction. These doubts will be dispelled by the systematic derivation of (30.7) that follows here.

Let it be required to map the positive quadrant¹¹ of a t -plane on the upper half of an s -plane; the simplest way to do this is by the relation

$$(1) \quad t = s^{\frac{1}{2}}.$$

The mapping is conformal everywhere in the finite domain with the exception of the origin of the two planes, where the straight angle π formed by the real axis at $s = 0$ is mapped into the angle $\pi/2$ between the positive

¹¹Our quadrant can be considered as a closed polygon, bounded by two straight lines and possessing two right angles at $t = 0$ and $t = \infty$ as one sees by stereographic projection. More generally, any polygon with arbitrary angles can be mapped on the half plane. There exists for this purpose a general integral formula of H. A. Schwarz and E. B. Christoffel, but we do not have to use it here.

real and the positive imaginary axes at $t = 0$. We consider now the ζ -plane connected with the t -plane by the bilinear transformation

$$(2) \quad t = \frac{\zeta + a}{\zeta - a}, \quad \zeta = a \frac{t + 1}{t - 1},$$

where a is real and positive. By (2) the positive-imaginary t -axis is mapped on the semicircular arc $|\zeta| = a$ which passes from $\zeta = -a$ through $\zeta = -ia$ to $\zeta = +a$ (bilinear transformations are known to map straight lines into circles or straight lines), while the positive real axis of the t -plane is mapped into the two parts of the real ζ -axis $a < \zeta < \infty$ and $-\infty < \zeta < -a$.

We now substitute (2) in (1) and obtain the mapping function

$$(3) \quad \frac{(\zeta + a)^2}{(\zeta - a)^2} = s,$$

which maps the upper half plane of the variable s on the region of the ζ -plane marked in Fig. 50.

Let us turn to the relation between s and f : here we wish to map the upper half plane of s on the f -plane cut along the negative real axis as indicated in Fig. 51. The angle π at $s = 0$ must be doubled in the mapping, so that the angle at $f = 0$ becomes 2π . The simple relation $s = \sqrt{f}$ of Eq. (1) would do this. We wish, however, to achieve at the same time the coordination of f -values and ζ -values prescribed by our table on p. 219, and therefore subject \sqrt{f} first to a bilinear transformation which we write

$$(3a) \quad s = \frac{\alpha \sqrt{f} + \beta}{\gamma \sqrt{f} + \delta}.$$

Combination with (3) and replacement of α by $1/q$ gives

$$(4) \quad \frac{(q\zeta + 1)^2}{(q\zeta - 1)^2} = \frac{\alpha \sqrt{f} + \beta}{\gamma \sqrt{f} + \delta}.$$

The coefficients $\alpha, \beta, \gamma, \delta$, determined¹² according to that table are

$q\zeta = -1,$	$f = f_0$	$\alpha \sqrt{f_0} + \beta = 0,$
$q\zeta = +1,$	$f = f_0$	$-\gamma \sqrt{f_0} + \delta = 0,$
$q\zeta = \infty,$	$f = 0$	$\beta = \delta,$
$q\zeta = -i,$	$f = \infty$	$\alpha = -\gamma.$

¹²The negative sign on γ in the second line of the table is obtained from Fig. 51 in the following way: \sqrt{f} changes its sign in a transition from the upper to the lower border of the cut, if this transition is carried out without leaving the hatched sheet in Fig. 51, that is without crossing the cut. The value $\sqrt{f_0}$ in the first line that corresponds to the point A is thus to be replaced by $-\sqrt{f_0}$ in the second line that corresponds to the point B .

Putting $\alpha = 1$, we obtain for the other constants

$$\gamma = -1, \quad \beta = \delta = -\sqrt{f_0},$$

and Eq. (4) assumes the form

$$(4a) \quad \frac{(q_1^2 + 1)^2}{(q_1^2 - 1)^2} = \frac{\sqrt{f} - \sqrt{f_0}}{-\sqrt{f} - \sqrt{f_0}} = \frac{1 - \sqrt{\frac{f}{f_0}}}{1 + \sqrt{\frac{f}{f_0}}}.$$

Thus we have achieved a more cogent derivation of Eq. (30.7) based on the known mapping properties of the bilinear function and the square root.

We now apply the same method to the classical problem connected with Torricelli's name, viz. the outflow from a large reservoir, already treated in 11, p. 87. At that time we took it for granted that the fluid leaves the orifice in the form of a jet. Now we wish to follow Helmholtz who was the first to realize that the problem of jet formation should be made the object of hydrodynamic investigation. In the paper quoted on p. 215 he actually gives the present problem as the only example to illustrate the idea of the discontinuity surface.

We shall treat here the two-dimensional equivalent of the problem of jet formation. This means replacing the orifice in the tank wall by an infinitely long slit of width $2c$ in a plane wall perpendicular to the drawing of Fig. 52. The action of gravity on the emerging jet will be disregarded.

FIG. 52. Two dimensional scheme of jet contraction.

The center line of the jet is taken as y -axis, the wall as x -axis. The two discontinuity lines that issue from the sharp edges of the slit will approach each other since the water enters the orifice also from the sides; the cross-section of the jet decreases therefore after its emergence from the orifice (vena contracta). The principal aim of our investigation is to determine the degree of contraction, that is to say, the ratio of the jet cross-section at large distance to that in the immediate neighborhood of the orifice. The details of the calculation need not be presented since the problem is mathematically identical with that of 30.

Fig. 52 has been drawn in the plane $z = x + iy$. In addition we consider as on p. 217 and p. 218 the planes

$$(5) \quad \zeta = \frac{1}{-v_x + iv_y} \quad \text{and} \quad f = \Phi + i\Psi.$$

Along the two discontinuity lines the pressure is constant; it is equal to the atmospheric pressure which we take as the zero level for p . From Bernoulli's equation (29.4) we then have $v^2 = \text{const}$ along the discontinuity lines, therefore

$$|\mathbf{v}| = \text{const} = q \quad \text{and from (30.3)} \quad |\zeta| = \frac{1}{q}.$$

Here q represents the magnitude of $|\mathbf{v}|$ at the points A and B , or, as we may also put it, the value of the velocity at sufficient distance from the orifice, as it is given by Torricelli's Eq. (11.10).

At the infinitely distant point U of the jet, where the side component v_x evidently vanishes, we obtain from (5)

$$(5a) \quad \zeta = -\frac{i}{q}.$$

Along the inside of the wall where v_x vanishes, ζ becomes real; for, we have from Fig. 52 and Eq. (5)

$$(5b) \quad \begin{aligned} +\infty > \zeta > \frac{1}{q} & \quad \text{at the wall } OA, \\ -\infty < \zeta < -\frac{1}{q} & \quad \text{at the wall } O'B. \end{aligned}$$

The region of flow in the ζ -plane of Fig. 53 has therefore the same shape as in Fig. 50. In addition, Fig. 53 shows the image of the infinitely distant point U' on the upstream prolongation of the center line of the jet. (In approaching the point U' from the orifice we have to assume $v_x = 0$, $v_y \rightarrow 0$, therefore $\text{Im}(\zeta) \rightarrow -\infty$.)

FIG. 53 (left). Mapping of the z -plane on the ζ -plane.

FIG. 54 (right). Mapping of the z -plane on the f -plane.

Fig. 54 shows the flow region of the f -plane. Let the stream line $\Psi = 0$ coincide with the axis of symmetry of the flow UU' (real axis of the f -

plane). Φ increases along this line in the direction from U to U' , since $v = v_x$ has here the direction from U' to U . We assign to the streamlines that run along the walls of the reservoir and the discontinuity lines the value¹³ of the stream function

$$\Psi = \pm \frac{\pi}{2} \Psi_0.$$

The entire region of flow is mapped on the strip of the f -plane bounded by these two Ψ -lines. If we now assign the zero level of the velocity potential Φ to the equipotential line that passes through the edges A and B of the slit, then the images A and B in Fig. 54 are located on the imaginary axis of the f -plane. The "lower" and "upper" tank walls are represented by the segments AO and BO' of the boundaries of the strip, while UA and UB are the images of the boundaries of the jet.

As before we have now to find the analytical relation between ζ and f , and use again a table that incorporates the correlations already indicated in Figs. 52-54.

	z	ζ	f
A	$+c$	$\frac{1}{q}$	$i \frac{\pi}{2} \Psi_0$
B	$-c$	$-\frac{1}{q}$	$-i \frac{\pi}{2} \Psi_0$
O	$+\infty$	$+\infty$	$\infty + \frac{i\pi}{2} \Psi_0$
O'	$-\infty$	$-\infty$	$\infty - \frac{i\pi}{2} \Psi_0$
U	$+i\infty$	$-\frac{i}{q}$	$-\infty$
U'	$-i\infty$	$-i\infty$	$+\infty$

In the previous problem we had to map the cut f -plane in its full extension on a specified part of the ζ -plane which we were able to do by using the square root as a mapping function. In the present case we want to map a mere strip of the f -plane on the same part of the ζ -plane as before. This can be achieved by the exponential function. We use Kirch-

¹³The factor $\pi/2$ of Ψ_0 simplifies some of the following formulas.

hoff's notation e'' where the variable w is proportional to f with a scale factor¹⁴ that depends on the choice of Ψ_0 :

$$(6) \quad w = \frac{f}{\Psi_0}.$$

The mapping function (4) takes now the following form

$$\frac{(q\zeta + 1)^2}{(q\zeta - 1)^2} = \frac{ie'' - 1}{ie'' + 1}.$$

Here $\alpha, \beta, \gamma, \delta$ have been determined according to the foregoing table, e.g., by satisfying the conditions required for the points B, A and U ; the conditions at the remaining points are then automatically fulfilled. In analogy to (30.7a) we obtain for q the quadratic equation

$$(q\zeta)^2 + 2ie''q\zeta + 1 = 0$$

with the solution

$$q\zeta = -i(e'' + \sqrt{e^{2''} + 1}).$$

Because of (30.4), where df is to be replaced by $\Psi_0 dw$, this yields the differential equation

$$(7) \quad dz = -\frac{i\Psi_0}{q}(e'' + \sqrt{e^{2''} + 1})dw.$$

Let us now consider the three straight lines of Fig. 54

$$\Psi = 0, \quad \Psi = \pm \frac{\pi}{2} \Psi_0.$$

The quantities f and w are real if $\Psi = 0$; the left member of (7) is then purely imaginary. The point z travels along the y -axis from $-\infty$ to $+\infty$ as it is expected to do (Fig. 52). Along the two other lines e'' becomes purely imaginary. On putting

$$e'' = \pm is, \quad dw = \frac{ds}{s},$$

Eq. (7) appears in the following form:

$$(8) \quad dz = \frac{\Psi_0}{q}(\pm s + \sqrt{s^2 - 1})\frac{ds}{s}.$$

¹⁴Note that Kirchhoff in his treatise *Vorlesungen über Mechanik*, Chap. XXII, 3, defines the velocity potential with reversed sign, chooses the coordinate axes not symmetrical to the jet, and does not set in evidence physical parameters of the problem such as q . This procedure, which amounts to putting q equal to 1, has been generally accepted in the literature. We are of the opinion, however, that a better grasp of Kirchhoff's ingenious method becomes possible by the introduction of definite units from the start.

The square root is real for $\infty > s > 1$; for these values of s , z is real and travels along the "upper" and "lower" tank wall $y = 0$, $x > c$ and $x < -c$.

As we are mainly interested in the *free boundaries of the jet* that issue from the slit, we must consider the range $s < 1$. This makes dz in (8) complex, as it has to be in the case of curved jet boundaries. We choose the upper sign in (8) which corresponds to the lower jet boundary in Fig. 52 and put

$$s = \sin \alpha, \quad \frac{\pi}{2} > \alpha > 0.$$

Eq. (8) takes now the form

$$dz = \frac{\Psi_0}{q} (\sin \alpha + i \cos \alpha) \frac{\cos \alpha}{\sin \alpha} d\alpha = \frac{i\Psi_0}{q} e^{-i\alpha} \frac{\cos \alpha}{\sin \alpha} d\alpha.$$

This yields after integration the result

$$(9) \quad z = i \frac{\Psi_0}{q} \left(e^{-i\alpha} - \frac{1}{2} \log \frac{1 + \cos \alpha}{1 - \cos \alpha} \right) + \text{const},$$

which may be checked by differentiation. The constant can be determined by requiring $z = c$ for $\alpha = \pi/2$, that is, at the point A . Then we obtain

$$\text{const} = c - \frac{\Psi_0}{q}, \text{ and}$$

$$(9a) \quad z = c - \frac{\Psi_0}{q} \left(1 - ie^{-i\alpha} + \frac{i}{2} \log \frac{1 + \cos \alpha}{1 - \cos \alpha} \right).$$

Separation into real and imaginary parts gives:

$$(10) \quad x = c - \frac{\Psi_0}{q} (1 - \sin \alpha),$$

$$y = \frac{\Psi_0}{q} \left(\cos \alpha - \frac{1}{2} \log \frac{1 + \cos \alpha}{1 - \cos \alpha} \right).$$

These equations are the parametric representation of one of the two jet boundaries; the other is obtained from (10) by changing the sign of x .

For $\alpha = 0$ we obtain from (10)

$$x = c - \frac{\Psi_0}{q}, \quad y = \infty,$$

that is, the behavior at the infinitely distant point U in Fig. 52. Half the width of the jet at U is therefore

$$(11) \quad b = c - \frac{\Psi_0}{q}.$$

Finally, we have to find the physical meaning of the constant Ψ_0 which is of course connected with the velocity q . We write down the second Cauchy-Riemann equation (19.5)

$$(12) \quad \frac{\partial \Psi}{\partial x} = - \frac{\partial \Phi}{\partial y}.$$

At the cross-section U , that is, at large distance from the orifice, we find the velocity uniformly equal to q and parallel to the y -axis; the right member of (12) is therefore constant. Integration of (12) between the limits $x = 0$ and $x = b$ which correspond to $\Psi = 0$ and $\Psi = (\pi/2)\Psi_0$ yields

$$(12a) \quad \frac{\pi}{2} \Psi_0 = qb.$$

In combination with Eq. (11) one has

$$b = c - \frac{2}{\pi} b, \quad \frac{2 + \pi}{\pi} b = c$$

so that the relative contraction of the jet is

$$\frac{b}{c} = \frac{\pi}{2 + \pi} = 0.611.$$

The actual contraction coefficients used in hydraulic practice are close to our theoretical result; they serve to predict the efflux through a given orifice from its geometry.

32. Kármán's Vortex Street

The analysis of a given physical situation usually requires a certain amount of idealization, so that the tools of mathematics can be successfully applied; to find workable idealizations is the art of the mathematical physicist. Bearing this in mind, let us investigate a problem already presented by Helmholtz (cf. p. 216): What is the nature of the mechanism that leads to the curling up of the discontinuity surface into a sequence of vortex filaments? In the case considered in 30, the vortices originate at the sharp edges of the plate; in general vortices may be generated by any obstacle that is in the way of the flow. The photographs 47 a, b give a good idea of them. Loosely speaking, the vortices operate like ball or roller bearings distributed along the discontinuity surface that separates the streaming fluid from the dead water. This visualization gives at least the

correct sense of rotation of the vortices on either side of the wake. There is however this difference: the vortices do not run along in the same way as the balls in the race of a bearing. They would move with the stream, but they influence each other; actually the mutual influence produces an *additional velocity* which is superimposed on the *principal velocity* of the flow and has in the simplest case the opposite direction as we shall see.

Kármán¹⁵ idealized the sequence of vortices produced at an obstacle by assuming an *infinitely long straight vortex street* and disregards the origin of the vortices by transferring it to infinity. The vortices on either side of the street are equidistantly arranged: this characterizes the steady state which has developed in the (infinitely) long time that passed after they had been generated. On either side of the street the sense of rotation is different; the "upper" vortices are clockwise, the "lower" vortices counterclockwise. The principal velocity points to the right, corresponding to that of a free flow that rolls on "bearings" along a wake at rest. Kármán restricts himself to the case in which the additional velocity is parallel to the street; we shall start our analysis with the same assumption.

The first consequence is, as we shall show, that the two rows of vortices must be either opposite as in Fig. 55 or alternating as in Fig. 56. (Note

FIG. 55. Kármán's vortex street consisting of two rows of vortices of different orientation. The vortices are in opposite position.

that "vortex" means concentrated vortex filament, indicated in the figure by a dot with semicircular arrow.)

Consider Fig. 55; number the vortices from $-\infty$ to $+\infty$ and choose the vortex 0 of the upper street as "field" vortex, that is, consider this vortex as subjected to the induction of all the other vortices as in 21. There are *no contributions to its velocity* from the neighboring vortices ± 1 on the *same* side of the street, since the induced velocity is normal to the line connecting with the inducing vortex and points in the sense of its rotation. The contributions of the pair $\pm k$ cancel for the same reason. The contribution of the opposite vortex 0 points in the *negative direction*

¹⁵Th. v. Kármán, Über den Mechanismus des Flüssigkeits- und Luftwiderstandes, Göttinger Nachr. 1911 und 1912. Cf. also Kármán and H. Rubach, Physikal. Z. 13 (1912) 49.

of the street. Also the contributions of the pair ± 1 on the other side, which, individually, are inclined to the street, give a resultant in the negative direction of the street, and the same is true for the pair $\pm k$.

When the vortices are not exactly opposite to each other, the same construction will give a total induction at our field vortex that is *oblique to the street* with the one exception of the alternating case of Fig. 56. Here we compound the inductions due to the vortices 0 and 1 on the opposite side (broken lines in Fig. 56), and generally the inductions of the pairs $(-k, k+1)$ and obtain again an additional velocity at the field vortex, pointing in the negative direction of the street. Fig. 56 gives in addition an idea of the presumable path of the fluid particles that wind in and out between the vortices, in reasonable agreement with the photographs in Fig. 47a and b.

These photographs suggest at the same time that the alternating arrangement of Fig. 56 rather than the one of Fig. 55 occurs in nature. In

Fig. 56. Kármán's vortex street; the vortices are in alternating position.

order to explain this preference Kármán investigates the *stability* of both arrangements.

The concept of stability applied to a problem such as ours needs some comment. In Figs. 55 and 56 the locations of the vortices

$$z_k = x_k + iy_k$$

are accurately given by the positive or negative integer number k so that the additional velocity can be calculated according to well known complex methods. To investigate the stability we have to impart small displacements or disturbances

$$\bar{z}_k = \bar{x}_k + i\bar{y}_k$$

to the vortices.¹⁶ The introduction of such disturbances changes also the

¹⁶This variation is actually too restricted since it occurs only in the x, y -plane while in the z -direction the displaced vortex filaments are still supposed to be straight as they originally were. A more general stability investigation which introduces variations in z -direction has been carried out by K. Schlayer in his Munich thesis [Z. angew. Mathem. und Mech. 8, (1928) 352]. One can defend the special variations admitted by Kármán, observing that "infinitely long" straight vortex filaments can at any rate only be produced in a flow between parallel plates at a small distance (see p. 160). The

additional velocity. For instance, the statement that the total induction of all vortices on the same side as the field vortex vanishes is no longer true. In the disturbed state the velocity of the field vortex depends on all \bar{z}_k regardless on which side of the street they are. We assume the dependence as linear neglecting the higher powers of \bar{z}_k . The variation of the induction produced by the variation of the \bar{z}_k determines the time rate of change $\dot{\bar{z}}_0$ of the field vortex as a linear function of all the other \bar{z}_k . Thus we obtain first an infinite system of linear differential equations of first order for the \bar{z}_k which can be reduced, however, to a system of only two differential equations of the same character (see later). According to the general theory of small oscillations^{16a}, one determines first the principal modes of the system, that is, one finds solutions with the time dependence $e^{\lambda t}$. This procedure was carried out in a very simple case in Vol. I, 3.24 and prob. IV, 2. If λ is purely imaginary the vortex street is considered stable since oscillations of constant amplitude would be attenuated by friction which has been neglected so far. But the occurrence of even one complex λ -value with a positive real part makes the vortex street unstable, since a system can only be stable if all principal modes are stable. Kármán¹⁷ has shown that an arrangement of vortices as in Fig. 55 is unstable for any value of h different from zero; the alternating arrangement of Fig. 56 is stable if and only if

$$(1) \quad \sinh \frac{h}{a} \pi = 1, \quad \text{hence} \quad \frac{h}{a} = 0.281.$$

Our Figs. 55 and 56 have been drawn with about this numerical value of h/a .

The complete representation of the stability investigation, which is rather an involved mathematical problem, would take up too much space here. We shall indicate only the main points of the calculation. In doing so we shall at the same time broaden the basis of our investigation by following a paper of Maue.¹⁸ We shall assume that one row of the street

stability of such an experimental arrangement is indeed demonstrable by means of the special variations used in the text, provided the plate distance is sufficiently small. According to Schlayer, there is, however, always a weak instability toward general variations, and it increases with increasing plate distance.

^{16a}For a discussion of the method of small oscillations see, for instance, Kármán, *Th. v. and Biot*, M. A. Mathematical methods in Engineering, New York, 1940, Chapters V and VI.

¹⁷Kármán's investigation has been supplemented by Bl. Dolaptschiew who considered terms of second order. [Z. angew. Mathem. u. Mech. 17 (1937) 313, 18 (1938) 203]

¹⁸A. W. Maue, Z. angew. Mathem. u. Mech. 20 (1940) 130. Eqs. (6) to (8) that go beyond Kármán's original investigation have been taken from this paper. Mr. Maue kindly contributed the appendix to the present article.

is shifted relative to the other by the amount $d < a$ (in Fig. 55, $d = 0$, in Fig. 56, $d = a/2$). This makes no formal difficulties if the origin of the z -plane is located at the center of the pair 0, 0 and if the points are numbered in such a way that the points $\pm k$ on the one side are diametrically opposite to the points $\mp k$ on the other side of the street, viz:

$$(2) \quad z_k^2 = -z_k^1, \quad z_k^1 = z_0 + ka, \quad z_0 = \frac{1}{2}(d + ih).$$

(The superscripts 1 and 2 refer to the upper and lower rows of the street respectively, z_0 indicates the location of the 0-vortex belonging to the upper side of the street.)

First, we give a very simple expression for the complex potential $f = \Phi + i\Psi$ valid for arbitrary d , as it depends on d only by z_0 . Our starting point is Eq. (19.10) which describes the combined action of a positive and a negative vortex; the numerator and also the denominator occurring there vanish respectively at the center of the positive and negative vortex. The generalization of this equation for our vortex street is simply

$$(3) \quad f = -\frac{i\mu}{\pi} \log \frac{\sin \frac{(z - z_0)\pi}{a}}{\sin \frac{(z + z_0)\pi}{a}}.$$

In fact, the numerator vanishes now for all points

$$z = z_0 + ka = z_k^1,$$

and the denominator for all points

$$z = -(z_0 + ka) = z_k^2$$

as required by (2). The periodicity of the sine makes each vortex act with the same strength. The factor A in (19.10) that characterizes the vortex strength has been changed in accordance with (19.8a) and the signs have been adjusted in such a way as to correspond to the orientation of the vortices in Fig. 56.

By differentiation of f with respect to z one obtains as in the familiar relations (30.3) and (30.4)

$$(4) \quad \frac{df}{dz} = -v^* \begin{cases} v = v_x + iv_y, \\ v^* = v_x - iv_y. \end{cases}$$

Here v is the velocity of a fluid particle characterized by its complex coordinate z . If we wish to apply this formula to one of the vortex points, e.g., to the field vortex $z = z_0$ itself, then we must keep in mind that its

induction upon itself is zero and has to be omitted in the expression for f . This can be done by adding to the right member of (3)

$$+ \frac{i\mu}{\pi} \log(z - z_0).$$

According to this, Eq. (4) yields, when we introduce $\mathbf{u} = u_x + iu_y$ to denote the velocity of the field vortex z_0 ,

$$\mathbf{u}^* = \frac{i\mu}{\pi} \frac{d}{dz} \left(\log \frac{\sin \frac{(z - z_0)\pi}{a}}{\sin \frac{(z + z_0)\pi}{a}} - \log(z - z_0) \right);$$

the differential quotient (4) is to be taken at $z = z_0$. We therefore introduce

$$(z - z_0) \frac{\pi}{a} = \epsilon, \quad (z + z_0) \frac{\pi}{a} = 2z_0 \frac{\pi}{a} + \epsilon,$$

and find in the limit $\epsilon \rightarrow 0$

$$(5) \quad \mathbf{u}^* = - \frac{i\mu}{a} \operatorname{ctg} \frac{2\pi z_0}{a}.$$

This formula is valid not only for the vortex $z = z_0$, but, because of the periodicity of the street, also for any other vortex. The condition for the "additional velocity" \mathbf{u} to point in the direction of the street is simply that (5) be real; consequently the expression

$$\operatorname{ctg} \frac{2\pi z_0}{a}, \quad \text{or because of (2)} \quad \operatorname{ctg} \frac{\pi}{a} (d + ih)$$

must be *purely imaginary*. This occurs only if $d = 0$ or $d = a/2$. In both cases we have from (5)

$$(5a) \quad d = 0, \quad \mathbf{u}^* = u_x = - \frac{\mu}{a} \coth \frac{h}{a} \pi,$$

$$d = \frac{a}{2}, \quad \mathbf{u}^* = u_x = - \frac{\mu}{a} \tanh \frac{h}{a} \pi.$$

By means of the stability criterion stated in (1), the second line of (5a) can be written in the form

$$(5b) \quad d = \frac{a}{2}, \quad \mathbf{u}^* = u_x = - \frac{1}{\sqrt{2}} \frac{\mu}{a}.$$

Thus the additional velocities constructed in Figs. 55 and 56 have been found. The principal velocity indicated in the same figures—it could be

denoted by q as in the plate problem—has the value zero for the particular frame of reference we have chosen (center of the pair 0, 0). This can be seen from Eq. (3): If z is allowed to go to infinity along some specified path lying outside the vortex street, then the quotient of the sines tends to a constant limit; thus f is constant and $q = 0$.

In all other cases \mathbf{u} is *oblique* relative to the vortex street. The angle of inclination γ follows from (5) by an elementary calculation:

$$(6) \quad \operatorname{tg} \gamma = \frac{u_y}{u_x} = \frac{\sin 2\pi \frac{d}{a}}{\sinh 2\pi \frac{h}{a}}.$$

The absolute value u of \mathbf{u} is also obtained from (5):

$$(6a) \quad u = \frac{\mu}{a} \sqrt{\frac{\cosh^2 \pi \frac{h}{a} - \sin^2 \pi \frac{d}{a}}{\cosh^2 \pi \frac{h}{a} - \cos^2 \pi \frac{d}{a}}}.$$

This formula is the generalization of u_x in Kármán's result, which is our u_x in Eq. (5a).

If we let the vortex street be generated by a flow past a plate, as at the beginning of this article, Eq. (6) must obviously be associated with the case of an *oblique plate*. This should not imply, however, that the angle γ in (6) is equal to the angle γ in Fig. 48 (the former is actually smaller than the latter). Unfortunately, the photograph 47b does not show clearly the obliquity of the street produced.

We have still to discuss the central part of our problem, viz. the investigation of stability. Following Maue, we choose a slightly modified approach: instead of prescribing displacements \bar{z}_k for the vortex points, we modify the sine functions occurring in the complex potential (3) in the following way:

$$(7) \quad \sin(z - z_0) \frac{\pi}{a} = \zeta_1(z) \quad \text{and} \quad \sin(z + z_0) \frac{\pi}{a} = \zeta_2(z).$$

The perturbations ζ_1, ζ_2 are supposed to be small. They are connected to the arbitrary variations \bar{z}_k by the requirement that the zeros of the functions (7) should occur at $z_k^1 + \bar{z}_k^1$ and $z_k^2 + \bar{z}_k^2$ respectively. This is achieved by putting

$$\zeta_1(z_0 + ka) = (-1)^k \frac{\pi}{a} \bar{z}_k^1, \quad \zeta_2(-z_0 + ka) = (-1)^k \frac{\pi}{a} \bar{z}_k^2.$$

In this way the functions ζ have been fixed except for a function of the period a . The velocity of the vortex points after perturbation is now found as in Eq. (4) by differentiation of the modified function f . Upon expressing the same velocity by the time derivatives of the perturbations one obtains two simultaneous linear differential equations between ζ_1, ζ_2 , their first and second derivatives with respect to z , and $\dot{\zeta}_1, \dot{\zeta}_2$. The discussion of these equations which we omit here yields the stability criterion

$$(8) \quad \sinh \frac{h}{a} \pi = \sin \frac{d}{a} \pi.$$

This is the direct generalization of Kármán's criterion (1). Thus there exists also in the case of a vortex street that advances in oblique direction, a certain value h/a for any given value $d \leq a$ such that the vortex street maintains its arrangement after perturbation except for small oscillations that do not increase.

Fig. 57 illustrates this result and at the same time Kármán's special

FIG. 57. Illustrating the generalized stability criterion. The width h of the vortex street as a function of the mutual displacement of the two rows of vortices.

case [Eq. (1)]. It is an h versus d plot for all possible stable vortex streets. If the \sinh in (8) were approximated by its tangent at the origin, the h versus d -curve would become an ordinary sine curve. Since the hyperbolic sine increases monotonically with its argument, the actual h, d -dependence is a slight distortion of the sine curve appearing on the right side of (8). The maximum ordinate corresponds to Kármán's case $d = a/2$. For $d = 0$ one has $h = 0$, just as in the geometrically identical case $d = a$. In both cases the two rows of vortex points coincide point by point and cancel each other: the end points of the stability curve have no physical significance.

One can expect that an experimental investigation such as was carried out by Kármán and Rubach for straight vortex streets (cf. footnote on p. 232) will also confirm the generalized stability criterion (8) for oblique vortex streets.

Appendix

The Drag Problem

Kármán's real aim in his investigation of the vortex street was to establish an analytic drag formula. For this purpose he considers a body moving through the fluid in the rear of which a vortex street has developed that reaches to infinity. The calculation is performed in the z -plane of the street, x being the direction of motion of the body. The body itself is considered as infinitely long in the direction normal to the z -plane. One delimits in the plane a sufficiently large rectangular region by a control surface, which includes the body and a sufficiently long stretch of the vortex street, and investigates the balance of momentum inside the control surface. The terms to be considered are: the pressure interaction between fluid and body, the increase of momentum inside the control surface due to the generation of new vortices, and the flux of momentum through the control surface. The first of these three terms is to be taken negative; its real part represents the drag, its imaginary part the side force normal to the direction of motion.

Even in the case where the direction of the vortex street coincides with the direction of motion of the body the calculation is rather involved. The more general case studied by Maue where the directions of the vortex street and that of the motion of the body form an angle with each other will probably always occur, unless there is a special relation of symmetry between the body and the direction of its motion. The drag formula is not given in Maue's paper quoted on p. 234 but has been kindly contributed by the author for use in the following discussion. It contains Kármán's formula as a particular case.

The notations used here conform to those of 30 in the plate problem. The drag P corresponds to the integral of the pressure over the width of the plate in (30.22). The effective width of the body normal to the direction of motion in the $x + iy$ -plane is now denoted by $2c$, while previously $2c$ was directly the width of the plate. In the present notation q is the velocity of the body relative to the fluid which is at rest at infinity; the previous q was the flow velocity at infinity while the plate was at rest. The dimensionless drag coefficient is denoted by λ (previously, 0.88). The distance of two neighbored vortices is a , h is the width of the street, and u its velocity of progression as calculated in (5).

According to Maue, the drag formula that replaces (30.22) is

$$(9) \quad \frac{P}{2c} = \lambda \frac{\rho}{2} q^2$$

where λ is given by

$$(10) \quad \lambda = \frac{a}{c} \left\{ A\eta - B\eta^2 \sqrt{1 - C\eta^2} - 2C\eta^3 \right\}.$$

Here, A , B , C stand for

$$(11) \quad A = \frac{2\sqrt{2}}{\pi} \beta \sinh \beta, \quad B = \frac{4}{\pi} \sinh \beta (\beta \cosh \beta - \sinh \beta),$$

$$C = \frac{1}{2} (1 - \sinh^2 \beta);$$

the numbers β and η are defined by

$$(12) \quad \beta = \pi \frac{h}{a}, \quad \eta = \frac{u}{q}.$$

The drag coefficient (10) thus depends on three ratios, viz. the two quantities appearing in (12) and a/c that appears in (10).

In Kármán's case $d = a/2$; hence, with $\sinh \beta = 1$ by (8), (11) gives

$$(13) \quad A = 0.794, \quad B = 0.31, \quad C = 0.$$

From (10) Kármán's drag coefficient is now obtained in the form

$$(14) \quad \lambda = \frac{a}{c} \left(0.794 \frac{u}{q} - 0.314 \left(\frac{u}{q} \right)^3 \right),$$

depending only on the ratios a/c and u/q . In the papers quoted on p. 232 these ratios have been obtained from experiments carried out with a flat plate:

$$(15) \quad a/2c = 5.5, \quad u/q = 0.20.$$

With these numerical values (14) gives

$$(16) \quad \lambda = 1.6,$$

a considerably larger value than Kirchhoff's coefficient 0.88 in (30.22). The latter value is too small as already mentioned in connection with the results of Prandtl and his coworkers.

W. Heisenberg¹⁹ has made an attempt to determine the quantities (15) theoretically from certain conservation theorems that should hold in the generation of vortices. He finds, in excellent agreement with Kármán, $a/2c = 5.5$, $u/q = 0.23$, which would yield, by (14), $\lambda = 1.8$.

¹⁹Physik. Z. 23 (1922), 363 with an additional remark of Prandtl.

33. Prandtl's Boundary Layer

It seems unsatisfactory that in all examples of potential flows³⁰ discussed in this chapter the fluid was supposed to be inviscid. However, in the case of an *incompressible* fluid in two- or three-dimensional potential flow the disregard of viscosity has no bearing on the *differential equations*, although it is of decisive importance for the *boundary conditions*.

This can be seen by a glance at the Navier-Stokes equations (16.1). If $\text{curl } \mathbf{v} = 0$ (potential flow) and $\text{div } \mathbf{v} = 0$ (incompressible fluid), the friction term $\mu \nabla^2 \mathbf{v}$ can be dropped entirely from Eqs. (16.1) because of the relation

$$\nabla^2 \mathbf{v} = \text{grad div } \mathbf{v} - \text{curl curl } \mathbf{v}.$$

Hence irrotational solutions of the Euler equations are always solutions of the Navier-Stokes equations: *the viscous forces have no dynamic effect in the interior of the fluid if the flow is irrotational.*

This is no longer true at the boundary between the fluid and a solid wall. While the boundary conditions for a perfect fluid are for this case

$$(1a) \quad v_n = 0, v_t \text{ arbitrary},$$

they read for a viscous fluid according to (10.9) (condition of adherence),

$$(1b) \quad v_n = 0, \quad v_t = 0.$$

It is only in the proximity of the wall that the viscous forces become dynamically important as a consequence of the modified boundary condition (1b). For a flow with large Reynolds numbers we may assume, however, that the modification of the perfect fluid stream pattern due to viscosity does not extend very far into the interior of the fluid.

The existence of the two different types of boundary conditions (1a) and (1b) has its *mathematical* basis in the occurrence of second (spatial) derivatives in the general Navier-Stokes equations in contrast to the Euler equations, that contain only first order derivatives. In order to single out a solution one therefore needs *two* vectorial boundary conditions in the first case and only *one* such condition in the second case. On the other hand, to reconcile *physically* the contradictory conditions (1a) and (1b), a fluid layer is inserted between the presumable region of validity of the potential flow and the wall. In passing through this layer, the thickness of which becomes arbitrarily small with decreasing μ , the tangential velocity v_t drops rapidly to zero. For small but finite μ (air, water), the

³⁰Kármán's vortex street is of course also a potential flow; its vorticity is concentrated in the vortex filaments, that is, in the singularities of the potential. Also the wave motions in Chap. V were treated as potential flows (see p. 168).

layer will still be reasonably thin, provided the overall dimensions of the wetted wall and the immersed bodies are large and the flow is sufficiently fast. The principal part of the flow lies then outside the layer and behaves like the potential flow of a perfect fluid. This idea forms the basis of the boundary layer theory first proposed by Prandtl in 1904.

The actual calculations by Prandtl²¹ and his coworkers have the character of an approximate theory.²² In the calculations which are mostly two-dimensional, inside the boundary layer the influence of the small velocity differences parallel to the layer on the friction terms is neglected. For small μ the thickness of the boundary layer is proportional to $\sqrt{\mu}$. Expressed in terms of the overall Reynolds number of the flow, R , it is proportional to $1/\sqrt{R}$. The pressure gradient normal to the boundary layer is neglected on account of its small width, and the pressure inside the layer therefore identified with the pressure of the adjacent potential flow which impresses, as it were, its own pressure on the whole boundary layer beneath. For the flow immediately adjacent to the boundary layer Bernoulli's equation applies, thus we have for a line element ds in the zone where the boundary layer passes over into the free stream

$$\frac{dp}{ds} = - \rho v_s \frac{dv_s}{ds}.$$

Note that the fluid begins to flow against the pressure gradient if dv_s/ds changes sign from plus to minus at some point.

Further calculation shows that $\partial^2 v_s / \partial n^2$ at $n = 0$ is negative in the region downstream from such a point. If the pressure gradient is large enough $(\partial v_s / \partial n)_{n=0}$ can also become negative, which means that the flow in the immediate neighborhood of the wall is reversed. This leads to the generation of vortices so that downstream from this point the laminar flow is replaced by flow processes of a different character.

The accuracy of this theory is quite high in spite of its approximate character, because the Reynolds numbers that occur in practical cases are usually large. In a given case the theory serves to decide whether the flow will everywhere stick to the rigid boundary and thus essentially remain a potential flow except for the thin boundary layer, or whether separation of the flow will occur, and, consequently, formation of eddies.

For very large v , (corresponding to very large R -values) the assumption of a laminar flow within the boundary layer is no longer correct; the flow

²²The discussion in the text follows a report of Th. v. Kármán in *Vorträge aus dem Gebiet der Hydro- und Aerodynamik* (Innsbruck 1922), Berlin 1924, Springer.

becomes turbulent even inside the narrow boundary layer. This is of importance for the overall flow pattern because the separation point may be shifted downstream quite considerably, if the boundary layer becomes turbulent. An approximate prediction of the behavior of turbulent boundary layers based on a semi-empirical theory, has likewise become feasible.

The flow past a wing is one of the problems which have been solved analytically in this sense, that is, by the application of potential flow theory. The two-dimensional wing theory, the beginnings of which go back to Kutta²³ and Joukowski,²⁴ represents the flow as a plane potential motion with non-vanishing circulation and uses freely the methods of conformal mapping. The mathematical form of the three-dimensional wing theory is due to Prandtl. Here the flow is represented as a three-dimensional potential flow with a discontinuity surface, that may be visualized as a two-dimensional system of vortex filaments. The theory furnishes not only the lift distribution over the span but also the (induced) drag, that is, the dynamic equivalent of the kinetic energy that remains in the flow field behind the wing.

A. Betz and his coworkers developed the theory of the finite wing into a tool for the aeronautical engineer so that today pressure distributions for wings of any plan form (also with deflected ailerons, etc.) can be computed.

SUPPLEMENTARY NOTES ON SELECTED HYDRODYNAMIC PROBLEMS

34. Lagrange's Equations of Motion

Lagrange's equations¹ have been referred to this supplement since they cannot compete with Euler's equations in importance as far as the setting up of hydrodynamic problems is concerned. Before we occupy ourselves with them, we wish to emphasize that Euler's equations, rather than Lagrange's, are the "unusual" equations. In ordinary mechanics we consider a mass point m , or some well defined part of a mechanical system, give it a certain tag q (coordinate) and determine the time rate of change of momentum p , corresponding to q , in accordance with the given forces and constraints. Now, in the case of Euler's equations we consider a *volume element* $d\tau$ and identify it rather than the mass element $\rho d\tau$, by coordinates; we again determine the change of momentum in accordance with the given forces and constraints, but we do this at the *space-fixed* element $d\tau$ (note that the pressure plays the role of a constraint, cf. 12). The mass element that occupies $d\tau$ at the given instant is lost sight of thereafter.

On the other hand, when setting up Lagrange's equations we follow the usual procedure and ascribe to the mass element dm certain tags a, b, c , e.g. its coordinates x_0, y_0, z_0 at the time $t = 0$. We ask then for the location x, y, z of this element dm at the time t . Thus x, y, z and the pressure p are the dependent variables, while a, b, c and the time t are the independent variables of Lagrange's equations.

No difference has now to be made between local acceleration $\partial v / \partial t$ and material acceleration dv / dt . The material acceleration which is the decisive parameter in the momentum balance, is now directly given by²

$$\frac{\partial^2 x}{\partial t^2}, \quad \frac{\partial^2 y}{\partial t^2}, \quad \frac{\partial^2 z}{\partial t^2},$$

¹The usual terminology is historically not correct, as it so often happens: "Lagrange's equation" occurs actually in the papers of Euler quoted on p. 84.

²This notation seems to be more consistent than the notation d^2x/dt^2 used by Kirchhoff and sometimes found in text books.

The equations that determine the acceleration vector are:

$$(1) \quad \frac{\partial^2 x}{\partial t^2} \frac{\partial x}{\partial a} + \frac{\partial^2 y}{\partial t^2} \frac{\partial y}{\partial a} + \frac{\partial^2 z}{\partial t^2} \frac{\partial z}{\partial a} = - \frac{\partial}{\partial a} \frac{U + p}{\rho}$$

and two corresponding equations to be formed with respect to b and c , instead of a . Eq. (1) follows from (11.2) if the component equations of (11.2) are multiplied by $\partial x/\partial a$, $\partial y/\partial a$, $\partial z/\partial a$, respectively and added, provided the fluid is incompressible ($\rho = \text{const}$) and the external force has a potential U ($\mathbf{F} = -\text{grad } U$). Equations (1) are non-linear, but so are Euler's equations; if Lagrange's equations were linear they would indeed present a tremendous advantage.

The derivative $\partial/\partial a$ means of course that b , c and also the fourth variable t are to be kept constant; we have e.g.

$$\frac{\partial U}{\partial a} = \frac{\partial U}{\partial x} \frac{\partial x}{\partial a} + \frac{\partial U}{\partial y} \frac{\partial y}{\partial a} + \frac{\partial U}{\partial z} \frac{\partial z}{\partial a}.$$

Note, that (1) contains no other differentiations than with respect to the four independent variables a , b , c , t and that they apply only to the four dependent variables x , y , z , p (and to the given function U).

The three equations (1) must be supplemented by the condition of incompressibility. Now the ratio of the instantaneous volume $d\tau$ to the initial volume $d\tau_0$ is (as in any point transformation) given by the functional determinant (Jacobian)

$$(2) \quad \frac{d\tau}{d\tau_0} = \begin{vmatrix} \frac{\partial x}{\partial x_0} & \frac{\partial x}{\partial y_0} & \frac{\partial x}{\partial z_0} \\ \frac{\partial y}{\partial x_0} & \frac{\partial y}{\partial y_0} & \frac{\partial y}{\partial z_0} \\ \frac{\partial z}{\partial x_0} & \frac{\partial z}{\partial y_0} & \frac{\partial z}{\partial z_0} \end{vmatrix}$$

or, with the usual abbreviation, by

$$(2a) \quad \frac{d\tau}{d\tau_0} = \frac{\partial(x, y, z)}{\partial(x_0, y_0, z_0)}.$$

The x_0 , y_0 , z_0 can be expressed in terms of the tags a , b , c ; according to the multiplication theorem for determinants the right member of (2) then becomes the product of the two functional determinants

$$\frac{\partial(x, y, z)}{\partial(a, b, c)} \quad \text{and} \quad \frac{\partial(a, b, c)}{\partial(x_0, y_0, z_0)}.$$

The last determinant is evidently independent of the time t . The invariability of (2) in course of time, i.e. the condition of incompressibility, can thus be written in the form:

$$(3) \quad \frac{\partial D}{\partial t} = 0, \quad D = \frac{\partial(x, y, z)}{\partial(a, b, c)}.$$

It contains only differentiations of the three dependent variables x, y, z with respect to the four independent variables a, b, c, t .

The set (1) and Eq. (3) are Lagrange's equations for incompressible fluids.

The corresponding relations for compressible fluids are obtained from (1), if one replaces

$$(3a) \quad \frac{p}{\rho} \quad \text{by} \quad \phi = \int \frac{dp}{\rho} \quad \text{and} \quad \frac{U}{\rho} \quad \text{by} \quad V,$$

where V is the potential per unit of mass of the external force. In addition, (3) must be replaced by

$$(3b) \quad \frac{\partial}{\partial t} (\rho D) = 0.$$

Kirchhoff* used Lagrange's equations in a rigorous proof of Helmholtz's theorems on vortex conservation and was therefore able to avoid the use of formula (18.8), which we had to use, since our proof starts from Euler's equations.

35. Stokes's Resistance Law

On p. 78 we discussed the very slow ("creeping") motion of a viscous incompressible fluid as an example for a flow the dynamics of which is almost exclusively determined by viscous forces; the next step would be neglecting the inertia forces altogether. According to the value of the Reynolds number (16.8)

$$R = \frac{va}{\nu}, \quad \nu = \frac{\mu}{\rho},$$

we decide when omission of the inertia terms is justifiable, the condition being

$$(1) \quad R \ll 1.$$

The problem which interests us here,—it is usually connected with the name of Stokes—is the steady motion of a sphere through a liquid. Let

*Vorlesungen über Mechanik, Chap. XIV, 1.

a be the radius of the sphere and v its velocity which has become uniform after a short initial period. The motion proceeds under the influence of an external force such as the difference of gravity and buoyancy, possibly an electric field, etc. Condition (1) can not only be satisfied by a large value of the kinematic viscosity ν , but also by sufficiently small values of a or v . Instead of moving the sphere through the fluid one may as well keep the sphere at rest and have the fluid flow past the sphere (inverse flow); the resultant pressure force acting on the sphere is then equal to the resistance force encountered by the sphere in the direct flow.

Stokes resistance law plays an important role in the evaluation of certain fundamental experiments in physics. Einstein made use of it in his theory of the Brownian motion which leads to a determination of Loschmidt's number (cf. p. 53). Later it has become important again in Millikan's determination of the electronic charge.

We consider the steady state of the motion. The weight of the sphere is then balanced by the resultant friction forces and cannot appear in the equations or boundary conditions. Adopting now the viewpoint of the inverse motion, we take as a starting point the *equilibrium conditions* for a viscous fluid (10.8a, b), that is, the Navier-Stokes equations with omission of the inertia terms. The body force F of gravity acting on the fluid can be disregarded. In other words, we have now a kinematic problem defined by a system of equations, which reads in Cartesian coordinates:

$$(2) \quad \frac{\partial p}{\partial x} = \mu \nabla^2 u, \quad \frac{\partial p}{\partial y} = \mu \nabla^2 v, \quad \frac{\partial p}{\partial z} = \mu \nabla^2 w;$$

it is to be supplemented by the condition of incompressibility

$$(2a) \quad \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0$$

and by the boundary conditions of the problem. Let the origin coincide with the center of the sphere, the z -axis pointing in the direction opposite to the motion of the sphere (the fluid flows past the sphere in the direction of the positive z -axis). From (2) and (2a) we have directly

$$(3) \quad \nabla^2 p = 0.$$

We now introduce spherical coordinates r, ϑ, φ referring again to the center of the sphere, so that e.g.

$$(4) \quad \cos \vartheta = \frac{z}{r}.$$

The spherically symmetric solution of (3) is, according to (19.22),

$$(5) \quad p = \frac{A_0}{r}.$$

but our problem is not spherically symmetric, the z -axis being the preferred direction in which the fluid moves toward the sphere. We consider therefore the expression

$$(5a) \quad p = A_1 \frac{\partial}{\partial z} \frac{1}{r},$$

which obviously is also a solution of (3). On carrying out the differentiation in (5a) and replacing A_1 by A , we obtain, because of (4),

$$(5b) \quad p = -\frac{A}{r^3} \cos \vartheta.$$

A much more general solution of (3) is obtained in the form of the series

$$(5c) \quad p = \sum_{n=0}^{\infty} A_n \frac{\partial^n}{\partial z^n} \frac{1}{r},$$

the first two terms of which coincide with (5) and (5a) respectively. Eq. (5c) represents an expansion in terms of negative powers of r , the coefficients being the spherical harmonics $P_n(\cos \vartheta)$. Without giving here the general definition of spherical harmonics, we note that the factors 1 and $\cos \vartheta$ appearing in (5) and (5a) are spherical harmonics in the usual normalization: $P_0(\cos \vartheta) = 1$, $P_1(\cos \vartheta) = \cos \vartheta$, and that the spherical harmonics with higher subscripts are polynomials in $\cos \vartheta$ of higher order. (Legendre's polynomials). Since in our boundary conditions [(12a, b), see below] only the first power of $\cos \vartheta$ appears, we conclude that in (5c) only the term with $n = 1$ lends itself to our purpose; when we put $A_0 = A_2 = A_3 = \dots = 0$, the series (5c) reduces to our trial solution (5b).

We first have to write equations (2) in their legitimate vectorial form. This is done by means of Eq. (3.10a) which supplies, because of $\text{div } \mathbf{v} = 0$,

$$(6) \quad \mu \text{curl curl } \mathbf{v} = -\text{grad } p$$

instead of (2). It is now easy to pass over to spherical coordinates. We denote the components of the velocity vector \mathbf{v} taken in direction r, ϑ, φ by $v_r, v_\vartheta, v_\varphi$, and observe that the φ -component must vanish because of the axial symmetry of the problem; also, all differential quotients with respect to φ must vanish, in other words,

$$(7) \quad v_\varphi = 0, \quad \frac{\partial}{\partial \varphi} = 0.$$

The r -component of Eq. (6) is, according to the solution of problem I.3, or, according to Appendix III and IV,

$$(8) \quad \frac{\mu}{r^2} \left[\frac{\partial^2 (r^2 v_r)}{\partial r^2} + \frac{1}{\sin \vartheta} \frac{\partial}{\partial \vartheta} \left(\sin \vartheta \frac{\partial v_r}{\partial \vartheta} \right) \right] = \frac{\partial p}{\partial r}.$$

Here we assume the r and ϑ dependence of v_r in the form

$$(8a) \quad v_r = R \cos \vartheta,$$

where R denotes a function dependent on r alone. Substituting in (8) and expressing p according to (5a), we obtain, after dropping the factor $\cos \vartheta$, the ordinary differential equation for R

$$\frac{\mu}{r^3} \left(\frac{d^2}{dr^2} (rR) - \frac{2}{r} R \right) = \frac{2A}{r^3},$$

which may also be written

$$(9) \quad r^3 R'' + 2rR' - 2R = \frac{2A}{\mu}.$$

A particular integral of (9) is $R = -A/\mu$ and the general integral of the associated homogeneous equation

$$R = Br + \frac{C}{r^2},$$

hence the general integral of (9) is according to a well known theorem

$$R = \frac{-A}{\mu} + Br + \frac{C}{r^2}$$

and the velocity component v_r is found

$$(10) \quad v_r = \left(-\frac{A}{\mu r} + B + \frac{C}{r^3} \right) \cos \vartheta.$$

The component v_ϑ may now be found from the condition of incompressibility (see solution of problem I.3) the form of which suggests a trial separation $v_\vartheta = R_1 \sin \vartheta$, where again R_1 depends on r alone. One finds easily

$$R_1 = \frac{A}{2\mu r} - B + \frac{C}{2r^3},$$

hence

$$(11) \quad v_\vartheta = \left(\frac{A}{2\mu r} - B + \frac{C}{2r^3} \right) \sin \vartheta.$$

The constants of integration A, B, C must be determined so as to satisfy the boundary conditions of the problem. If q denotes the undisturbed flow velocity at infinity, the boundary conditions are

$$(12a) \quad r = a : v_r = v_\vartheta = 0$$

$$(12b) \quad r = \infty : v_r = q \cos \vartheta, \quad v_\vartheta = -q \sin \vartheta.$$

Eq. (12b) is fulfilled if we put $B = q$; then Eqs. (12a) can be solved for A and C and give

$$\frac{A}{\mu} = \frac{3q}{2} a, \quad C = \frac{q}{2} a^3;$$

hence we obtain finally

$$\begin{aligned} v_r &= q \left(1 - \frac{3}{2} \frac{a}{r} + \frac{1}{2} \frac{a^3}{r^3} \right) \cos \vartheta \\ (13) \quad v_\vartheta &= q \left(-1 + \frac{3}{4} \frac{a}{r} + \frac{1}{4} \frac{a^3}{r^3} \right) \sin \vartheta \end{aligned}$$

and by (5b)

$$(13a) \quad p = -\frac{3}{2} \mu q a \frac{\cos \vartheta}{r^2}.$$

The result shows that the choice of the special solution (5b) in place of the more general one (5c) was in order. It is true that we have not proved that (13) and (13a) are the only possible solutions of our problem. On the other hand we are convinced that every problem of mathematical physics that has been correctly formulated can have only *one* solution.

We have yet to derive the formula for the *resistance* experienced by the *moving* sphere or, which is the same, for the pressure force acting on the sphere at *rest*; it is composed of the following two parts: the component of the hydrodynamic pressure force in the direction of the positive z -axis and the contribution of the viscous pressure force in the same direction.

The *hydrodynamic* pressure acts *radially*. According to (13a) its component in the positive z -direction is at the surface of the sphere, that is for $r = a$

$$-p \cos \vartheta = \frac{3}{2} \mu \frac{q}{a} \cos^2 \vartheta.$$

Integration over the sphere whose surface element is $2\pi a^2 \sin \vartheta d\vartheta$ gives

$$(14) \quad 3\pi\mu a q \int_0^\pi \cos^2 \vartheta \sin \vartheta d\vartheta = 3\pi\mu a q \int_{-1}^{+1} x^2 dx = 2\pi\mu a q.$$

To calculate the *viscous pressures*, we start from Eq. (10.2) which correlates the tensors p_{ik} and $\dot{\epsilon}_{ik}$ and is valid in any orthogonal coordinate system, hence also in our polar coordinates. In the present notation we have

$$(15) \quad p_{rr} = -2\mu \dot{\epsilon}_{rr}, \quad p_{r\vartheta} = -2\mu \dot{\epsilon}_{r\vartheta}.$$

The displacements ϵ have been defined in curvilinear coordinates in Eqs. (4.26) and (4.28). The rates of displacement $\dot{\epsilon}$ are obtained from these equations if the $\delta q_1, \delta q_2, \delta q_3$ are replaced by the components of the velocity

$$v_r, v_\vartheta, v_\varphi, \quad (v_\varphi = 0)$$

and the p_1, p_2, p_3 by r, ϑ, φ . Since $ds^2 = dr^2 + r^2 d\vartheta^2 + r^2 \sin^2 \vartheta d\varphi^2$, one has $g_1 = 1, g_2 = r, g_3 = r \sin \vartheta$. Hence (4.26) yields

$$(16) \quad \dot{\epsilon}_{rr} = \frac{\partial v_r}{\partial r}$$

and (4.28)

$$(17) \quad 2\dot{\epsilon}_{r\vartheta} = \frac{1}{r} \frac{\partial v_r}{\partial \vartheta} + \frac{\partial v_\vartheta}{\partial r} - \frac{1}{r} v_\vartheta.$$

When we substitute for the velocity components according to (13), only the middle term of (17) gives a non-vanishing contribution for $r = a$, so that

$$\dot{\epsilon}_{rr} = 0, \quad \dot{\epsilon}_{r\vartheta} = -\frac{3}{4} \frac{q}{a} \sin \vartheta.$$

According to (15), the friction pressures are then

$$(18) \quad p_{rr} = 0, \quad p_{r\vartheta} = \frac{3}{2} \frac{\mu q}{a} \sin \vartheta.$$

The component of $p_{r\vartheta}$ in the positive z -direction is

$$p_{r\vartheta} \sin \vartheta = \frac{3}{2} \frac{\mu q}{a} \sin^2 \vartheta$$

which must be integrated over the sphere:

$$(19) \quad 3\pi\mu a q \int_0^\pi \sin^3 \vartheta d\vartheta = 3\pi\mu a q \int_{-1}^{+1} (1-x^2) dx = 4\pi\mu a q.$$

This together with the contribution (19) gives Stokes's famous resistance formula

$$(20) \quad D = 6\pi\mu a q.$$

Analogous to the problem of the sphere in uniform translatory motion q is the problem of a sphere rotating uniformly, with angular velocity ω . In this case the opposing moment⁴ (see problem VII.4) is

$$(21) \quad M = 8\pi\mu a^3 \omega.$$

⁴Cf. Kirchhoff, Vorlesungen über Mechanik, Chap. XXVI, 3.

These results are valid for liquids and gases at ordinary pressures. For gases at low pressures one has to add a correction term to Eq. (20) which is due to Cunningham. In the corrected formula the right member of (20) appears with the denominator

$$(22) \quad 1 + \alpha \frac{l}{a},$$

where l is the *mean free path* of the gas molecules, which increases with decreasing pressure; the physical interpretation of the numerical coefficient α is somewhat problematical.⁴ Cunningham's correction was of great importance in the determination of the electronic charge according to Millikan's method.

To introduce the concept of the mean free path means to leave behind the framework of a continuum theory and enter the domain of statistical mechanics. The continuum theory which has led us to Stokes' formula is only valid on a scale that is large in comparison with l . In our case, the scale is set by the radius a . Cunningham's correction term is subject to the same condition if it is to be considered a correction: this is no longer the case if $l \sim a$, as one sees directly from (22), and a comprehensive treatment of the problem is then no longer feasible.

Another limitation of our considerations is that they are only good for *small* Reynolds numbers [cf. inequality (1)]. When R increases, the inertia terms that have been neglected so far gain in importance; the laminar character of the flow, however, is still maintained, disregarding some vortices in the wake. The resistance law, which was linear in q for Stokes's case now assumes by and by a quadratic character. Full turbulence is only reached at a certain $R = R_{crit}$, at which, in addition to the wake, the entire flow field in the neighborhood of the sphere becomes turbulent. At this point the resistance law changes its character suddenly.

Let us now have a critical look at the omission of the inertia terms in the preceding analysis. According to (5b), we have the following asymptotic behavior at $r \rightarrow \infty$:

$$p \sim \frac{1}{r^2}, \quad \text{hence } \text{grad } p \sim \frac{1}{r^3}.$$

The terms $\nabla^2 u$, $\nabla^2 v$, $\nabla^2 w$ retained in Eq. (2) have the same order of magnitude as $\text{grad } p$. The inertia terms which we neglected vanish at $r \rightarrow \infty$ partly with the third, but partly with a smaller power of $1/r$. The latter happens in the case of those inertia terms which read in Cartesian components u , v , w

⁴Th. Sexl, Zur gaskinetischen Begründung der Stokes-Cunningham'schen Formel, Ann. Physik. 81 (1926) 855.

$$(23) \quad \rho w \frac{\partial u}{\partial z}, \quad \rho w \frac{\partial v}{\partial z}, \quad \rho w \frac{\partial w}{\partial z}.$$

When these terms are calculated from (13) they are found to vanish only as $1/r^2$. It is true that the Navier-Stokes equations can be rewritten in such a way that the Reynolds number $R = qa/\nu$ appears in these terms (introduce the dimensionless coordinates x/a , etc. and suitably rearrange the factors ρ , μ , and a , cf. 16). But although R is supposed to be small, this cannot change the fact that the ratio of the neglected terms (23) to the terms retained becomes arbitrarily large if $r \rightarrow \infty$.

On account of this Oseen devised a treatment of the problem that retains the terms (23) in principle, but replaces them by their first order approximation⁶

$$(23a) \quad \rho q \frac{\partial u}{\partial z}, \quad \rho q \frac{\partial v}{\partial z}, \quad \rho q \frac{\partial w}{\partial z}.$$

The integration of the equations so augmented is by no means simple and forms one of the principal parts of Oseen's book quoted on p. 210. In the light of his result our preceding formulas appear as the first term of a power series expansion in terms of the Reynolds number R . In particular, the resistance law (20) has the form

$$(24) \quad W = 6\pi\mu a q \left(1 + \frac{3}{8}R\right),$$

when the first order term is retained.

Fortunately the validity of Stokes result which has found such wide acceptance in experimental and theoretical physics is not perceptibly affected by this correction; this is due to condition (1), the fulfillment of which we have assumed throughout our discussion of laminar motion. On account of Eq. (24) one can now comprehend why the transition from the linear to the quadratic resistance law mentioned before does not proceed suddenly but gradually. The onset of full turbulence, however, at $R = R_{crit}$, cannot be understood in this way.

36. The Hydrodynamic Theory of Lubrication

Lubrication today is essentially a problem of "creeping" motion. In older text books of applied mechanics the friction between journal and bearing was treated as a problem of *dry* friction. The arguments put forth had nothing to do with hydrodynamics and are only mentioned here to point out the contrast to the later developments.

⁶Thus an error is introduced at $r = a$, where actually $w = 0$ and not $= q$, and the error for $r \rightarrow \infty$ is diminished but that should not imply that Oseen's calculation leaves anything to be desired in the way of mathematical rigor.

In order to apply the ordinary concepts of friction theory developed in Vol. I, 14⁷ one must assume direct contact between journal and bearing. In Fig. 58 the journal pressure P , which is referred to the unit of length of the bearing, has been drawn vertically downward. This should not imply that it is actually vertical. In general it is composed of the gravity load, possible components of the driving force and inertia effects; it will therefore be inclined to the vertical.

At the point of contact B the acting forces are the friction R , which is opposite to the sense of rotation, and the normal pressure N . The re-

FIG. 58 (left). Relative position of journal and bearing according to the assumption of dry friction.

FIG. 59 (right). Fluid friction in the case of the centered journal.

sultant of the two, Q , forms the angle of friction α with N (α means here the kinetic angle of friction, defined by the coefficient of kinetic friction f according to $f = \tan \alpha$). The equilibrium condition requires that Q and P are antiparallel and equal. The remaining couple QP then represents the moment of friction about the centerline of the journal which is balanced by an opposite driving moment. If r denotes the radius of the journal and $r \sin \alpha$ the arm of the couple, we have

$$(1) \quad M = Pr \sin \alpha.$$

According to this the moment of friction should be *independent of the circumferential velocity U and proportional to the journal pressure P* ; the point of contact B should be situated *behind* the vector of the journal pressure, in reference to the sense of rotation.

The Russian engineer and officer N. Petroff was the first to look at this problem from the point of view of the viscosity of the lubricant.* In

⁷See e.g. Synge and Griffith, *op. cit.*, Sec. 3.2.

*Cf. Petroff, N. Friction in Machines and the Effect of the Lubricant (in Russian), Eng. Jour., St. Petersburg. 1883, a German translation in Ostwalds Klassiker, No. 218 (Leipzig). In the same volume also the following papers: Reynolds, On the Theory of Lubrication etc., Phil. Trans. Roy. Soc. Vol. 177 pt. I, 1886, or Papers, Cambridge 1901,

his conception the journal is exactly centered in the bearing so that the surrounding lubricant forms a layer of uniform thickness d (see Fig. 59). Throughout this layer the velocity drops from its value U at the journal to the value zero at the bearing in an approximately linear way. The tangential friction pressure at the bearing is then $\mu U/d$. By summation over the circumference one obtains the moment of friction per unit of length

$$(2) \quad M = 2\pi\mu \frac{U}{d} r^2.$$

This dependence is inverse to that of (1), since we have now *proportionality with U and independence of P* ; also, the factor μ points to the lubricant and not to the materials of journal and bearing like $\sin \alpha$ in (1).

The equilibrium conditions of statics, however, are not satisfied by (2) since the journal pressure P can never be balanced by the friction forces. Reynolds came therefore to the conclusion that the actual position of the journal in the bearing is not the central one; it could only be central for infinitely large circumferential velocity U . In addition Reynolds showed that the point of smallest layer thickness h is not behind P but *in front* of it. Unfortunately, Reynolds formulas are difficult to understand, since his calculations refer to bearings with only partially encased journals, as of railroad cars.

Fully encased journals with complete peripheral lubrication, the most desirable type for high speed electrical machinery, lend themselves to a comprehensive analysis, (cf. the third of the papers quoted in the footnote. Only a little later and under the influence of this paper Mitchell carried out his construction of the particular type of step bearing that has been named after him and has become important for heavy thrust bearings in turbines with vertical shafts.)

The essential point is that the journal is displaced in the direction normal to the journal pressure while it runs (see Fig. 60). The foundation of the theory of the *bearing* is obtained by an approximate calculation of the flow pattern of the *fluid wedge* in Fig. 61, where we neglect the y -component v of the velocity in comparison with the x -component u ; w is exactly zero, since the problem is considered as two-dimensional. According to the fundamental equations of "creeping" motion (35.2) and (35.2a) we then have

Vol. II; Sommerfeld, Zur hydrodyn. Theorie der Schmiermittelreibung, Z. Math. Phys., 50, 1904. Mitchell, A. G. M. The Lubrication of Plane Surfaces, Z. Math. Phys., 52, 1905; Sommerfeld, Zur Theorie der Schmiermittelreibung, Z. techn. Phys., 2, 1921.—More recent literature e.g. in Hersey, M. D., Theory of Lubrication, New York 1938, Wiley.

$$p = p(x), \quad u = u(y), \quad \frac{dp}{dx} = \mu \frac{d^2 u}{dy^2},$$

or

$$u = \frac{1}{2\mu} \frac{dp}{dx} y^2 + ay + b;$$

this yields because of the boundary condition $u = U$ for $y = 0$ (journal) and $u = 0$ for $y = h$ (bearing)

$$(3) \quad u = U \left(1 - \frac{y}{h}\right) - \frac{1}{2\mu} \frac{dp}{dx} y h \left(1 - \frac{y}{h}\right).$$

The flux through the cross-section is

$$\int_0^h u \, dy = \frac{h}{2} U - \frac{h^3}{12\mu} \frac{dp}{dx}.$$

Although h is variable in Fig. 61, the flux must be the same for all cross-sections (condition of incompressibility!). Thus, if h_0 denotes an assumed cross-section at which $dp/dx = 0$, we have

$$(4) \quad \frac{h^3}{6\mu} \frac{dp}{dx} = (h - h_0) U.$$

From (3) and (4) the friction pressure per unit of area of the boundary $y = 0$ is found

$$(4a) \quad p_{zs} = \mu \frac{du}{dy} = -\mu \frac{4h - 3h_0}{h^3} U.$$

Now transfer these results from Fig. 61 to Fig. 60, introducing the following notations: O , r and O' , r' are center and radius of journal and bearing, respectively, the excentricity $e = \text{distance } OO'$, $d = r' - r$ is

FIG. 60 (left). The journal is shifted normal to the direction of the journal pressure.

FIG. 61 (right). Simplified scheme of a lubricant film of variable thickness.

the play, A is a variable point at the bearing surface, characterized by the angle φ whose vertex is at O . We have correspondingly

$$OA = r + h, \quad O'A = r', \quad r + h = e \cos \varphi + r'.$$

The last (approximate) equation, obtained by projecting the segments OO' and $O'A$ on the line OA , can be written in the form

$$(5) \quad h = d + e \cos \varphi.$$

This meaning of h is now introduced into Eqs. (4) and (4a) in order to adapt⁹ them to the conditions of Fig. 60:

$$(6) \quad \frac{1}{r} \frac{dp}{d\varphi} = 6\mu U \left(\frac{1}{h^2} - \frac{h_0}{h^3} \right),$$

$$(6a) \quad p_{,r} = -\mu U \left(\frac{4}{h} - \frac{3h_0}{h^2} \right).$$

By integration with respect to φ between the limits 0 and 2π one has

$$(7) \quad p(2\pi) - p(0) = 6\mu r U (J_2 - h_0 J_3),$$

$$(7a) \quad M = -\mu r^2 U (4J_1 - 3h_0 J_2).$$

As before, M stands for the friction moment transferred to the journal per unit of length; the J 's serve as abbreviations for

$$(8) \quad \begin{aligned} J_1 &= \int_0^{2\pi} \frac{d\varphi}{d + e \cos \varphi} = 2\pi(d^2 - e^2)^{-1/2}, \\ J_2 &= \int_0^{2\pi} \frac{d\varphi}{(d + e \cos \varphi)^2} = 2\pi d(d^2 - e^2)^{-3/2}, \\ J_3 &= \int_0^{2\pi} \frac{d\varphi}{(d + e \cos \varphi)^3} = 2\pi \left(d^2 + \frac{1}{2} e^2 \right) (d^2 - e^2)^{-5/2}. \end{aligned}$$

If the value given for the integral J_1 is known, the values of J_2 and J_3 can be found according to

$$J_2 = -\frac{\partial J_1}{\partial d}, \quad J_3 = -\frac{1}{2} \frac{\partial J_2}{\partial d}.$$

Since p must have the period 2π , one concludes from (7) and (8)

$$(9) \quad h_0 = \frac{J_2}{J_3} = d \frac{d^2 - e^2}{d^2 + \frac{1}{2} e^2}.$$

⁹It would not have been difficult to derive these equations directly in polar coordinates instead of in coordinates x, y, z as we did it.

With this value of h_0 the moment becomes

$$(10) \quad M = - \frac{2\pi\mu r^2 U}{\sqrt{d^2 - e^2}} \frac{d^2 + 2e^2}{d^2 + \frac{1}{2}e^2}.$$

Putting in analogy to (5)

$$(11) \quad h_0 = d + e \cos \varphi_0,$$

one obtains from (9)

$$(11a) \quad \cos \varphi_0 = - \frac{3}{2} \frac{de}{d^2 + \frac{1}{2}e^2}.$$

If $e = 0$ (centered position of the bearing), we have

$$\cos \varphi_0 = 0, \quad \varphi_0 = \frac{\pi}{2} \quad \text{or} \quad \frac{3\pi}{2};$$

on the other hand, we obtain in the case of the largest possible eccentricity $e = d$

$$\cos \varphi_0 = -1, \quad \varphi_0 = \pi.$$

Now, the definition of h_0 according to (6) has been

$$\frac{dp}{d\varphi} = 0 \quad \text{for} \quad h = h_0,$$

therefore the two values φ_0 belonging to h_0 determine the points of minimum and maximum pressure. In the centered position these points are diametrically opposite to each other. At maximum eccentricity, that is to say, if contact is made between journal and bearing, they coincide at the point of contact.

FIG. 62. Equilibrium between the hydrodynamic pressures p , q , and the bearing pressure P .

Our next task is to relate the pressure distribution to the direction of the vector of the journal pressure.

We notice that the pressure gradient $dp/d\varphi$ depends only on h [see (6)], and is therefore an *even* function of φ , as h is itself, when we count φ from

the zero line OO' . The pressure itself is consequently an *odd* function of φ , say p_1 , plus an integration constant, say p_0 . In forming the sum total of the pressure forces, the contribution of the *constant* pressures p_0 obviously vanishes. Denoting by p_A and $p_{\bar{A}}$ the pressure values p_1 at two symmetrically situated points relative to $\varphi = 0$, we find the resultant action on the journal indicated in the larger of the two force parallelograms in Fig. 62: it is normal to OO' .

Applying the same reasoning to Eq. (6a), we see that the *friction pressures* (shear stresses) at the journal surface are *even* functions of φ ; they are indicated by q_A , $q_{\bar{A}}$ in the figure (note, however, their tangential direction opposite to the sense of increasing φ). By construction of the corresponding parallelogram of forces at O we see that the friction pressures at A and A' give also a resultant *normal* to OO' . Thus the overall resultant of the hydrodynamic forces acting on the journal is normal to OO' . Since this resultant balances the journal pressure P , it must be opposite to P , in other words, *the displacement of the journal is normal to the journal pressure P* , a result anticipated in Fig. 60.

The *value* of the displacement e can now be determined. One has only to form the sum of the resultants of p and q and balance it against the prescribed value of P :

$$(12) \quad \frac{P}{r} = \int p \sin \varphi \, d\varphi - \int q \cos \varphi \, d\varphi.$$

The first term can be transformed by partial integration; one of the two resulting terms, $[-p \cos \varphi]_0^{2\pi}$, vanishes because of the periodicity. Altogether (12) becomes

$$(12a) \quad \frac{P}{r} = \int \left(\frac{dp}{d\varphi} - q \right) \cos \varphi \, d\varphi.$$

Here the term q may be omitted since $dp/d\varphi$ outweighs $q = p_{r\varphi}$ by a full order of magnitude of r/h [cf. Eqs. (6) and (6a)]. Hence we obtain the simpler relation

$$(12b) \quad \frac{P}{r} = 6\mu r U (J_4 - h_0 J_6)$$

where

$$J_4 = \int \frac{\cos \varphi \, d\varphi}{(d + e \cos \varphi)^3}, \quad J_6 = \int \frac{\cos \varphi \, d\varphi}{(d + e \cos \varphi)^5}.$$

From (8) we find easily

$$J_4 = \frac{1}{e} (J_1 - d \cdot J_2), \quad J_6 = \frac{1}{e} (J_2 - d \cdot J_3).$$

If this is substituted in (12b) and the value of h_0 taken from (9), an elementary calculation gives the result

$$(13) \quad \frac{P}{2\pi\mu U} \frac{d^2}{r^2} = \frac{3e}{\sqrt{d^2 - e^2}} \frac{d^2}{d^2 + \frac{1}{2}e^2}.$$

The excentricity e or rather the ratio e/d is here determined as a function of the left member of (13). This value of e , substituted in (10), leads to the determination of the moment M . In what follows we are only interested in the magnitude and not in the sign of the moment. Note, that a particularly simple expression for M is obtained, if (10) is divided by (13):

$$(13a) \quad \frac{M}{P} = \frac{d^2 + 2e^2}{3e}.$$

In discussing this result, we first consider two limiting cases:

a) $U \rightarrow \infty$. From (13) we have $e = 0$, that is, the journal is centered; Eq. (10) yields immediately

$$(14) \quad M = 2\pi\mu r^2 \frac{U}{d},$$

which is Petroff's equation.

b) $U \rightarrow 0$. In this case, (13) requires $e = d$, that is, contact between journal and bearing. Eq. (13a) gives accordingly $M = Pd$ which we may also write in the form

$$(15) \quad M = rP \cdot \frac{d}{r}.$$

This becomes identical with our formula (1) for dry friction if we define the angle of friction in the present case by $\sin \alpha = d/r$.

c) We are also interested in the case where M is a minimum for given journal pressure P and given play d . When the differential quotient of the right member of (13a) with respect to e is set equal to zero, one obtains

$$-\frac{d^2}{e^3} + 2 = 0, \quad e = \frac{d}{\sqrt{2}}.$$

With this value of e Eq. (13a) gives for the moment of friction

$$(16) \quad M = \frac{2\sqrt{2}}{3} Pd = 0.94 Pd.$$

that is, only 6% less than the limit of M for $U \rightarrow 0$, which has been determined in (15).

These results are collected in the diagram of Fig. 63. Here the dimensionless quantity $y = M/Pd$ has been plotted as ordinate over the abscissa z , which is the reciprocal of the left side of (13), viz.

$$(17) \quad z = \frac{2\pi\mu U}{P} \frac{r^2}{d^2}^{10}$$

The solid curve represents the content of the two Eqs. (10) and (13), that is to say, the result of the elimination of the displacement e . It is best computed from the following parametric representation which is identical with (13a) and (13) or (10) and (13):

$$(18) \quad y = \frac{1 + 2\beta^2}{3\beta}, \quad z = \sqrt{1 - \beta^2} \frac{1 + \frac{1}{2}\beta^2}{3\beta}, \quad \beta = \frac{e}{d}.$$

In the same figure formulas (1) and (2) have been plotted as broken lines; in the present variables they simply read $y = 1$ and $y = z$, the tangents

FIG. 63. Comparison between theory and experiment in terms of the dimensionless variables $y = M/Pd$ and $z = 2\pi\mu U r^2 / Pd^2$.

of the solid curve at $z = 0$ and $z = \infty$. The fact that our curve depends solely on the dimensionless quantity z expresses a *similarity law* which is valid in the hydrodynamic theory of lubrication: No matter what particular values of the dimensions r and d , the lubricant μ , the speed U , and the load P combine to give a certain z , it will always lead to the same $\beta = e/d$ and thus to the same value $y = M/Pd$ by (18).

When we now ask how well this theoretical result is confirmed by measurements on actual bearings, the answer is this: in the neighborhood of the minimum and to the right of it for not too large z -values we have not only qualitative but numerical agreement between theoretical and experimental values. One would then conclude that in this range the phenomenon of lubrication is determined entirely by the coefficient of viscosity μ , and that the laminar character of the motion, which we have assumed throughout this analysis, actually occurs. But for large and for very small z -values deviations from the theoretical curve occur, as indicated by the

¹⁰This expression is sometimes called the Sommerfeld variable in lubrication literature.

dotted branches in the figure. Since in these regions the similarity law is no longer valid, the proper representation should consist of a family of curves y vs. z depending on the variation of one of the parameters P , U etc.

The empirical curve does not rise nearly so steeply for large z -values as the theoretical curve, which has been interpreted to indicate that the motion of the lubricant is no longer laminar but turbulent.

For very small z -values the actual rise is very much steeper than it should be according to our theory. Here, qualities of the lubricant other than its viscosity become prevalent; they have been given the name of *oiliness* and refer to the adhesion of the lubricant to the metallic boundaries of the bearing. It is highly probable that the strength of adhesion be connected with the formation of monomolecular layers as studied by Langmuir, which originate in the parallel orientation of the chain molecules along the surface of the oil. However, a discussion of the physical problems of "boundary lubrication" would lead us far beyond the limits of classical hydrodynamics.

So far we have treated our problem as two-dimensional, assuming an *infinitely long* bearing. Introducing a finite bearing length means to impose new boundary conditions on pressure and velocity. For the designer the practical problem arises to regulate the inflow of the lubricant and its outflow at the ends of the bearing in such a way that the free bearing space is filled by the lubricant all along the bearing. There is also the difficulty of negative pressures. The variable part of p , denoted by p_1 , is an *odd* function of the angle φ , as we have seen. While p_1 rises in the narrowing sector between the journal and bearing wall, it must drop again to negative values when the point of proximity is passed. There is thus the danger that the layer breaks in the region of minimum p_1 , unless the constant part of p_0 of the total pressure p is large enough to make $p = p_0 + p_1$ everywhere positive. The quantity p_0 which depends on the inflow and outflow conditions of the lubricant is in our theory an arbitrary parameter; its proper choice is left to the skill of the designer.

One cannot expect an idealizing theory to do better than to establish general rules in an eminently practical problem like ours. Yet these rules may be quite important for the practical design as is born out by the success of Mitchell's segmental bearings.

37. Riemann's Shock Waves. General Integration of Euler's Equations for a Compressible Fluid in One-dimensional Flow

We have so far successfully avoided dealing with the quadratic terms in the equations of hydrodynamics assuming either infinitesimal amplitudes (wave motion) or "creeping" flow, in which case those terms were dropped

as part of the effect of inertia. In the present article, however, we shall finally attack the quadratic terms directly. Riemann¹¹ was the first to brave the challenge of this problem. Hugoniot, Hadamard and many others followed in his steps.

Riemann's method consists in transforming the *non-linear* hydrodynamic equations by an interchange of the dependent and independent variables; this leads to *linear* equations in the case of one-dimensional states. Riemann then shows how to integrate the resulting linear differential equations, and his method has become the model for the general integration problem of linear partial differential equations of second order of the corresponding (hyperbolic) type. This will be taken up in Vol. VI.

We first present a preliminary review of the results of Riemann's investigation: two waves proceed in opposite directions from each point of the initial disturbance in a similar way as in d'Alembert's solution of the corresponding problem for infinitesimal amplitudes (see Fig. 16, 13). Let the pressure be given as function of the density, $p = \varphi(\rho)$, for example in the polytropic form of (7.1); then we have according to Riemann:¹² "The velocity of propagation of both waves relative to the gas is $\sqrt{\varphi'(\rho)}$, but in space it is increased by the velocity of the gas flow measured in the direction of the propagation of the wave. If it is supposed that $\varphi'(\rho)$ does not decrease with increasing ρ , an assumption that holds in reality, stronger compressions must advance with larger velocities; it follows that the waves of compression will diminish in breadth and must finally become compression shocks".

So much for an introduction. We start now with the transition from the non-linear to the linear equations. Disregarding gravity or other external forces we choose the x -axis parallel to the direction of motion. If differentiations are indicated by the usual subscript notation the original hydrodynamic equations for a one-dimensional gas read:

$$(1) \quad \rho_t + u\rho_x + \rho u_x = 0,$$

$$(2) \quad u_t + uu_x + \frac{1}{\rho} p_x = 0.$$

In (2) p_x can be expressed by ρ_x since according to the assumption $p = \varphi(\rho)$

$$(3) \quad p_x = c^2 \rho_x, \quad c^2 = \frac{dp}{d\rho} = \varphi'(\rho).$$

As in (13.5) c is again the *sound velocity*; in the case of infinitesimal amplitude c could be considered as a constant, but now c is a function of ρ .

¹¹Über die Fortpflanzung ebener Luftwellen von endlicher Schwingungsweite. Abh. d. Gött. Ges. d. Wiss. 1860. Also Ges. Werke, p. 156.

¹²From Riemann's abstract of his paper in Göttinger Nachr. 1859, No. 19.

Eq. (2) can be rewritten by the use of (3):

$$(4) \quad u_t + uu_x + \frac{c^2}{\rho} \rho_x = 0.$$

Eqs. (1) and (4) are linear and homogeneous in the differentials of the independent variables x and t , while these variables themselves do not occur in the equations. On the other hand, the quantities ρ and u and their differentials occur in non-linear form. We therefore introduce with Riemann the pair x, t as dependent and the pair ρ, u as independent variables by putting

$$x = x(\rho, u), \quad t = t(\rho, u)$$

$$dx = x_\rho d\rho + x_u du, \quad dt = t_\rho d\rho + t_u du.$$

If these expressions for dx and dt are introduced in the differentials

$$du = u_x dx + u_t dt \quad \text{and} \quad d\rho = \rho_x dx + \rho_t dt,$$

the following identities result:

$$(5) \quad du = (u_x x_\rho + u_t t_\rho) d\rho + (u_x x_u + u_t t_u) du$$

$$(6) \quad d\rho = (\rho_x x_\rho + \rho_t t_\rho) d\rho + (\rho_x x_u + \rho_t t_u) du.$$

Since $d\rho$ and du are now independent we conclude from (5)

$$(7) \quad \begin{aligned} u_x x_\rho + u_t t_\rho &= 0 \\ u_x x_u + u_t t_u &= 1 \end{aligned} \quad \text{or} \quad u_x = \frac{t_\rho}{\Delta}, \quad u_t = -\frac{x_\rho}{\Delta},$$

where we assume that the functional determinant

$$(7a) \quad \Delta = \begin{vmatrix} x_u & t_u \\ x_\rho & t_\rho \end{vmatrix}$$

does not vanish. In the same way we conclude from (6)

$$(8) \quad \begin{aligned} \rho_x x_\rho + \rho_t t_\rho &= 1 \\ \rho_x x_u + \rho_t t_u &= 0 \end{aligned} \quad \text{or} \quad \rho_x = -\frac{t_u}{\Delta}, \quad \rho_t = \frac{x_u}{\Delta}.$$

Eqs. (7) and (8) represent the formulas for u_x, u_t, ρ_x, ρ_t , to be used in transforming (1) and (4). Substituting in (1) and (4), we obtain the system

$$(9) \quad x_u - ut_u + \rho t_\rho = 0, \quad x_\rho - ut_\rho + \frac{c^2}{\rho} t_u = 0.$$

The second equation can be transformed as follows:

$$\frac{\partial}{\partial \rho} (x - ut) = \frac{-c^2}{\rho} \frac{\partial}{\partial u} t = \frac{\partial^2 V}{\partial \rho \partial u},$$

where we have introduced a new dependent variable $V = V(\rho, u)$. The variables x and t are connected with V in the following way (c depends only on ρ):

$$(10) \quad x - ut = V_u, \quad t = -\frac{\rho}{c^2} V_\rho,$$

so that the second equation (9) is identically fulfilled. The new variable V is now introduced¹⁹ in the first equation (9); this gives

$$(11) \quad V_{uu} - \frac{\partial}{\partial \rho} \left(\frac{\rho^2}{c^2} V_\rho \right) = 0,$$

which is a *linear partial differential equation of second order* for the single unknown V .

This equation is simplified if we introduce instead of ρ the new independent variable

$$(12) \quad \xi = \int_0^\rho \frac{c}{\rho} d\rho; \quad \frac{d\xi}{d\rho} = \frac{c}{\rho}.$$

Writing at the same time η instead of u , we have the following relations:

$$\frac{\rho^2}{c^2} V_\rho = \frac{\rho^2}{c^2} V_\xi \frac{d\xi}{d\rho} = \frac{\rho}{c} V_\xi,$$

$$\frac{\partial}{\partial \rho} \left(\frac{\rho^2}{c^2} V_\rho \right) = \frac{c}{\rho} \frac{\partial}{\partial \xi} \left(\frac{\rho}{c} V_\xi \right) = V_{\xi\xi} + \frac{c}{\rho} V_\xi \frac{d}{d\xi} \frac{\rho}{c} = V_{\xi\xi} + V_\xi \frac{d}{d\rho} \frac{\rho}{c}.$$

We now assume the polytropic p, ρ -relation as in (7.1), such that

$$p = a\rho^n, \quad \frac{dp}{d\rho} = c^2 = na\rho^{n-1}, \quad \frac{c}{\rho} = \sqrt{na} \rho^{(n-3)/2}.$$

The relation between ξ and ρ and the expression $d(\rho/c)/d\rho$ is then

$$(12a) \quad \xi = \frac{2\sqrt{na}}{n-1} \rho^{(n-1)/2}, \quad \frac{d}{d\rho} \frac{\rho}{c} = \frac{3-n}{n-1} \frac{1}{\xi},$$

and our differential equation (11) reads in the new variables

$$(13) \quad V_{\xi\xi} - V_{\eta\eta} + \frac{k}{\xi} V_\xi = 0,$$

¹⁹From the first and second equation (10) one has respectively $x_u - ut_u - t = V_{uu}$ and $\rho t_\rho + t = -\partial/\partial \rho (\rho^2 V_\rho / c^2)$.

where for brevity we have put

$$(14) \quad k = \frac{3-n}{n-1}.$$

In the case $k = 0$, Eq. (13) reduces to the equation of the vibrating string, and we have d'Alembert's solution (13.11)

$$(15) \quad V = V_0 = F(\xi + \eta) + G(\xi - \eta),$$

where F and G are *arbitrary* functions that have only to meet certain continuity conditions. More generally, we have the following lemma due to Bechert:¹⁴ If W is a solution of the equation

$$(16) \quad W_{\xi\xi} - W_{\eta\eta} + \frac{l}{\xi} W_{\xi} = 0$$

then

$$(16a) \quad V = \frac{1}{\xi} \frac{\partial W}{\partial \xi}$$

is a solution of the equation

$$(16b) \quad V_{\xi\xi} - V_{\eta\eta} + \frac{l+2}{\xi} V_{\xi} = 0.$$

This can be shown simply by differentiating (16) partially with respect to ξ and putting $W_{\xi} = \xi V$ according to (16a). One obtains then

$$\frac{\partial^2}{\partial \xi^2} (\xi V) - \frac{\partial^2}{\partial \eta^2} (\xi V) + l V_{\xi} = 0$$

which becomes identical with (16b) on carrying out the differentiations and dropping the factor ξ .

Since the general solution (15) of Eq. (13) is known in the case $k = 0$, we have the general solution in the cases $k = 2, 4, 6 \dots$ in the following form:

$$(17) \quad V_2 = \frac{1}{\xi} \frac{\partial V_0}{\partial \xi}, \quad V_4 = \frac{1}{\xi} \frac{\partial}{\partial \xi} \frac{1}{\xi} \frac{\partial V_0}{\partial \xi}, \quad V_6 = \frac{1}{\xi} \frac{\partial}{\partial \xi} \frac{1}{\xi} \frac{\partial}{\partial \xi} \frac{1}{\xi} \frac{\partial V_0}{\partial \xi}, \quad \dots$$

These elementary integrable cases may be written comprehensively by setting k in (14) equal to an arbitrary even integer $2h$. The polytropic exponent (in the sense of p. 49) associated with h is found from (14) as

$$(18) \quad n = 1 + \frac{2}{2h+1}.$$

¹⁴K. Bechert, Zur Theorie ebener Störungen in reibungsfreien Gasen. Ann. d. Phys. 37 (1940) 89; 38 (1940) 1.

It is this rational form of n which makes Bechert's result so interesting since it discloses a surprising thermodynamic side view.

For an adiabatic change of state of a gas we have according to p. 50

$$(18a) \quad n = 1 + \frac{2}{f},$$

where f is the number of degrees of freedom of the molecule. For diatomic gases (e.g. for air) f equals 5, as already mentioned on p. 50. For monatomic gases f equals 3. In this case there are only the three degrees of freedom of *translation* since those of rotation cannot be excited. In present day physics this follows directly from a quantum-theoretical argument, while Boltzmann had still to make the rather artificial assumption that the monatomic molecules were spheres and the diatomic molecules were ellipsoids of revolution, in order to understand the cases $f = 3$ and $f = 5$. In these two cases there is

$$f = 2h + 1 \begin{cases} h = 1 & \text{for monatomic gases} \\ h = 2 & \text{for diatomic gases} \end{cases}$$

Thus it turns out that just the physically most interesting cases are distinguished in that they can be integrated¹⁸ by the elementary expressions V_2 and V_4 of Eq. (17).

It is difficult not to be impressed by what appears to be a "pre-established harmony" between mathematics and physics. An idea suggests itself that the performance of mathematics is adapted in some miraculous way to the exigencies of physics. Yet, the scope of the miracle is rather a limited one: For molecules consisting of three and more atoms such as H_2O or NH_3 , the number $f = 6$: three translatory degrees of freedom plus *three* of rotation. These gases do not belong to the integrable cases in this sense. On the other hand, the case $f = 1$, $k = 0$, which is the simplest integrable case, is not realized in nature; one would have to imagine a strictly "one-dimensional gas" whose atoms can only move in one direction and cannot rotate.

It would be a mistake to think that the integration becomes impossible unless n is one of the rational numbers defined in (18). To show this we¹⁹ write the sequence of equations in (17) once more in general form:

$$(19) \quad V_{2h} = \left(\frac{\partial}{\partial \xi} \right)^h V_0 \quad \text{with} \quad \xi = \frac{\xi^2}{2}, \quad \xi = \sqrt{2\zeta}.$$

¹⁸Mr. Bechert kindly informed me that this peculiar behavior of the cases (18) had been noticed before by A. E. H. Love and F. B. Pidduck. Cf. Trans. R. Soc. London 222, 167 (1922).

¹⁹Similarly as in Bechert's second paper quoted on p. 266.

According to a well known extension of Cauchy's integral formula in the theory of complex functions it is possible to express the h -fold differential quotient in (19) by a complex integral:

$$(20) \quad V_{2h} = \frac{1}{2\pi i} \frac{(-1)^h}{h!} \oint \frac{V_0(\sqrt{2w}, \eta)}{(w - \zeta)^{h+1}} dw.$$

Here h is supposed to be an integer number, and integration refers to a closed path in the w -plane, surrounding the point $w = \zeta$. The argument of V_0 as it is written in (20) indicates that the original dependence on ξ is to be replaced by that on $\sqrt{2w}$ while the dependence on η remains unchanged. However, in the representation (20) the fact that h is an integer is unessential. One may replace $2h$ by the arbitrary quantity k the specialization of which led us to $2h$, if one replaces at the same time

$$h + 1 \quad \text{by} \quad \frac{k}{2} + 1, \quad \frac{(-1)^h}{h!} \quad \text{by} \quad \frac{\exp\left(\frac{i\pi}{2} k\right)}{\Gamma\left(\frac{k}{2} + 1\right)}.$$

In this way one has instead of (20)¹⁷

$$(21) \quad V_k = \frac{1}{2\pi i} \frac{\exp\left(\frac{i\pi}{2} k\right)}{\Gamma\left(\frac{k}{2} + 1\right)} \oint \frac{V_0(\sqrt{2w}, \eta)}{(w - \zeta)^{(k/2)+1}} dw.$$

Evidently (21) satisfies the differential equation in the same way as (20); it represents the general solution since it contains two arbitrary functions F and G in the expression for V_0 under the integral sign. Our statement that just the physically interesting cases of the monatomic and diatomic gases are *integrable*, should now be put more precisely: they are distinguished from the other cases by the elementary form of their general integral.

We have limited this discussion to Riemann's case of *one* spatial coordinate. The generalization to two or three variables¹⁸ presents great difficulties. The differential equation which is the analogue of (13) in the general case has so far resisted all attempts at a general solution.

¹⁷The sign \oint does not mean here a *single* loop about the point $w = \zeta$, since this would not be a closed path because of the branch points of $(w - \zeta)^{(k/2)+1}$ at ζ and at infinity; the path must now be a double loop about $w = \zeta$ and $w = \infty$. Such paths occur in theory of functions at various occasions.

¹⁸K. Bechert, Ann. Phys. 39 (1941) 169 and 357, 40 (1941) 207. In the first of these papers a class of cylindrical and spherical waves is treated, in the second friction and heat conduction is taken into account.

In the foregoing we have only dealt with the formal side of the problem. Although this presents enough interest, it is now time to turn to the *physical aspect* of the motion as it was described above in Riemann's summary. For this purpose we do not need the integral V in its completeness, but go back to the definition of the variables ξ and η [see Eq. (12) and after]. We put with Riemann

$$(22) \quad r = \frac{1}{2} (\xi + \eta) = \frac{1}{2} \left(\int_0^p \frac{c}{\rho} d\rho + u \right),$$

$$s = \frac{1}{2} (\xi - \eta) = \frac{1}{2} \left(\int_0^p \frac{c}{\rho} d\rho - u \right),$$

and note that the assumption of a polytropic p, ρ -relation is immaterial for what follows. The quantities r and s represent in our particular case the *characteristics* of the differential equation (13) and play a decisive part in the general theory of differential equations of this type. (For further details see Vol. VI).

From (22) we calculate the derivatives

$$(23) \quad r_t = \frac{1}{2} \left(\frac{c}{\rho} \rho_t + u_t \right), \quad r_x = \frac{1}{2} \left(\frac{c}{\rho} \rho_x + u_x \right).$$

(differentiations with respect to the original variables x and t are again represented by subscripts.) A glance at the expression

$$(24) \quad r_t + (u + c)r_x = \frac{c}{2\rho} \left\{ \rho_t + (u + c)\rho_x + \frac{\rho}{c} u_t + \frac{\rho}{c} (u + c)u_x \right\}$$

shows that the right member vanishes because of the equations of motion (1) and (4). If we compute in the same way s_t and s_x from (22) and form the expression $s_t + (u - c)s_x$ we find again the right member zero as before. Both results may be indicated in the following way:

$$(25) \quad \frac{\partial}{\partial t} \left\{ \begin{matrix} r \\ s \end{matrix} \right\} + (u \pm c) \frac{\partial}{\partial x} \left\{ \begin{matrix} r \\ s \end{matrix} \right\} = 0.$$

If we form the total differentials dr and ds with respect to x and t and express the partial derivatives r_t and s_t by r_x and s_x respectively according to (25), we obtain

$$dr = r_x dx - (u + c)r_x dt \quad \text{and} \quad ds = s_x dx - (u - c)s_x dt.$$

These are differential identities between the original independent variables x and t and the variables r and s , which are valid if u and ρ (of which c is a known function) fulfill the differential equations (1) and (4). Consider

now the point x varying in course of time. The total derivatives of r and s with respect to t , if $x = x(t)$, are

$$(26) \quad \frac{dr}{dt} = \left(\frac{dx}{dt} - u - c \right) r_x, \quad \frac{ds}{dt} = \left(\frac{dx}{dt} - u + c \right) s_x.$$

These relations can be interpreted as follows: at a point (*not a particle*) that travels in such a way that

$$(27) \quad \text{either} \quad \frac{dx}{dt} = u + c \quad \text{or} \quad \frac{dx}{dt} = u - c$$

the quantities r or s keep their values. In other words, a certain value of r respectively s travels with the variable velocity $u + c$ respectively $u - c$. As long as $|u| < c$, the first moves in the positive the second in the negative x -direction.

As an example take the case of an initial pressure disturbance restricted to a short interval of the x -axis. Compression waves issue in both directions from the interval if we assume an initial disturbance in the form of a pressure *increase*. However, the two wave profiles do not preserve their shape as in Fig. 16; the wave front becomes steeper since larger densities travel faster according to (27). Hence it is understood that the compression waves finally become compression *shocks*. At this point our calculation which disregards friction and heat conduction, ceases to be valid. The extensions of the theory that are necessary in the case of shocks have been investigated by Hugoniot and Hadamard.¹⁰

FIG. 64. The waves caused by an initial disturbance progress in both directions and are deformed in this process. The notations V and W of the figure have the same meaning as the parameters of the characteristics, r and s , as functions of x and t . In comparing Figs. 64 and 16, note that the central curve in the present figure represents the disturbances V and W *individually*, while the corresponding *sum* is represented in Fig. 16.

This may suffice for an exposition of Riemann's results which we quoted on p. 263. Fig. 64 has been taken from Bechert's first paper quoted

¹⁰Cf. the comprehensive representation by G. Zemplén in Enc. d. Math. Wiss., Vol. IV.3, Art. 19, which is to be supplemented by a more recent paper of R. Becker, Z. Phys. 8 (1922) 321.

on p. 266. It refers to the simplest case of a strictly "one-dimensional" gas (see p. 267) which shows, as Bechert points out, the characteristic traits of wave propagation in spite of the extreme idealization.

38. On Turbulence

With the present report which is divided in a number of sections we enter the most difficult part of hydrodynamics. Under (A) we have collected a series of *half empirical, half theoretical statements* about the properties of turbulent flow. Inasmuch as they are of a theoretical nature, they are based on the Stokes-Navier equations and the diffusion of momentum which these equations can be considered to express (see p. 76).

Under (B) we approach the fundamental question whether it is at all possible to explain the observed facts on the basis of the Navier-Stokes equations. In particular, one asks whether these equations give account of the instability of the laminar motion that sets in at a certain Reynolds number. Earlier attempts to settle this question by the method of small oscillations failed; it had been impossible to find a critical limit, and the laminar motion appeared to be stable at any value of R . The method of small oscillations had been applied to the fully developed laminar flow, that is to the Hagen-Poiseuille flow and to the Couette flow with the aim of investigating the stability of a flow in a pipe and between plates, respectively.

Considering these negative results, such experts in the field of turbulence as Th. v. Kármán and Sir Geoffrey Taylor have occasionally in their papers favored the idea that turbulence like gas theory can only be understood by statistical methods. The underlying physical fact is that a fluid is a system of very many (in principle infinitely many) degrees of freedom, all of which come into play at large Reynolds numbers. The motion becomes then so complicated that one can expect simple answers only to those questions that concern the *average* behavior of the moving particles. This is especially true for the limiting case of the so-called isotropic turbulence; some preliminary remarks according to hitherto unpublished work of C. F. v. Weizsäcker and W. Heisenberg will be made on this topic under (D) where we are concerned with what one may call fully developed *turbulent equilibrium*.

Previous to that we shall briefly discuss under (C) investigations of *the process of generation of laminar flow in its relation to turbulence*: the processes at the inlet in pipe flow experiments and the formation of Prandtl's boundary layer when the plate is set in motion. This was Prandtl's own view of the problem, and was soon taken up successfully by Tollmien, Tietjens, Görtler, and Schlichting, all of whom belong to Prandtl's school.

In these investigations the method of small oscillations is not applied to the velocity profile of the developed laminar flow, but to the intermediate profiles that occur while the laminar flow comes into existence. The significance of the velocity profile for the stability of the flow had been anticipated in much older investigations of Lord Rayleigh which, however, dealt only with inviscid fluids. The more recent investigations of Prandtl's group start from the complete Navier-Stokes equations (i.e. in their abbreviated form for *small* oscillations) and actually result in stability limits, which, to be sure, do not refer to the final laminar motion but to the way of its generation.

Under (E) we shall bring a mathematical example of a system of differential equations that lead to phenomena similar to those of turbulence in fluids. It is a non-linear system that resembles the Navier-Stokes equations in structure, but is much simpler than those. This example, which is due to I. M. Burgers, may strengthen our belief that turbulence does belong to classical hydrodynamics, although to a part of it that presents great difficulties to the mathematical attack.

A. Some Properties of Turbulent Flow

Empirical data on the turbulent state in pipes and channels are very extensive, having been compiled by hydraulic engineers over a long time. In organizing this material two principles have to be observed: The flow must be referred to equal Reynolds numbers and the wall roughness must be taken into account. As to the second requirement we shall restrict ourselves to *smooth* walls so that we do not have to digress too far into technological details. "Smooth" is, of course, meant in the sense of the limit: wall roughness $\rightarrow 0$. Under these conditions one obtains the general result: *In the fully developed turbulent state the velocity distribution in pipes with geometrically similar cross-sections is similar*, or, the ratio of the velocity at a certain point to the velocity average over the entire cross-section is independent of the Reynolds number.

Fig. 65 shows this velocity distribution for a circular cross-section in

FIG. 65. The velocity profile in a circular pipe for the turbulent and laminar states of flow (solid and dotted lines respectively).

comparison with that of the Hagen-Poiseuille flow. In the latter case we had a parabolic velocity profile; the velocity at the center being equal to twice the average velocity. In the turbulent case the velocity at the axis of the tube is only a little larger than the average velocity, which has

been assumed the same for both cases in the diagram. Only in the proximity of the wall the velocity drops quickly to zero; a narrow wall zone develops in this region, where the flow is more or less laminar, and the viscosity the important quantity.

The term velocity as it is used here with reference to the turbulent state is to be understood in the sense of the *time average of the velocity*. The individual particle velocity at a given point is by no means constant in time. The *spectrum* of its temporal and spatial variability covers a wide range; it has been possible to obtain more detailed information about it in a characteristic limiting case [see section (D)]. We denote the time average of the velocity by U , a velocity in the direction of the axis of the pipe (x -axis); the additional components of the individual velocities are denoted by u, v, w . Likewise, P stands for the time average of the pressure and p is the individual instantaneous pressure difference relative to P .

In addition to the law of turbulent velocity distribution we have the law of the turbulent *pressure drop*. In the laminar case the pressure gradient was proportional to the velocity, in our case it is proportional to the square or in better approximation to the $7/4^{\text{th}}$ power of the velocity (Blasius Law, see p. 120). When this law is expressed according to (16.11) and (16.13) by means of the similarity invariants R and S , it reads

$$\frac{\Pi}{l} = \frac{\rho v^3}{a} S, \quad S = \lambda R^{-1/4},$$

where a is the radius of the pipe and λ a numerical coefficient. Written in our present notation, it takes the form

$$(1) \quad -\frac{dP}{dx} = \frac{\lambda \rho U^2}{a} R^{-1/4} = \frac{\lambda \rho}{a} \left(\frac{\nu}{a}\right)^{1/4} U^{7/4}.$$

This equation shows that the coefficient of viscosity is no longer of decisive importance for the state of the flow; its influence expresses itself by the factor $\nu^{1/4}$ and is rather weak. Another kind of energy loss prevails which is connected with inertia effects and becomes evident in the factor ρ , or rather $\rho^{3/4}$ if the dependence of the kinematic viscosity ν on ρ is also considered.

Prandtl and Kármán were able to deduce the velocity distribution in the wall zone from (1), using certain additional assumptions. Consider a fluid element of thickness dx extending over the pipe cross-section: The difference of the average pressures P acting on the two faces of the element must be balanced by the shear forces acting between fluid and pipe wall. Thus we have

$$-\frac{dP}{dx} dx \pi a^2 = \tau_0 dx 2\pi a,$$

or, according to (1),

$$(2) \quad \tau_0 = -\frac{dP}{dx} \frac{a}{2} = \frac{\lambda \rho}{2} \left(\frac{y}{a}\right)^{1/4} U^{7/4}.$$

Let now $y = a - r$ be the distance between a point inside the wall zone and the wall. According to Prandtl and Kármán there is only one way to construct a dimensionally correct and physically meaningful expression that approximates²⁰ the shear stress τ at the point y , viz.

$$(2a) \quad \tau = \text{const } \rho \left(\frac{y}{y_0}\right)^{1/4} U^{7/4}.$$

From (2a) one obtains directly

$$(3) \quad U = \text{const} \left(\frac{y}{y_0}\right)^{1/7} \left(\frac{\tau}{\rho}\right)^{4/7}.$$

Hence the velocity inside the wall zone increases from zero at the wall with the $1/7^{\text{th}}$ power of the distance from the wall. This agrees well with experimental results. Kármán was also able to develop from the same assumptions a formula for the heat conduction in the wall zone, which is in good agreement with the observations.

We shall now discuss the original approach to the turbulence problem made by Reynolds²¹ and, in connection with his work, by H. A. Lorentz.²² We restrict ourselves to a steady main flow along the x -direction with a pressure gradient $-dP/dx$ on which a non-steady quasiperiodic additional motion is superimposed. Let the state be two-dimensional, i.e. depending only on x and y . The main flow depends then only on y , the turbulent additional motion has the components u and v that depend on t , x and y . We shall consider the time averages of the total velocity \mathbf{v} and of the total pressure Q , that is of the quantities

$$(4) \quad v_x = U + u, \quad v_y = v, \quad Q = P + p$$

for which we stipulate

$$(5) \quad \bar{v}_x = U, \bar{v}_y = 0, \bar{Q} = P, \text{ hence } \bar{u} = 0, \bar{v} = 0, \bar{p} = 0.$$

²⁰Note that (2a) does not give (2) for $y = 0$, but becomes infinite. According to Kármán (Z. angew. Mathem. u. Mech. 1, 1921, p. 233) the reason is that (2a) is only asymptotically valid (i.e., for infinitely large Reynolds numbers).

²¹In the paper quoted in footnote 18 on p. 114.

²²Akad. Amsterdam, Zittingsverlag, 6. p. 28, 1897 and Ges. Abhandlungen, Teubner 1907, p. 43.

This implies

$$\begin{aligned} \overline{v_x v_x} &= U^2 + 2U\bar{u} + \bar{uu} = U^2 + \bar{uu} \\ (5a) \quad \overline{v_x v_y} &= U\bar{v} + \bar{uv} = \bar{uv} \end{aligned}$$

and

$$(5b) \quad \frac{\partial}{\partial x} \overline{v_x v_x} = \frac{\partial}{\partial x} \bar{uu}, \quad \frac{\partial}{\partial y} \overline{v_x v_y} = \frac{\partial}{\partial y} \bar{uv}.$$

Furthermore, in a quasiperiodic motion the averages of the time derivatives such as $\partial u / \partial t$ vanish:

$$(5c) \quad \overline{\frac{\partial u}{\partial t}} = 0;$$

and because of (4) and (5)

$$(5d) \quad \frac{\partial U}{\partial t} = \frac{\partial U}{\partial x} = 0, \quad \overline{\nabla^2 u} = 0, \quad \overline{\nabla^2 v} = 0, \quad \overline{\frac{\partial p}{\partial x}} = 0.$$

We now write the equation of motion in the abbreviated vectorial form (16.1) and set $\mathbf{F} = 0$:

$$(6) \quad \rho \frac{\partial \mathbf{v}}{\partial t} + \rho(\mathbf{v} \text{ grad})\mathbf{v} = -\text{grad } Q + \mu \nabla^2 \mathbf{v}.$$

As a consequence of the condition $\text{div } \mathbf{v} = 0$ we have the identity

$$v_x \frac{\partial v_x}{\partial x} + v_y \frac{\partial v_x}{\partial y} = \frac{\partial}{\partial x} v_x v_x + \frac{\partial}{\partial y} v_x v_y$$

which permits us to write the x -component of (6) in the form

$$(6a) \quad \rho \frac{\partial v_x}{\partial t} + \rho \frac{\partial}{\partial x} v_x v_x + \rho \frac{\partial}{\partial y} v_x v_y = -\frac{\partial Q}{\partial x} + \mu \nabla^2 v_x.$$

Forming the time average of this equation we obtain with the use of (4), (5), and (5a, b, c, d)

$$(7) \quad \frac{\partial}{\partial x} \rho \bar{uu} + \frac{\partial}{\partial y} \rho \bar{uv} = -\frac{\partial P}{\partial x} + \mu \nabla^2 U.$$

The quantities on the left side are gradients of *friction pressures* which appear here alongside with the gradient of the normal pressure P . To be in accordance with our system of notations (10.4) these quantities ought to be denoted as follows:

$$(7a) \quad \frac{\partial}{\partial x} p_{xx} + \frac{\partial}{\partial y} p_{xy} \quad \text{where} \quad p_{xx} = \rho \bar{uu}, \quad p_{xy} = \rho \bar{uv}.$$

Now it should be remembered that the term $\mu \nabla^2 U$ to the right is also due to friction pressures; this was pointed out in Eqs. (10.6)-(10.8b). But the previous p_{ix} originate in the *molecular* disorder of fluid particles on a microscopic scale, while the present p_{xx} , p_{xy} , in (7a) are caused by the *molar* disorder of fluid domains of macroscopic size engaged in turbulent motion. In either case the physical origin of the friction pressures is the *transfer of momentum*. Take as an example the molar friction pressure p_{xy} : momentum is transferred from the motion in x -direction to the side motion y , a process that cannot remain without influence on the momentum balance of the main flow U . In this sense we should interpret the appearance of the terms (7a) on the left side of Eq. (7) of the main flow. But the average pressures (7a) do not lend themselves to the ordinary methods of differential analysis; this is the reason why in this approach to the turbulence problem recourse is taken to statistical methods.

Of the two friction pressures p_{xy} and p_{xx} the first is the important one, hence we shall indicate the contribution of the second only by \dots . Let us also adopt in what follows the usual terminology in this branch of hydrodynamics and speak of frictional *shear stress* rather than of frictional pressure; we write accordingly

$$(8) \quad \tau = \sigma_{xy} = -p_{xy} = -\rho \overline{uv}$$

Instead of Eq. (7) we have then

$$(9) \quad \frac{\partial P}{\partial x} = \mu \nabla^2 U + \frac{\partial \tau}{\partial y} + \dots,$$

For $\nabla^2 U$ we may also write $d^2 U/dy^2$ since U is a function of y alone. Eq. (9) is the *determinative equation of the main flow*.

We obtain the equation of the x -component of the turbulent additional motion by introducing (4) into (6) and by subsequent reduction with the help of (9) and (5d):

$$(10) \quad \frac{\partial u}{\partial t} + U \frac{\partial u}{\partial x} + v \frac{\partial U}{\partial y} = -\frac{1}{\rho} \left(\frac{\partial p}{\partial x} + \frac{\partial \tau}{\partial y} \right) + \frac{\mu}{\rho} \nabla^2 u + \dots$$

Here the sign \dots covers also the terms of second order in u and v . There is a corresponding equation for the y -component v of the turbulent motion and a second equation (9) for $\partial P/\partial y$.

Quantitative information about the character of the turbulence can hardly be expected from these very involved equations. We have mentioned them here mainly for the purpose of later reference in section (E) and to point out the significance of the molar friction stress τ . The latter concept leads to the idea of a length l characteristic for the turbulence, viz. the *mixing length*, introduced by Prandtl in 1926; it corresponds to the notion of the mean free path in gases:

Prandtl's argument²³ is this: Suppose a "fluid lump" of average velocity $U(y)$ is shifted from y to $y + l$; in terms of the additional motion, this means a fluctuation of approximately

$$u = l \frac{\partial U}{\partial y}.$$

It is a reasonable assumption that the fluctuation of the side motion v in the mixing process will be of the same order of magnitude. This admitted, one obtains for τ according to (8) an expression of the following form

$$(11) \quad \tau = \rho l^2 \left| \frac{\partial U}{\partial y} \right| \frac{\partial U}{\partial y}.$$

If this is introduced in (9), the result is a differential equation that depends only on the quantities of the main flow and can be used for its analysis. However, the results obtainable in this way require continual experimental checking because of the hypothetical character of the relation (11),

B. Older Attempts at a Mathematical Theory of Reynolds' Turbulence Criterion

Even before Reynolds started his theoretical investigations, Lord Kelvin²⁴ had treated the problem of flow stability by the method of small oscillations, but did not obtain definite results. Twenty years later the problem was attacked again; the object at this time was to study the stability of the form of the Couette flow²⁵ represented in Eq. (16.14), which is mathematically so very simple. If a small disturbance (u, v) with stream function ψ is superimposed on the main flow U , which has a rectilinear velocity profile, the resulting differential equation of fourth order

$$(12) \quad \frac{\partial \nabla^2 \psi}{\partial t} + U \frac{\partial \nabla^2 \psi}{\partial x} - \frac{d^2 U}{dy^2} \frac{\partial \psi}{\partial x} = \nu \nabla^2 \nabla^2 \psi$$

that describes the problem in the general case, splits up, because of $d^2 U/dy^2 = 0$, into

$$(12a) \quad \left(\frac{\partial}{\partial t} + U \frac{\partial}{\partial x} - \nu \nabla^2 \right) \chi = 0, \quad \nabla^2 \psi = \chi.$$

One resolves now ψ and χ in Fourier components by putting

$$(12b) \quad \psi = f(y)e^{i(\alpha x - \beta t)}, \quad \chi = F(y)e^{i(\alpha x - \beta t)}.$$

²⁵W. M. F. Orr, Proc. Irish Acad. 27 (1907). — A. Sommerfeld, Internat. Mathem. Congress, Rome, 1908, Vol. III, p. 116.

The resulting ordinary differential equations for f and F are of second order and can be solved by known functions over the whole range $0 < y < h$ (Bessel functions of order $\frac{1}{2}$ and $\frac{3}{2}$). The boundary conditions at $y = 0$ and $y = h$ give a *transcendental equation* for β in the form of a certain second order determinant that must vanish if non trivial values of the integration constants are to be obtained. If for a given real α this equation has a solution with positive-imaginary part, then *instability* prevails in the sense that disturbances of the wave number α increase in time. The *critical Reynolds number* would thus be determined by that α -value for which the imaginary part of β vanishes for the first time.

However, Mises²⁶ was able to deduce from the nature of the transcendental equation that such a value of β cannot exist, or that the straight Couette flow is seemingly stable toward all disturbances α . This conclusion has been confirmed by Hopf²⁷ in a more direct way by a detailed discussion of the corresponding types of oscillations. Moreover, it seems that according to Noether²⁸ the stability proof can be extended to all flows between two plane parallel plates (unless special discontinuities occur in the initial velocity profile).

Detailed calculations in the sense of Eqs. (12) and (12b) have been carried out by Sexl²⁹ not only for the flow between plane plates but also for the Couette flow proper³⁰ between coaxial cylinders, and likewise for the Hagen-Poiseuille flow. In every case the transcendental equation associated with the problem leads to the conclusion that the flow is stable.

Thus we have striking contradiction between theory and experiment. What conclusions should we draw? Should we suspect the method of small oscillations that has proved reliable in all other domains of mechanics including astronomy? Should we rather assume that for such a proof of instability *finite* instead of (infinitely) small disturbances ought to be resorted to just because the object of investigation is the laminar motion?

Or should we blame the Navier-Stokes equations as inadequate for our problem? This does not seem justifiable either, particularly since in the last analysis they form the foundation for all previous theoretical statements, including Reynolds's laws of similarity.

³⁰In the more refined experiments on Couette flow performed by Sir G. Taylor (cf. p. 121) the deviation from the laminar motion occurring beyond the stability limit turned out to be helical (hence three-dimensional) rather than axially-symmetric.

C. Reformulation of the Turbulence Problem; the Origin of the Turbulence

It was possible to find a way out of these difficulties when investigators directed their attention, as Prandtl had done it, to the *manner in which turbulence comes into being* in a given flow arrangement (cf. also our discussion of pipe flow experiments on p. 118). Here again the Couette flow, in which the flow field is bounded by a plane plate moving in x -direction, proved simpler than the pipe flow. At the beginning of the motion a boundary layer develops along the plate; the other plate bounding the flow field may be supposed at infinite distance, for the time being. The fluid that fills the space between the boundary layer and that plate is considered at rest or in laminar motion according to a preassigned law $U(y)$. The decisive factor for the stability is the velocity profile of the boundary layer, as was first recognized by Tollmien.³¹ Tollmien's stability criterion (Gött. Nachr. 1935) states that velocity profiles with inflexion points, such as occur in a boundary layer with positive pressure gradient, are extremely likely to become unstable. To characterize the investigations that aim in this direction (determination of the eigenvalues and approximate calculation of the eigenfunctions in the strip between the plates) we quote a paper³² of Schlichting: "The main flow is not assumed to have a fully developed linear velocity distribution; one rather investigates one by one the velocity profiles that occur between two parallel plane walls when one wall is suddenly set in motion, changing from a state of rest to one of constant velocity. A boundary layer then forms along the moving wall, the thickness of which increases with time, and if the main flow stays laminar, its velocity profile approaches asymptotically a straight line. In contrast to this, the earliest among these transient profiles have finite critical Reynolds numbers whose magnitudes depend on the shape of the profile. The actual Reynolds number of the Couette flow is then obtained as the lowest stability limit during the initial period".

If the problem is formulated in this way, its solution is of course much more difficult than the problem contained in our Eqs. (12). It can only be solved by the use of step by step approximations, carried out by numerical and graphical methods, which we can only mention here. They lead to a definite, practically meaningful value of the stability limit which depends, however, on how the turbulent state was produced.

³¹W. Tollmien, Über die Entstehung der Turbulenz, Göttinger Nachr. 1929.

³²H. Schlichting, Ann. Phys. 14 (1932) 905. He refers to previous work done by other authors in Prandtl's group: O. Tietjens, Z. angew. Mathem. Mech. 5 (1925) 200, W. Tollmien, l. c., cf. also later papers of Schlichting in Gött. Nachr. 1932, 1933, 1935.

To illustrate once more the changed view point we could perhaps say: Not the instability of the laminar flow as such is proved as it was tried under (B), but it is shown that the road toward it is blocked by unstable states. Thus the instability is not an inherent quality of the final state but of its *history*.

D. The Limiting Case of Isotropic Turbulence

In view of this complicated state of the problem one can ask whether there exist ideal flow conditions that are approached by the turbulent fluid in the limit of infinitely increasing Reynolds number; this final state could be called turbulent equilibrium. We suppose that no spatial direction is preferred and thus speak of *isotropic turbulence*. In the state of isotropic turbulence the space of the fluid is divided into turbulence elements or turbulence cells of ever changing size that are arranged in some statistical way. The eddies in the cells follow the Navier-Stokes equations, but are too complicated for complete mathematical treatment. Thus the equilibrium between the different turbulence elements can only be described statistically. One asks for the probability that a certain size of the turbulence elements occurs. This brings us back to the search for the spectrum of the turbulence elements which was already mentioned on p. 271.

The kinetic theory of gases may serve as an approximate model of this theory. Although the mathematically exact state of the gas (position and velocity of the gas molecules) is entirely determined by the history of the gas (i.e., the preceding states), one is only interested in the *statistically most probable distribution* (sometimes also in the probability of a given deviation from that distribution) which is given by the Maxwell-Boltzmann law. Similarly in the turbulence problem, where one is interested in the *statistically most probable distribution* of the vortices, which can be described in the form of a statement about the frequency of vortices of a certain size and a certain rotational speed.

Weizsäcker obtains the velocity spectrum of the isotropic turbulence by a similarity consideration in which turbulence cells of different sizes are compared under the assumption of a quasisteady state (i.e., its change in time is small compared with the time needed to establish statistical equilibrium). A further assumption is the random nature of the state. As a result the following spectral law is obtained: The mean velocity of a particle relative to its surrounding neighbors varies as *the third root of its diameter*. As a consequence, the energy density in function of the wave number is proportional to the $-5/3$ power of the wave number. However, these laws are only valid in the middle part of the spectrum, which part is very extended in the case of large Reynolds numbers. For *small wave*

numbers (large turbulence elements that are comparable in size with the container) the statistical treatment must be replaced by the consideration of the individual hydrodynamic boundary value problem; for very large wave numbers (small turbulence cells) the Navier-Stokes friction causes the spectral intensity to drop to zero very quickly.

Heisenberg substantiates the same results by the use of Fourier analysis and supplements them by the calculation of the factors of proportionality, by a more exact investigation of the limiting cases of small and large wave numbers, and by the determination of the pressure fluctuations.

For all details and in particular, for the comparison with the experiment we refer to the papers of the two authors.*

E. A Mathematical Model to Illustrate the Turbulence Problem

To J. M. Burgers who had been trying to explain the facts of turbulence on an statistical basis, we owe a mathematical model³³ from which properties analogous to those observed in actual turbulence can be deduced with mathematical rigor. The simplified system of equations which Burgers puts tentatively in place of preceding Eqs. (9) and (10), is

$$\frac{dU}{dt} = P - u^2 - \nu U, \quad (13)$$

$$\frac{du}{dt} = Uu - \nu u.$$

These equations are non-linear like the actual equations of turbulence (u^2 occurs in the first and Uu in the second equation), each equation contains a dissipative friction term [νU in the first and νu in the second equation, corresponding to the terms $\mu \nabla^2 U$ in (9) and $(\mu/\rho) \nabla^2 u$ in (10)]. The constant P in (13) replaces the pressure gradient dP/dx in (9) and, like it, represents a driving force. The independent variables are U and u as before; U is the main motion, u the turbulent additional motion. However, Eqs. (9) and (10) refer to a domain of three independent variables x, y, t , while there is only *one independent variable* t in (13).

*C. F. v. Weizsäcker, Das Spektrum der Turbulenz bei grossen Reynoldsschen Zahlen; W. Heisenberg, Zur statistischen Theorie der Turbulenz, Z. f. Phys., 124, (1948) p. 608-657. See also W. Heisenberg, On the theory of statistical and isotropic turbulence, Proc. R. Soc., 195, (1948) p. 402, and Th. v. Kármán and C. C. Lin, The statistical theory of turbulence, Advances in Applied Mechanics, II, Academic Press, New York, 1950.

³³Mathematical Examples illustrating relations occurring in the theory of turbulent fluid motion, Akad. Amsterdam 17 (1939)1.

The non-linear terms in (13) have been chosen in such a way that they drop out when the expression for the "energy" is formed; for we require the permanence of the general rule, according to which two equations of the form (13) should be added after multiplication with U and u respectively, and so would yield the energy expression. In our case one obtains

$$(13a) \quad \frac{1}{2} \frac{d}{dt} (U^2 + u^2) = PU - \nu(U^2 + u^2).$$

In the right member, the first term is the work per unit of time performed by the driving force P which, supposedly, acts only upon the main motion; the second term is the energy dissipated by friction.

There exists a "laminar" solution of (13), viz.

$$(14) \quad U = U_0 = \frac{P}{\nu}, \quad u = 0.$$

It is stable as long as

$$(14a) \quad P < \nu^2.$$

This can be seen directly if the method of small oscillations is applied. One puts

$$U = U_0 + \xi, \quad u = \eta$$

and neglects higher powers of ξ and η . Then, by (13), one has

$$(14b) \quad \frac{d\xi}{dt} = -\nu\xi$$

$$\frac{d\eta}{dt} = (U_0 - \nu)\eta.$$

The first of these equations represents an exponentially decreasing disturbance; this is also true for the second equation but only if $U_0 < \nu$; hence by (14) we have condition (14a). For $U_0 > \nu$ and, therefore, $P > \nu^2$, Eq. (14) is still a solution of (13), but it is unstable because of the second Eq. (14b).

There exist, however, two solutions for $P > \nu^2$ which we characterize as turbulent, since they include a contribution of the additional motion. They are

$$(15) \quad U = \nu, \quad u = u_0 = \pm \sqrt{P - \nu^2}.$$

Both solutions are stable for $P > \nu^2$, for, if one puts

$$U = \nu + \xi, \quad u = u_0 + \eta$$

and again neglects higher powers of ξ and η in accordance with the method of small oscillations, (13) becomes

$$(15a) \quad \frac{d\xi}{dt} = -\nu\xi - 2u_0\eta,$$

$$\frac{d\eta}{dt} = u_0\xi.$$

If one sets up a trial solution in the usual form

$$(15b) \quad \xi = Ae^{\lambda t}, \quad \eta = Be^{\lambda t},$$

one obtains the following conditions which determine λ and B/A :

$$\lambda A = -\nu A - 2u_0 B,$$

$$\lambda B = u_0 A;$$

they yield on elimination of B/A

$$(15c) \quad \lambda^2 + \nu\lambda = -2u_0^2$$

$$\lambda = -\frac{\nu}{2} \pm \sqrt{\frac{\nu^2}{4} - 2u_0^2} = -\frac{\nu}{2} \pm \sqrt{\frac{9}{4}\nu^2 - 2P}.$$

The roots λ are *negative real* for

$$\nu^2 < P < \frac{9}{8}\nu^2$$

and turn complex with *negative real part* when

$$P > \frac{9}{8}\nu^2.$$

The disturbance (15b) thus attenuates exponentially for any $P > \nu^2$, which means that the solution (15) is *stable* for these values of P . The stability limit lies at $P = \nu^2$ where one of the roots (15c) vanishes. The same value of P is the stability limit of the laminar solution and thus reflects Reynolds criterion of stability. It is true that, in contrast to the hydrodynamic reality, in our case both the laminar and the turbulent motion are steady, i.e., independent of t , but the example should be taken as a model and does not attempt to explain the turbulence. (There is also this difference that in the model *two* forms of turbulent motion are equally possible [see (15)], while in reality the laws of turbulent motion appear to be *uniquely* determined by the Reynolds number.)

Following Burgers, we give a graphic representation of the results by drawing in Figs. 66 and 67 a u , U -diagram of the two curves

$$(16) \quad \frac{dU}{dt} = 0 \quad \text{and} \quad \frac{du}{dt} = 0.$$

The equations are given by (13), viz.

$$(16a) \quad u^2 + \nu U = P \quad \text{and} \quad (16b) \quad u = 0, U = \nu \text{ respectively}$$

Eq. (16a) is a parabola, Eq. (16b) a pair of lines consisting of the U -axis and a parallel line to the u -axis. Since we have got two steady solutions in (14) and (15), their representations in our diagram are the intersection

FIG. 66 (left). Diagram of Burger's turbulence model in the "laminar" case $P < \nu^2$.

FIG. 67 (right). Diagram of Burger's turbulence model in the "turbulent" case $P > \nu^2$.

points of (16a) and (16b). In Fig. 66 the parabola lies entirely to the left of the line $U = \nu$, hence there is only one intersection point; it belongs to the solution (14) and is unstable. There are three intersection points in Fig. 67. One of them lies on the U -axis. It belongs to solution (14) that is now unstable; the two others belong to the stable solution (15).

Burgers³⁴ extended his method of "mathematical models" in several steps in the attempt to bring it closer to the actual behavior of a turbulent fluid. He considers a system of three simultaneous differential equations in which the main "flow" U is coupled with two additional motions, u and v , and permits these motions to depend not only on time but also on a spatial coordinate. This we shall not discuss here since the simple model of Eq. (13) in our opinion illustrates the mathematical situation sufficiently: *By the non-linear character of the equations the occurrence of (two) entirely different types of motion is made possible.* These types, which we again distinguish by the terms "laminar" and "turbulent" are in some ways analogous to those of the turbulence problem; they branch off from one another at a certain stability limit, which we can compare with Reynolds stability criterion.

³⁴Advances in Applied Mechanics, ed. R. v. Mises and Th. v. Kármán, Vol. I., Academic Press, New York, 1948.

SUPPLEMENTS TO THE THEORY OF ELASTICITY

39. *Elastic Limit, Proportional Limit, Yield Point, Plasticity, and Strength*

Up to this point we have assumed the solid body to be homogeneous and isotropic, and only permitted small deformations. In the following discussion we shall consider very briefly the principal deviations which appear under more general conditions.

Let us consider a cylindrical steel bar which is clamped at one end and subject to a tensile force P acting at the other end. We shall first refer the tensile stress σ to the unloaded cross section of the bar F_0 , as is customary in engineering practice. Thus

$$(1) \quad \sigma = \frac{P}{F_0}$$

or the stress is proportional to the load P .

If we plot the measured strains ϵ as abscissas to the tensile stresses σ calculated according to (1) as ordinates, we obtain for loads that produce very small deformations ϵ a curve which is practically an exact straight

FIG. 68. Stress-strain diagram of a tensile test with a tough material (steel).

line (see solid curve in Fig. 68). This is valid up to a point P that is called the proportional limit.

The elastic limit designates a point on the diagram, below which a decrease or removal of the load produces a decrease or removal of strain. For steel, the elastic limit lies slightly below the proportional limit.

Beyond the proportional limit, the stress-strain line becomes curved and reaches a maximum, which is called the upper yield point (also flow or plasticity limit) S_u . The curve drops now to the lower yield point S_l ; following the point S_l the curve remains in the mean parallel to the ϵ -axis over a short distance, usually presenting a few small waves in this section, the behavior of a given sample depending upon the composition and previous treatment of the steel.

This transition region is followed by the plastic or flow region in which permanent deformations occur. A small change of load causes a rapid change of strain, so that in this range the curve first rises slowly with little curvature only, turning its concave side towards the ϵ -axis. The maximum ordinate B corresponds to the ultimate load or ultimate stress, but fracture occurs only at the point Z , where the stress-strain curve ends abruptly. Note in addition that

1. the bar undergoes lateral contraction everywhere and that
2. in the neighborhood of the place where fracture is to occur the reduction of the cross-section is particularly large; the constriction or "neck" formed there becomes quite noticeable once the point B in the diagram is passed. If we refer the load to the (variable) smallest cross-section F , that is, if we put

$$(2) \quad \sigma = \frac{P}{F}$$

and plot the tensile stress so calculated against the measured strain, we obtain the dashed curve in the plastic region. Within the elastic region, the two curves obviously coincide.

Steel is the most important example of *tough* materials, while cast iron is typical for *brittle* materials. There is no plastic range in the latter case and no constriction either. Fracture follows almost immediately at the end of the sharply limited elastic range. According to earlier experiments, Hooke's law did not seem to hold for cast iron altogether, but Grüneisen¹ has shown that for sufficiently small strains proportionality exists between stress and strain.

Materials that can be formed into a given shape like loam, clay, and lead show hardly any elastic properties, but exhibit plastic behavior throughout.

¹E. Grüneisen, Ber. d. Deutsch. Phys. Ges. 1906.

Similar results as in the tension test described above are obtained in compression, bending, and torsion tests. It should be noted, however, that pure compression causes fracture only in brittle but not in tough materials. It is further assumed that in all these experiments the load is applied slowly, since the deformation depends not only upon the load, but also upon the duration of the application of the load.

In connection with this last point we mention the *elastic aftereffect*. Even in the elastic range the deformation connected with a particular load assumes its final value only after a considerable time. We speak of the *creep* of the material in question.

In analogy to the behavior of ferro-magnetic bodies we find also an *elastic hysteresis*. As in the magnetic case, the area enclosed by the hysteresis loop in the ϵ , σ -plane represents the input of deformation energy per cycle.

In the previous discussion the load was assumed constant or slowly varying. Of more importance, especially in machine design, is the case of periodic loading, where the stress oscillates above and below a mean value. In such cases fracture occurs at a much lower loading than in the case of stationary load; one speaks of the *fatigue* of the material.

When we plot the number of load cycles until fracture, z , against the average stress σ_m as ordinate, we obtain a monotonically decreasing curve (so-called Wöhler diagram), which approaches a horizontal asymptote σ_{∞} as z increases. This indicates that the average stress must be kept smaller than the value of σ_{∞} (fatigue limit) in order to prevent a fatigue failure with certainty.

When the load that finally causes the fracture has been applied *slowly*, the cross section at the fracture will exhibit coarse grained structure; in the case of failure under oscillating load, however, a portion of the broken cross-section will be fine grained, possibly showing the spread of an imperfection (see below). The remaining portion of the section has the same appearance as in an ordinary fracture. We may conclude from this that the first part contributes only little to load bearing capacity, so that the remainder simply fails in a fracture by overload. Moreover, we know that the number of cycles z depends greatly upon the quality of the surface of the specimen. Small invisible cracks reduce z considerably. It may be mentioned in this connection that Voigt's measurements of the breaking strength of sodium chloride crystals gave only 1/400 of the value calculated from the lattice theory. In this case, too, small cracks and surface irregularities are the cause of the discrepancy, since tests made under water, where the crystal surface is smoothed out in the process of dissolution, gave 3/4 of the theoretical value of the breaking strength.

Solid bodies used in engineering are mainly metals and metal alloys

composed of small crystal grains. Fine grained layers of foreign substances are interspersed between the crystals of the basic material. These intermediate layers can transfer considerable cohesive forces and give the solid body a certain degree of homogeneity. But in the same layers are also found places of lesser strength, imperfections of the structure from which a fracture develops. Organic materials like wood and leather, are composed of chains of crystal-like cells, in which other materials are imbedded. Glass, on the other hand, is an example of an amorphous material.

Concerning the crystalline structure of metals we know today that every crystal is a spatial lattice. The elementary units of the crystal lattice are the atoms of the metal, which are arranged in lattice planes and, within these planes, in lattice lines. The lattice planes can be arranged in three families of parallel planes which are not necessarily orthogonal to each other.

At small loads in the proportional range, the space lattice suffers a continuous deformation without essential changes in shape; the deformation disappears as the load is removed. Within the plastic range, the crystal deforms with a change of shape. The lattice planes of that family which contains the most densely occupied lattice lines, slide in the direction of these lattice lines. In this process the intermediate layers are also distorted.

40. Crystal Elasticity

The entire field of physical phenomena in anisotropic bodies has been expertly surveyed in "Lehrbuch der Kristallphysik" by Waldemar Voigt.² In this work the most general relations are developed that are compatible with the symmetry properties of the crystal and with the geometrical characteristic of the physical phenomenon under consideration, which may be a scalar field, a vector field or a tensor field of second or higher order (cf. p. 60). In crystal elasticity we are concerned with the relation between stress and strain tensor. Since both are symmetrical tensors of second order and have six components, the most general linear stress-strain relation will depend upon $6 \times 6 = 36$ coefficients.

This number will reduce, however, to

$$(1) \quad 6 + \frac{6 \times 5}{1 \times 2} = 21,$$

when the strain energy W is a *function of state*, as Green first postulated.

²Taubner 1910, second impression 1928. Beside dielectric and conductive properties such phenomena as pyroelectricity and piezoelectricity are treated; the latter has gained special interest in the meantime. Crystal optics, however, has been considered beyond the scope of this work.

We have pointed out (p. 73) that this assumption is justified both in the cases of an isothermal process (problems of equilibrium) and of an adiabatic change (rapid oscillations). In these cases then, which alone will interest us in the following dW is a total differential. Replacing for the present our general notation σ_{ik} and ϵ_{ik} by a single subscript notation we set³

$$(2) \quad \begin{aligned} \sigma_{11} &= \sigma_1, & \sigma_{22} &= \sigma_2, & \sigma_{33} &= \sigma_3, & \sigma_{23} &= \sigma_4, & \sigma_{31} &= \sigma_5, & \sigma_{12} &= \sigma_6 \\ \epsilon_{11} &= \epsilon_1, & \epsilon_{22} &= \epsilon_2, & \epsilon_{33} &= \epsilon_3, & 2\epsilon_{23} &= \epsilon_4, & 2\epsilon_{31} &= \epsilon_5, & 2\epsilon_{12} &= \epsilon_6. \end{aligned}$$

Then the double sum of Eq. (9.24) becomes

$$(3) \quad dW = \sum_{k=1}^6 \sigma_k d\epsilon_k$$

and the general stress-strain relation appears in the form

$$(4) \quad \sigma_k = \sum_{i=1}^6 s_{ki} \epsilon_i.$$

where the s_{ik} are now the moduli of elasticity.⁴ If (3) is to be a total differential, we have

$$\frac{\partial \sigma_k}{\partial \epsilon_i} = \frac{\partial \sigma_i}{\partial \epsilon_k},$$

which according to (4) means

$$(5) \quad s_{ki} = s_{ik}.$$

When we write the coefficients s in a quadratic array of 6 rows, it follows that they are *symmetrical with respect to the diagonal* s_{11}, \dots, s_{66} . This immediately leads us to the count in Eq. (1). The same is of course true for the elasticity constants c .

Let us insert here the remark that the older molecular theory of Navier, Cauchy, and Poisson based on the idea of central forces between molecules led to a further reduction of that number to 15. We know, however, that this theory is too narrow in the case of the isotropic body. It would assign the universal value $\frac{1}{2}$ to the Poisson ratio ν in equation (9.9) and in this way reduce the required number of 2 elastic constants for

³The strains $\epsilon_1, \epsilon_2, \epsilon_3$ introduced in (2) are defined in the same way as Kirchhoff's y_1, y_2, y_3 (cf. the table on p. 600). At this point the omission of the factor $\frac{1}{2}$ which was introduced in our definition of the ϵ_{ik} with a view to the general structure of tensor algebra proves advantageous.

⁴This notation is due to Voigt who uses it throughout (cf. footnote on p. 64). The coefficients in the strain-stress relations obtained by solving Eqs. (4) for the quantities ϵ are denoted by c_{ik} according to Voigt (constants of elasticity).

isotropic bodies to 1. Moreover, modern crystal lattice theory, which was already mentioned at the end of the previous article, has shown that the cause of this difficulty lay not so much in the molecular theory as such, as in its too narrow formulation: since the crystal in general consists of several superposed lattices which can move with respect to each other in the elastic deformation, the concept of pure central forces becomes inadequate.

The number 21 mentioned previously refers to a crystal without symmetry, that is to a triclinic crystal. The state of symmetry of a physical process acting on a crystal is determined according to the following principle (Voigt, L.d.K., 53): *The symmetry of the physical process is superimposed on the symmetry of the crystal.* Now, the elastic deformation has a center of symmetry since the strain in any one direction is the same as in the opposite direction. On the other hand, there are two possible cases of symmetry relations in a triclinic crystal, one with, and one without center of symmetry. In the latter case, however, the missing center of symmetry is supplied, as one might say, by the center of symmetry of the strain. Both sub-groups of the triclinic system therefore behave in the same way as far as elasticity is concerned.

There exists a total of 32 groups of symmetry^{4a} which make up the 7 crystal systems, viz. the triclinic, monoclinic, orthorhombic, tetragonal, trigonal, hexagonal, and cubic systems. The principle quoted before implies in our case that the first three systems and the last two are uniform in regard to their elastic constants while the tetragonal as well as the trigonal systems must be divided each into two subclasses with different schemes of elastic constants. We shall give a few examples below of these $5 + 2 \times 2 = 9$ different schemes.

The crystal axes are generally designated by a, b, c . In the triclinic system the axes have different lengths and arbitrary directions. In the monoclinic system, one of the axes is perpendicular to the other two and represents an axis of symmetry for rotations through 180° . If we choose this axis as z -axis of an orthogonal coordinate system x, y, z , and call the elastic displacements ξ, η, ζ , a rotation through 180° about the z -axis will cause the changes

$$(a) \quad x, y, z \rightarrow -x, -y, z, \quad \xi, \eta, \zeta \rightarrow -\xi, -\eta, \zeta;$$

the associated changes in the strains are according to (2) on the one hand

$$(b) \quad \epsilon_1, \epsilon_2, \epsilon_3, \epsilon_6 \rightarrow \epsilon_1, \epsilon_2, \epsilon_3, \epsilon_6$$

^{4a}As is well known, they are distinguished from each other according to their symmetry relative to a point. The more basic classification according to the spatial symmetry character that leads to 230 groups need not interest us here.

on the other hand

$$(c) \quad \epsilon_4, \epsilon_5 \rightarrow -\epsilon_4, -\epsilon_5;$$

One verifies easily that the expressions

$$\epsilon_4 = \frac{\partial \eta}{\partial z} + \frac{\partial \zeta}{\partial y} \quad \text{and} \quad \epsilon_5 = \frac{\partial \zeta}{\partial x} + \frac{\partial \xi}{\partial z}$$

change their signs in the operation (a), while for example the expression

$$\epsilon_6 = \frac{\partial \xi}{\partial y} + \frac{\partial \eta}{\partial x}$$

keeps its sign. Since the stresses σ behave in the same way as the strains ϵ , they must follow the same commutation rules (b) and (c). We now rewrite the stress-strain relations (4), marking the terms whose signs change in the operation (a) by \pm and indicating the remaining terms on the right side by \dots . In this way we obtain for $k = 1, 2, 3, 6$

$$(d) \quad \sigma_k = \dots \pm s_{k4} \epsilon_4 \pm s_{k5} \epsilon_5 \dots,$$

but for $k = 4, 5$

$$(e) \quad \pm \sigma_k = \dots \pm s_{k4} \epsilon_4 \pm s_{k5} \epsilon_5 + \dots.$$

For fixed k , (d) represents two equations which, on subtraction, lead to the following relation:

$$(f) \quad s_{k4} \epsilon_4 + s_{k5} \epsilon_5 = 0 \quad \text{for} \quad k = 1, 2, 3, 6.$$

Similarly, the pair (e) gives on addition

$$(g) \quad s_{k1} \epsilon_1 + s_{k2} \epsilon_2 + s_{k3} \epsilon_3 + s_{k6} \epsilon_6 = 0 \quad \text{for} \quad k = 4, 5.$$

From (f) we conclude

$$(6) \quad 0 = s_{14} = s_{24} = s_{34} = s_{64} = s_{15} = s_{25} = s_{35} = s_{65},$$

and the same result follows from (g) because of the relation $s_{ik} = s_{ki}$.

On the basis of (6) the behavior of the moduli of elasticity in the transition from the triclinic to the monoclinic system has now been established:

Triclinic system

no symmetry axis

21 constants

s_{11}	s_{12}	s_{13}	s_{14}	s_{15}	s_{16}
	s_{22}	s_{23}	s_{24}	s_{25}	s_{26}
		s_{33}	s_{34}	s_{35}	s_{36}
			s_{44}	s_{45}	s_{46}
				s_{55}	s_{56}
					s_{66}

Monoclinic system

one digonal axis of symmetry A_z^2	s_{11}	s_{12}	s_{13}	0	0	s_{16}
13 constants		s_{22}	s_{23}	0	0	s_{26}
			s_{33}	0	0	s_{36}
				s_{44}	s_{45}	0
					s_{55}	0
						s_{66}

In the orthorhombic system where a , b , and c are mutually orthogonal another digonal axis of symmetry A_z^2 is added to A_x^2 ; the axis A_y^2 which is also present can be considered as a consequence of the two other axes and must not be taken into separate account.

By repeating the argument that leads to equation (6) one obtains in the present case

Orthorhombic system

two digonal axes of symmetry	s_{11}	s_{12}	s_{13}	0	0	0
A_x^2 and A_z^2 , 9 constants		s_{22}	s_{23}	0	0	0
			s_{33}	0	0	0
				s_{44}	0	0
					s_{55}	0
						s_{66}

Similarly, one has for the

Cubic system

three interchangeable tetragonal	s_{11}	s_{12}	s_{12}	0	0	0
axes of symmetry, 3 constants		s_{11}	s_{12}	0	0	0
			s_{11}	0	0	0
				s_{44}	0	0
					s_{44}	0
						s_{44}

From the last scheme we conclude that the cubic single crystal has an elastic behavior *different from the isotropic body*. The former possesses only

two independent moduli of elasticity, for example, our previous μ and λ . In order to adapt the above scheme to that of equation (9.6), we would have to specialize the three constants as follows:

$$s_{11} = 2\mu + \lambda, \quad s_{12} = \lambda, \quad s_{44} = \mu,$$

that is, we should add the following condition which is not fulfilled in the cubic single crystal:

$$s_{11} = s_{12} + 2s_{44}.$$

From a physical point of view this is connected with the fact that the so called isotropic solid body has no uniform structure, but is a polycrystal. The elastic behavior which we actually observe is simpler than that of the single crystal, but it is only the result of averaging the elastic reactions of a very large number of single crystals that are in random positions with respect to each other. For an example we refer to the metals discussed in the previous article.

Quite different is the answer to the corresponding question in the field of optics. Cubic single crystals of fluorite or rock salt are frequently preferred as lense materials for optical instruments in certain ranges of the spectrum, where they are superior in transmissivity to ordinary isotropic (amorphous) glass lenses. This is possible, because the cubic single crystal is optically isotropic. In the framework of Voigt's general system the cause for this different behavior must be seen in the following distinction: in elasticity the basic relation is a tensor-tensor relation (stress-strain), in optics it is a vector-vector relation (electric field- dielectric displacement).

We cannot further pursue the interesting details of crystal elasticity. Our principal aim was to characterize the elastic behavior of isotropic bodies as contrasted with that of the uniform anisotropic bodies.

41. The Bending of Beams

Loaded and bent beams are among the principal elements of all building constructions. In planning a new structure bending loads are calculated and must be legally approved. The theory employed for this purpose is simple and has been in use for 200 years; its origin dates back to Daniel Bernoulli. We shall discuss below how this theory can be substantially justified through more rigorous methods (St.-Venant), but we shall first follow the historical development.

We limit ourselves to the simplest case of a *straight* beam subject to slight bending. The cross-section of the beam is arbitrary (one may think of a *T* or *I* section), but it is assumed as constant over the length of the beam.

Let us first disregard the weight of the beam. At one end the beam supports a vertical load, while the other end is clamped rigidly; thus the upper fibers of the beam are stretched and the lower ones compressed.

Bernoulli assumes that each plane cross-section of the beam remains plane also after bending. Navier concludes from this that the normal stresses transmitted by a cross-section are distributed according to a *linear law*. We consider two neighboring sections originally separated by the distance dx (x is taken from right to left as indicated in Fig. 69a). The

FIG. 69. Illustrating the elementary bending theory. An element of a beam (a) in the original state and (b) in the bent state.

fibers running between the two cross-sections have the length $dx + \delta dx$ after bending. Due to the assumed planeness of both cross sections, the extension of the fibers decreases linearly from the upper face of the beam downward and becomes zero at some particular layer NN ; δdx now stays negative down to the lower face of the beam and represents the contraction of the fibers. The strains are distributed in the same linear way.

$$\epsilon = \frac{\delta dx}{dx},$$

and so are the stresses [cf. (9.8)]:

$$(1) \quad \sigma = E\epsilon.$$

When σ_{\max} is the stress in the (upper or lower) boundary fiber and h its distance from NN , (cf. Fig. 69b), the linear law states that

$$(2) \quad \sigma = \frac{\sigma_{\max}}{h} y \cdots y = \text{distance between fiber with stress } \sigma \text{ and } NN$$

In order to determine the maximum stress σ_{\max} , we shall investigate the equilibrium of forces acting on an isolated beam section of length x (cf. Fig. 70); in doing so we may disregard the deflection of the beam. We

are mainly concerned with the *equilibrium of moments* taken about an axis normal to the plane of Fig. 70 and containing the point N at the cross-section x , but we shall also consider the *equilibrium of force components in the horizontal x -direction*. Equilibrium of forces in the vertical y -direction will be considered later.

FIG. 70. Equilibrium between the bending moment M and the moment of the normal stresses σ .

For the particular loading here assumed the moment of the external forces, usually designated as *bending moment* M , is

$$(3) \quad M = Px.$$

According to Eq. (2) the forces σdf have the moment

$$(4) \quad \int y \sigma df = \frac{\sigma_{\max}}{h} I, \quad I = \int y^2 df.$$

The quantity I is called the *moment of inertia of the cross-section*. In Vol. I the moment of inertia of a plane mass distribution has already been introduced and a distinction made between *polar* and *equatorial* moments of inertia. Here, however, we are dealing with a plane area and not with a plane mass distribution, hence the dimension of I is not gm^2 but rather cm^4 . Since the axis through N for which I is computed lies within the cross-section, I is to be considered as an *equatorial moment of inertia*. When the opposite direction of the moment arrows shown in Fig. 70 is considered, the moment equilibrium requires according to (3) and (4)

$$(5) \quad \sigma_{\max} = \frac{hM}{I}.$$

This relation together with (2) determines the stress σ for any other point of the cross-section.

The engineer is particularly interested in σ_{\max} since it is his task to keep the maximum occurring stress below the *legally admissible limit*, σ_{adm} . He has to find the cross-section with the largest loading, that is, with the largest bending moment, and proportions the beam in such a way that in this cross-section the stress at the boundary face $\sigma_{\max} < \sigma_{\text{adm}}$. For beam profiles used in engineering, the values of I and I/h are tabulated in tables of moments of inertia and section moduli. For a circular cross-section of radius a we have⁶ (cf. Vol. I, Problem IV. 1)

⁶Cf. Synge and Griffith, *op. cit.*, p. 220.

$$(6) \quad I = \frac{1}{4} P a^2 = \frac{\pi}{4} a^4;$$

for a rectangular cross-section of width b and depth $2h$

$$(6a) \quad I = \frac{2}{3} b h^3.$$

In both cases we have anticipated that the axis $y = 0$ passes through the *centroid* of the area of the circle or rectangle, being parallel to b in the latter case.

To show this in general we have to use the *equilibrium condition for force components in x -direction*. The external forces do not contribute anything to the equilibrium equation, neither in our particular case where the external force P is vertical, nor in general, since otherwise the problem would not be one of pure bending but of combined bending and tension or compression. The condition is then simply

$$\int \sigma df = 0,$$

or, because of (2),

$$\int y df = 0.$$

On the other hand, the *centroid* of the cross-sectional area is defined by the fact that the first moment⁶ of the area with respect to its centroid is zero, equivalent to $\int y df = 0$. The fiber passing through the consecutive centroids of all cross-sections of the beam is called its *neutral fiber* or *neutral line*. The horizontal plane containing the points $y = 0$, is known as the *neutral plane*. This has already been indicated by the notation NN .

We now determine the shape of the neutral line in its deflected position. For this purpose we have to set up the *differential equation of the elastic line*, which can be derived on the basis of Fig. 69b: Here the center of curvature C of the elastic line NN has been indicated as the intersection of the prolonged traces of the cross-sections at x and $x + dx$. The sides of the triangle CNN are ρ , ρ , and dx where ρ is the radius of curvature. If we draw through one of the points N a parallel to the trace of the other cross-section we obtain a triangle similar to CNN the third side of which is the face of the beam. The sides of this triangle are h , h , $\delta dx_{\max} = \epsilon_{\max} dx$. Hence the following proportion holds:

$$\frac{dx}{\rho} = \frac{\epsilon_{\max} dx}{h}.$$

⁶Sometimes the term static moment is used which is not a very appropriate expression. Likewise, second moment should be preferred to moment of inertia.

By the use of (1) and (5), it may also be written

$$(7) \quad \frac{1}{\rho} = \frac{M}{EI}.$$

As to the choice of the sign in this equation we refer to Fig. 69b for the sake of brevity and omit the introduction of sign rules for ρ . The right hand side is a known function of x or, more generally, a *known point function along line NN*. (The second formulation refers to finite deflections where the abscissa must be replaced by the arc length s of the elastic line.) The left hand side of (7) is the curvature, a differential invariant of the curve; thus equation (7) is the differential equation required.

For sufficiently small deflections we know that approximately

$$\frac{1}{\rho} = \frac{d^2y}{dx^2},$$

and consequently

$$(8) \quad \frac{d^2y}{dx^2} = \frac{M(x)}{EI}.$$

Referring to the particular loading (3), we obtain

$$(9) \quad \frac{d^2y}{dx^2} = \frac{P}{EI} x$$

and after integration

$$(9a) \quad y = \frac{P}{EI} \left\{ \frac{x^3}{6} + Ax + B \right\},$$

which is a cubic parabola. The integration constants A and B result from the conditions at the point of support:

$$(9b) \quad \text{for } x = l \left\{ \begin{array}{l} y = 0 \\ \frac{dy}{dx} = 0 \end{array} \right\} \cdots A = -\frac{l^2}{2}, \quad B = \frac{l^3}{3}.$$

The maximum deflection occurs at $x = 0$:

$$(9c) \quad y_0 = \frac{1}{3} \frac{P}{EI} l^3.$$

We consider now a beam simply supported at each end by a pair of uprights at distance l from each other, and loaded only by its own weight. The (constant) weight per unit length being p , the reactions at each support will be $-pl/2$, where the minus sign indicates the upward direc-

tion of these forces. The bending moment at any point is composed of the moment of the weight and the moment of one of the end reactions:

$$(10) \quad M(x) = \frac{p}{2} x(x - l).$$

Integration of (8) then gives

$$(10a) \quad y = \frac{p}{2EI} \left\{ \frac{x^4}{12} - \frac{x^3 l}{6} + Ax + B \right\},$$

a parabola of the fourth order.

Instead of the conditions (9b) we have now

$$\left. \begin{array}{l} \text{for } x = 0 \\ \text{for } x = l \end{array} \right\} y = 0 \dots \quad B = 0; \quad A = \frac{p}{12}.$$

The largest deflection occurs, of course, at the central cross-section and amounts to

$$(10b) \quad y_{\max} = \frac{5}{16 \times 24} \frac{p}{EI} l^4.$$

Of more interest for the following is the case where a *couple* acts at the end of the beam instead of a single force as in Fig. 70. This could be physically realized by two equal forces of opposite direction, acting in close proximity to each other and having such magnitude that their moment has a finite value. Then M can be considered as constant and according to (8)

$$(11) \quad y = \frac{M}{EI} \left\{ \frac{x^2}{2} + Ax + B \right\}.$$

If the beam is clamped at the other end ($x = l$) we have the same conditions as in (9b), and it follows that $A = -l$, $B = \frac{1}{2}l^2$. The deflection at $x = 0$ is then

$$(11a) \quad y = \frac{1}{2} \frac{M}{EI} l^2.$$

In this case the shape of the elastic axis can be more accurately described than by the parabola (11): according to (7) it is a circular arc, since its curvature is constant.

This last case is the only one in which we are led to a clear-cut result by our equilibrium conditions. The *third equilibrium condition* which we have to stipulate, viz.

$$(12) \quad \text{Sum of all vertical components} = 0$$

is here satisfied, whereas this condition requires in general that at every cross-section x a vertical shear force opposes the external loads. This shear force results from the combined action of all shear stresses of the section under consideration. If we take the beam of Fig. 70 as an example, shear stresses σ_{xy} would have to occur in addition to the normal stresses σ_{xx} , so that for every cross-section

$$(13) \quad \int \sigma_{xy} df = P.$$

This, however, would imply the occurrence of angular changes γ_{xy} , causing the originally plane cross-section to warp. In other words, Bernoulli's hypothesis, in asserting the permanent planeness of the cross-sections, contradicts the general fundamentals of statics. *Thus it would seem that Navier's law of linear variation of the normal stress which is based on Bernoulli's hypothesis, is also invalidated.*

Before we show a way to overcome this difficulty, we wish to determine the magnitude of the required shear stresses. The integral condition (13) is not suitable for this purpose, but we can make use of the differential relation (8.11). In the absence of external body forces and with σ_{xx} evidently vanishing if for instance a rectangular cross-section is assumed, this relation may be written

$$\frac{\partial \sigma_{xx}}{\partial x} + \frac{\partial \sigma_{xy}}{\partial y} = 0.$$

Notwithstanding the previous critical remarks, the statements of equations (2), (5) and (3) may be considered as approximations. We have then

$$(14) \quad \frac{\partial \sigma_{xx}}{\partial y} = \frac{-Py}{I}, \quad \sigma_{xy} = \frac{P}{2I} (A - y^2) = \frac{P}{2I} (h^2 - y^2).$$

The integration constant A in the last equation must equal h^2 , so that $\sigma_{xy} = 0$ for $y = \pm h$. This must be required since the value of σ_{xy} at the upper or lower edge of the cross-section determines the shear stress σ_{yx} acting within the face of the beam; the face, however, must be completely free of stress. It is not difficult to determine the warping of the rectangular cross-section that results from the σ_{xy} and the associated shear angle γ_{xy} .

We now wish to point out briefly how the bending theory can be freed from the internal contradiction revealed above. St.-Venant⁷ accomplished this in 1855. First of all, it must be emphasized that the relations between stress and external forces used so far are not sufficient to describe the

⁷A complete representation is found in de Saint-Venant's translation of Clebsch's lectures: *Théorie de l'élasticité des corps solides*, trad. par Saint-Venant and Flamant, Paris, 1883.

elastic state completely. One must make recourse to the elastic displacements ξ , η , ζ , as they occur in the fundamental elastic equations (9.18). Then we note that nowhere in the preceding argument we have mentioned the stresses σ_{yy} , σ_{zz} , σ_{yz} . In fact, they do not enter into the consideration of the equilibrium of a bent beam and can therefore be set equal to zero. If we express them in terms of ξ , η , ζ , we obtain simple differential relations between these quantities by the use of which the equations (9.18) can be greatly simplified and finally come out as:⁸

$$(15) \quad \left\{ \frac{\partial^2}{\partial x^2} = \frac{\partial^2}{\partial y^2} = \frac{\partial^2}{\partial z^2} = \frac{\partial^2}{\partial y \partial z} \right\} \frac{\partial \xi}{\partial x} = 0.$$

From this we conclude first: the strain $\partial \xi / \partial x$ of the x fibers and consequently also their stress $\sigma = \sigma_{xx}$ is a linear function of the coordinates in the cross-section y and z . The linear distribution law for σ_{xx} is thus a necessary consequence of the fundamental laws of elasticity and Bernoulli's hypothesis is not required for its derivation.

Eq. (15) shows further that the extension of the x -fibers is also a linear function of x ; this implies together with Eq. (5) that the bending moment M should be a linear function of x , which is actually the case for one or several single loads or single moments (but not for the continuously distributed load of the weight of the beam itself). The following restriction should be noticed, however: the single load ought to be applied in such a way that it can be balanced by the shear forces σ_{xy} that act across the cross-section at which the load acts; in other words, the load should be distributed over the cross-section in the same way as previously computed for σ_{xy} . This is, of course, never fulfilled in reality. We may, however, take the following view: whether we have a lumped or a distributed load can only make a difference in the neighborhood of the cross-section under consideration, provided, of course, the loads in both cases are statically equivalent. This can be demonstrated by suitably chosen experiments as well as by theoretical examples and is often formulated as a general theorem under the name of *Saint-Venant's principle*.

Thus the simple method of computing beams set forth at the beginning of this article that has given satisfactory results in innumerable cases has been vindicated from a more rigorous point of view.

42. Torsion

We first consider the simplest case of the torsion of a rod with circular cross-section, which, in a way, is also the most important case. We

⁸Cf. for this calculation A. Föppl, Vorl. üb. techn. Mechanik, 4th ed. Leipzig, 1909, Vol. III, 73.

think of the fact that every engine shaft is subject to torsional loading: a torque about the axis of the shaft is produced at one end by the driving mechanism, at the other end an opposite torque acts which originates in the mechanism that receives the power; in steady motion both torques have the same magnitude. This example shows the general characteristic of torsional loading. For a straight rod of arbitrary cross-section it consists in a torque that acts about the rod axis at one end; whether the other end is kept fixed or subject to the opposite moment makes no difference; an additional tensile loading, e.g., in the direction of the axis of the rod would mean that we deal no longer with pure torsion.

It is easy to imagine the kind of deformation that is established by twisting a rod of circular cross-section whose one end is kept fixed, but we shall have to show that the deformation we think of is theoretically admissible. We assume (cf. Fig. 71) that every cross-section of the rod is

FIG. 71. The torsion of a rod of circular cross-section. The base is rigidly clamped, a torsional moment M acts on the free end.

rotated through a certain angle φ which is proportional to the x -coordinate. This means

$$(1) \quad \varphi = \alpha x, \quad \alpha = \text{Const.}$$

The originally straight generatrices of the rod are transformed into circular helices; the components of the displacement vector \mathbf{s} are according to (1) in cylindrical polar coordinates r, φ, x

$$(2) \quad s_r = 0, \quad s_\varphi = \alpha x, \quad s_x = 0.$$

In order to obtain the strains we have simply to introduce the quantities (2) in Eqs. (4.26) and (4.28) for $\delta q_1, \delta q_2, \delta q_3$, putting, because of $ds^2 = dr^2 + r^2 d\varphi^2 + dx^2$,

$$g_1 = 1, \quad g_2 = r, \quad g_3 = 1.$$

This leads to

$$(3) \quad \begin{aligned} \epsilon_{rr} = \epsilon_{\varphi\varphi} = \epsilon_{zz} &= 0 \\ \epsilon_{r\varphi} &= 0, \quad 2\epsilon_{\varphi z} = \alpha r, \quad \epsilon_{zr} = 0. \end{aligned}$$

The associated stresses σ are now found according to Eqs. (9.7), which are relations between tensors and therefore valid in arbitrary orthogonal coordinates:

$$(4) \quad \begin{aligned} \sigma_{rr} = \sigma_{\varphi\varphi} = \sigma_{zz} = \sigma_{zr} = \sigma_{r\varphi} &= 0 \\ \sigma_{z\varphi} = \tau = \mu\alpha r. \end{aligned}$$

In agreement with common engineering usage the notation τ is here applied to the only shear stress that acts in the cross-section $x = \text{const.}$

In the state of stress described by (4) we have again a *linear* stress distribution law as we had it in bending; in fact, we can write (4) in the form

$$(4a) \quad \tau = \frac{r}{a} \tau_{\max} \quad \text{where} \quad \tau_{\max} = \mu\alpha a.$$

In this simplest case of torsion the planeness of the cross-sections is strictly preserved, as already anticipated in the assumption $\epsilon_z = 0$ in (2). We have previously seen that this is not true in bending; in torsion it is only correct if the cross-section is circular, as we shall see.

We now prove that our system of stresses is in agreement with the boundary conditions of the problem. This is obviously true for the curved surface of the rod, $r = a$, which must be free of stress. There ought to be

$$\sigma_{rr} = \sigma_{r\varphi} = \sigma_{rz} = 0,$$

which, according to (4), is in fact fulfilled. Across the base the condition of vanishing stress must be replaced by the condition of vanishing displacements. This is satisfied by (2), if $x = 0$. For the free end cross-section we should at least stipulate as a *necessary* condition that

$$(5) \quad M = \int r\tau \, df,$$

where M is the moment of the forces P that produce the torsion (cf. Fig. 71). By (4a) this may be rewritten in the following form:

$$(5a) \quad M = \frac{\tau_{\max}}{a} \int r^2 \, df = \frac{\tau_{\max}}{a} J_p = \mu\alpha J_p, \quad J_p = \frac{\pi}{2} a^4,$$

where J_p stands for the polar moment of inertia of the cross-section which

in the case of a circular area is twice the equatorial moment of inertia given in (41.6).

Strictly speaking, this is not a *sufficient* condition. The external moment M should not only be equal to the total moment of the shear forces about the axis of the rod, but the distribution of M over the cross-section should be point by point identical with the distribution of τdf . The couple $M = Pd$ as it appears in the figure obviously does not satisfy this condition. This difficulty is again taken care of by the Saint-Venant principle (see p. 300), according to which the local disturbance of equilibrium produced by the dissimilarity between the actual and the theoretical load is limited to the proximity of the end face and does not influence the elastic equilibrium anywhere else in the rod.

To be on the safe side we would have to show that the differential equations of elasticity, which the displacements must obey, are satisfied by our special solution (2). These relations written in Cartesian displacement components are given by Eqs. (9.18); in their place we should have to use Eqs. (9.20) which refer to general orthogonal coordinates. A glance at the quantities Θ and P_i that appear in these equations shows that in our case

$$\Theta = 0, \quad P_1 = -\alpha x, \quad P_2 = 0, \quad P_3 = 2\alpha x.$$

This is easily checked with the aid of Eqs. (9.20a), and it follows immediately that Eqs. (9.20) are satisfied (F is of course equal to zero).

We have now to study in greater detail Eq. (5a) which determines the only remaining unknown in our problem, viz. the angular torsion per unit of rod length. We may as well determine the total *torsion angle* of the rod which becomes according to (1)

$$\varphi_1 = \alpha l, \quad \text{where } l = \text{length of rod.}$$

From (5a) we obtain

$$(6) \quad \varphi_1 = \frac{Ml}{\mu J_p}.$$

This equation is quite evident as regards the proportionality with the torsion moment M and the length l and also as to the inverse proportionality with the torsion modulus μ . More important is what Eq. (6) says about the dependence on the *dimensions* of the cross-section. This expresses itself in the factor J_p of the denominator. Note, however, that the dependence on the polar moment J_p that occurs here does not hold for arbitrary cross-sections, like the moment I in the bending problem; if the cross-section is not a circle this dependence is by no means expressible through the polar moment J_p . This applies e.g. to the elliptic cross-section as will be seen below.

For cross-sections of *unspecified shape* we have no preferred coordinate system, such as the cylindrical polar coordinates in the previous case, and we must take recourse to Cartesian coordinates and displacements $x, y, z; \xi, \eta, \zeta$, the equilibrium conditions now being given by Eq. (9.18) with $\mathbf{F} = 0$.

In general we shall now have to admit the possibility of warping of the cross-section. Taking the axis of the rod as x -axis, there is then no longer $\xi = 0$ [corresponding to the previous $s_x = 0$ in (2)]. As a consequence of the prismatic shape of the rod we may, however, assume that the warping is independent of the location of the cross-section, that is to say, the warping function ξ is independent of the x -coordinate:

$$(7) \quad \xi = \Phi(y, z), \quad \frac{\partial \xi}{\partial x} = 0.$$

We further assume that the deformation, as in the case of the circular cross-section, is free of dilatation. This would mean $\Theta = 0$; let us, however, introduce the more restricted conditions

$$(8) \quad \frac{\partial \eta}{\partial y} = \frac{\partial \zeta}{\partial z} = 0,$$

and finally assume that, similarly to $\epsilon_{r,\varphi} = 0$ in Eq. (3),

$$(9) \quad 2\epsilon_{yz} = \frac{\partial \eta}{\partial z} + \frac{\partial \zeta}{\partial y} = 0.$$

These various assumptions will have to be justified in the course of our investigation.

By (7) and (8), the differential equations (9.18) take the following simple form

$$(10) \quad \begin{aligned} \frac{\partial^2 \xi}{\partial y^2} + \frac{\partial^2 \xi}{\partial z^2} &= 0 \\ \frac{\partial^2 \eta}{\partial x^2} + \frac{\partial^2 \eta}{\partial z^2} &= 0 \\ \frac{\partial^2 \zeta}{\partial x^2} + \frac{\partial^2 \zeta}{\partial y^2} &= 0. \end{aligned}$$

The first of these equations states that the warping function ξ introduced in (7) satisfies the *two-dimensional potential equation*.

$$(11) \quad \nabla^2 \Phi = 0,$$

The two remaining equations (10) can be fulfilled together with (8) if η and ζ are taken as bilinear functions as follows:

$$(12) \quad \eta = b_0 + b_1x + b_2z + b_3xz,$$

$$\zeta = c_0 + c_1x + c_2y + c_3xy.$$

According to (9), the following relation must hold for the constants b and c identically in x :

$$b_2 + b_3x + c_2 + c_3x = 0;$$

or

$$(13) \quad b_2 = -c_2, \quad b_3 = -c_3.$$

As in Fig. 71, the base of the rod is kept fixed, in the sense that lateral displacements are excluded. For $x = 0$ we have therefore identically in y and z

$$b_0 + b_2z = 0, \quad c_0 + c_2y = 0,$$

or

$$(13a) \quad b_0 = c_0 = b_2 = c_2 = 0.$$

If we finally wish to retain the right angle between x -axis and end face, we have for $x = 0$

$$(13b) \quad \frac{\partial \eta}{\partial x} = b_1 = 0, \quad \frac{\partial \zeta}{\partial x} = c_1 = 0.$$

Because of (13) and (13a, b) the Eqs. (12) take the form

$$(14) \quad \eta = -\alpha xz, \quad \zeta = +\alpha xy$$

where α has been written instead of c_3 .

The elastic differential equations and the boundary conditions at the end face are certainly satisfied by the assumptions about ξ , η , ζ , expressed in (7), (11), and (14), but the question remains whether *the boundary conditions for the curved surface of the rod* can be satisfied in this way. If n denotes the normal at a point P of the curved surface and s the direction tangential to the contour of the cross-section at P , the conditions are

$$(15) \quad \sigma_{nn} = 0 \quad \text{and} \quad \sigma_{ns} = 0.$$

The first of these equations can certainly be satisfied: We may draw the y -axis which so far has not been fixed parallel to n so that the z -axis becomes parallel to s and σ_{nn} coincides with σ_{ss} at the point P . But since $\epsilon_{ss} = 0$ by (9), it follows that σ_{ss} vanishes also at P . This argument can

obviously be applied to each point P of the curved surface. As to the second condition (15), we base our argument, on the general tensor relation (8.5) which becomes in our case

$$(16) \quad \begin{aligned} \sigma_{nz} &= \beta_1 \sigma_{yz} + \gamma_1 \sigma_{xz} = 2\mu(\beta_1 \epsilon_{yz} + \gamma_1 \epsilon_{xz}) \\ &= \mu \left(\beta_1 \left\{ \frac{\partial \xi}{\partial y} + \frac{\partial \eta}{\partial x} \right\} + \gamma_1 \left\{ \frac{\partial \xi}{\partial z} + \frac{\partial \zeta}{\partial x} \right\} \right). \end{aligned}$$

Here β_1 and γ_1 are the cosines of angles between the n direction and the y and z directions respectively. If s is oriented in such a way that the sense of rotation $s \rightarrow n$ coincides with $y \rightarrow z$, we have

$$(17) \quad \begin{aligned} \beta_1 &= \cos(n, y) = -\cos(s, z) = -\frac{dz}{ds}, \\ \gamma_1 &= \cos(n, z) = +\cos(s, y) = +\frac{dy}{ds}. \end{aligned}$$

Using (16), (17), (7), and (14) the second condition (15) can be written in the following form:

$$(18) \quad 0 = -\left(\frac{\partial \Phi}{\partial y} - \alpha z\right) dz + \left(\frac{\partial \Phi}{\partial z} + \alpha y\right) dy.$$

This equation must be satisfied at each point of the contour. It can be simplified by introducing the *conjugate* of the potential function Φ (corresponding to the *stream function* in hydrodynamics), which is connected with Φ by the Cauchy-Riemann equations (19.5). In our present coordinates (y, z instead of x, y) we have therefore

$$(18a) \quad \frac{\partial \Phi}{\partial y} = \frac{\partial \Psi}{\partial z}, \quad \frac{\partial \Phi}{\partial z} = -\frac{\partial \Psi}{\partial y}.$$

Eq. (18) thus transforms into

$$\left(\frac{\partial \Psi}{\partial z} - \alpha z\right) dz + \left(\frac{\partial \Psi}{\partial y} - \alpha y\right) dy = 0,$$

or

$$d\Psi = \alpha(y dy + z dz) = \frac{\alpha}{2} d(y^2 + z^2)$$

or, integrated,

$$(19) \quad \Psi = \frac{\alpha}{2} (y^2 + z^2) + C \dots \quad (\text{boundary condition}).$$

The conjugate potential Ψ satisfies also the differential Eq. (11):

$$(19a) \quad \nabla^2 \Psi = 0.$$

By (19) and (19a) the potential function Ψ is uniquely determined being the (always existing) solution of a simple potential problem. We have therefore proved that our boundary condition (18) can be fulfilled. At the same time the special assumptions made in (8), (9), and (12) have been justified.

Let us now consider once more the circular cross-section. The contour is given by $y^2 + z^2 = a^2$, the origin coinciding with the center of the circle. Eq. (19) becomes therefore

$$\Psi = \text{const.}$$

along the contour and, according to (19a), also in the interior. From (18a) we have then

$$\Phi = \text{Const} \quad \text{and by} \quad (7) \quad \xi = \text{Const.}$$

which means: *the cross-sections remain plane*. Conversely, if, for a certain shape of the cross-section, ξ vanishes along the rod, we have $\Phi = 0$ by (7) and therefore $\Psi = \text{const}$ by (18a). From (19) the contour is obtained in the form $y^2 + z^2 = \text{const}$: *The cross-section is circular*.

Take now as a less trivial example the elliptical cross-section, the contour of which may be given as

$$(20) \quad \frac{y^2}{a^2} + \frac{z^2}{b^2} = 1.$$

Since the general solution of (19a) is

$$\Psi = \text{Re } f(y + iz), \quad (\text{Re} = \text{real part of})$$

we shall assume f as the second power of the argument $y + iz$ so that

$$(21) \quad \Psi = A(y^2 - z^2).$$

Along the contour we have according to (19)

$$A(y^2 - z^2) = \frac{\alpha}{2}(y^2 + z^2) + C.$$

On substituting z^2 from (20), an identity in y results from which A follows as

$$(21a) \quad A = \frac{\alpha}{2} \frac{a^2 - b^2}{a^2 + b^2}.$$

From (18a) and (21) we can now calculate

$$\frac{\partial \Phi}{\partial y} = -\alpha \frac{a^2 - b^2}{a^2 + b^2} z, \quad \frac{\partial \Phi}{\partial z} = -\alpha \frac{a^2 - b^2}{a^2 + b^2} y$$

and obtain the shear stresses according to (7) and (14):

$$\begin{aligned} \sigma_{xy} &= 2\mu\epsilon_{xy} = \mu\left(\frac{\partial \Phi}{\partial y} + \frac{\partial \eta}{\partial x}\right) = -\mu\alpha\left(\frac{a^2 - b^2}{a^2 + b^2} + 1\right)z = -2\mu\frac{\alpha a^2}{a^2 + b^2}z, \\ (22) \quad \sigma_{xz} &= 2\mu\epsilon_{xz} = \mu\left(\frac{\partial \Phi}{\partial z} + \frac{\partial \xi}{\partial x}\right) = -\mu\alpha\left(\frac{a^2 - b^2}{a^2 + b^2} - 1\right)y = 2\mu\frac{\alpha b^2}{a^2 + b^2}y. \end{aligned}$$

The shear stress τ resulting from σ_{xy} and σ_{xz} is at any point of the cross-section parallel to the tangent that passes through the intersection point of the contour with the prolonged radius vector. Along the radius vector, τ follows a linear law. The moment of the shear stresses about the x -axis results from (22) in the form of the following formula which is a generalization of our previous formula (5):

$$(23) \quad M = \iint (y\sigma_{xz} - z\sigma_{xy}) dy dz = \frac{2\mu\alpha}{a^2 + b^2} \iint (b^2 y^2 + a^2 z^2) dy dz.$$

If the integration is carried out one obtains instead of the factor J_p , which appears in (5a) as the coefficient of $\mu\alpha$, the expression

$$(24) \quad \pi \frac{a^3 b^3}{a^2 + b^2},$$

which is not equal to the polar moment of inertia of the area of an ellipse (cf. problem VIII.4).

The simultaneous consideration of the potential function Φ and the stream function Ψ suggests a hydrodynamic analogy which has proved useful in the approximate solution of more complicated problems such as the torsion of an I -beam.

43. Torsion and Bending of a Helical Spring

Imagine a coil consisting of a single layer of thin wire wound on a circular cylinder. On removing the mandrel, we obtain a helical spring which we fasten at one end in some way, loading the other end with a disk, the weight of which is supposed to be small enough so that the resulting pitch of the spring is *small* compared to the radius of the cylinder. If we now put additional weight on the disk so as to have a small load acting along the axis of the spring, this will result in a slightly increased pitch and a corresponding lengthening of the spring. *This kind of loading is accompanied by a torsion of the wire.* If, on the other hand, a couple

acts on the disk (e.g., when the disk is turned in its own plane) the pitch remains essentially unchanged and the spring yields to the torque by a slight diminution of the cylinder radius. *In this case the wire is bent.*

Both facts seem paradoxical at first, but can be easily clarified: In *torsion* the individual cross-sections of the wire are loaded by a torque about the *polar axis* while in *bending* the moment acts about an *equatorial axis*, that is an axis in the plane of the cross-section. With this in mind let us examine in Figs. 72a and 72b what happens in the planes that pass in either case through the cylinder axis and the cross-sections marked in the respective figures. The load P acting along the cylinder axis in Fig. 72a has the moment PR about the center of the cross-section; we call it

FIG. 72a, b. A helical spring subject (a) to torsion (force P , vertical displacement y) and (b) to bending (moment QR , rotational displacement x).

the *torsional moment* M_T since its axial vector is normal to the cross-section. In Fig. 72b the couple QR acts upon the disk whose diameter has been assumed as $2R$ so that the two single forces of the couple can be denoted by $Q/2$. This moment has the character of a *bending moment* M_B since its axial vector coincides with the cylinder axis and can be transferred parallel to itself to the center of the marked cross-section. We denote its position by NN indicating in this way that it coincides with the trace of the neutral layer in the bent cross-section. In the loading according to Fig. 72a there will be *shear stresses* in the plane of the cross-section; they increase proportionally to the distance from the wire axis and will be denoted by τ as in the previous article. We have therefore

$$(1) \quad \int r \tau \, df = M_T .$$

In the loading according to Fig. 72b *normal stresses* σ act upon the cross-section. They are proportional to the distance y from the equatorial axis NN . Again we have

$$(2) \quad \int y \sigma \, df = M_B .$$

Eqs. (1) and (2) may be evaluated according to (42.4a) and (42.5a), or (41.5):

$$(3) \quad \frac{\tau_{\max}}{a} J_p = M_\tau \quad \text{respectively} \quad \frac{\sigma_{\max}}{a} I = M_B .$$

Apart from the maximum stresses τ_{\max} and σ_{\max} we should like to know the displacement of the spring in vertical direction y and horizontal direction x for the two respective kinds of loading. For this purpose we should have to know the shape of the elastic line of an *originally curved* rod in torsion and bending. There is, however, a simpler way to answer our question when use is made of the *energy principle*: one calculates the work of deformation expended in the torsion or bending of the spring and compares it with the work of the external forces P or Q . This, by the way, is a welcome opportunity to come back to the topic of energy of deformation which is highly important in engineering applications.⁹

So far we have only derived the general expression (9.26b) for the energy of deformation. In the case of pure shear, where

$$\sigma_{12} = \sigma_{21} = \tau, \quad \epsilon_{12} = \epsilon_{21} = \frac{\tau}{2\mu},$$

or in the case of pure extension and compression (bending), where

$$\sigma_{11} = \sigma, \quad \epsilon_{11} = \frac{\sigma}{E},$$

(9.26b) reduces to

$$(4) \quad W = \frac{1}{2} (\sigma_{12}\epsilon_{12} + \sigma_{21}\epsilon_{21}) = \frac{1}{2} \frac{\tau^2}{\mu}$$

or to

$$(5) \quad W = \frac{1}{2} \sigma_{11}\epsilon_{11} = \frac{1}{2} \frac{\sigma^2}{E},$$

respectively. These expressions refer to the unit volume and must be applied in the case of locally variable stresses to each single volume element $df \, ds$, where df is the area element of the cross section and ds the length element of the axis of the rod. Thus we obtain from (4) in the case of torsion

$$(6) \quad dW = \frac{1}{2} \frac{\tau^2}{\mu} df \, ds, \quad \tau = \frac{r}{a} \tau_{\max} \quad \text{from (42.4a).}$$

⁹In all statically indeterminate systems, in particular in the theory of trusses, Castigliano's theorems about the *minimum of the energy of deformation* play an important role, and so does *Maxwell's theorem of the reciprocity of the displacements*.

Integration over the cross-section yields

$$(6a) \quad \int dW = \frac{1}{2\mu} \frac{\tau_{\max}^2}{a^2} \int r^2 df ds = \frac{\tau_{\max}^2}{2\mu a^2} J, ds,$$

and, by (3),

$$(6b) \quad \int dW = \frac{M_T^2}{2\mu J} ds.$$

The entire torsional energy W_T follows by integration over the length l of the rod (in our case the length of the spring):

$$(7) \quad W_T = \frac{M_T^2 l}{2\mu J} = \frac{P^2 R^2 l}{2\mu J}.$$

Likewise one obtains in the case of bending from (5)

$$(8) \quad dW = \frac{1}{2} \frac{\sigma^2}{E} df ds, \quad \sigma = \frac{y}{a} \sigma_{\max} \quad \text{according to (41.2),}$$

and by integration over the cross-section

$$(8a) \quad \int dW = \frac{1}{2E} \frac{\sigma_{\max}^2}{a^2} \int y^2 df ds = \frac{\sigma_{\max}^2}{2E a^2} I ds.$$

The entire bending energy contained in the spring is obtained from (8a) and (3) as

$$(9) \quad W_B = \frac{M_B^2 l}{2EI} = \frac{Q^2 R^2 l}{2EI}.$$

Expressions (7) and (9) represent the energy intake of the spring in an *elastic* deformation in which the spring passes through a sequence of states of equilibrium. It must be compared with the *mechanical* work performed along the paths y (or x) when the load P (or the couple QR) increases *gradually* from zero to its final value. The work is therefore

$$(10) \quad W_T = \frac{Py}{2}, \quad \text{respectively} \quad W_B = 2 \frac{(Q/2)x}{2} = \frac{Qx}{2}.$$

Comparison with (7) and (9) gives

$$(11) \quad y = \frac{R^2 l}{\mu J} P, \quad x = \frac{R^2 l}{EI} Q.$$

Thus the use of the energy principle leads indeed to a very simple determination of the displacements x and y . Note that Eqs. (11) can also

be obtained from the first principle of Castigliano in the following way:¹⁰

$$(11a) \quad W(P, Q) = W_T + W_B, \quad y = \frac{\partial W}{\partial P}, \quad x = \frac{\partial W}{\partial Q}.$$

From these equations we can easily pass to the *free oscillations* of the spring when we replace P and Q by the inertia forces

$$(12) \quad P = -M \frac{d^2 y}{dt^2}, \quad Q = -M_{\text{red}} \frac{d^2 x}{dt^2}.$$

Here the masses M and M_{red} have to be given the appropriate physical meaning. M is essentially the mass M_0 of the disk that oscillates up and down, but since the mass m of the spring partakes also in the oscillation, (its lower portion more strongly than its upper one) a fraction of this mass must be added as a correction to the mass of the disk. According to Lord Rayleigh this fraction is $\frac{1}{3}$, hence M is to be interpreted as $M_0 + m/3$. On the other hand, the inertia force governing the oscillations about the cylinder axis is $-\Theta \, d^2 \varphi / dt^2$, where $\varphi = x/R$ is the angular displacement of the disk according to the meaning of x in Fig. 72b. Again Θ is essentially the moment of inertia Θ_0 of the disk augmented by $\frac{1}{3}$ of the moment of inertia of the coil mR^2 . Consequently M_{red} is to be defined as

$$M_{\text{red}} R^2 = \Theta = \Theta_0 + \frac{1}{3} m R^2.$$

The equations of the free torsional and bending oscillations are according to (12) and (11)

$$(13) \quad \frac{d^2 y}{dt^2} + \frac{\mu J_p}{MR^2 l} y = 0, \quad \frac{d^2 x}{dt^2} + \frac{EI}{M_{\text{red}} R^2 l} x = 0$$

and the associated circular frequencies

$$(14) \quad \omega_T = \sqrt{\frac{\mu J_p}{MR^2 l}}, \quad \omega_B = \sqrt{\frac{EI}{M_{\text{red}} R^2 l}}.$$

In general they are different from each other.¹¹ If they are equal, the two

¹⁰The rule (11a) presupposes that y , x and P , Q are linearly connected so that $W(P, Q)$ is a quadratic expression in P and Q as in (7) and (9). In the general case one would have to replace W by the "modified" expression for the energy $U(P, Q) = yP + xQ - W(x, y)$. Cf. about this transformation Vol. I. 42.7 and E. L. Ince, *Ordinary Differential Equations*, Dover Publ., New York, 1944, Chapter 2.5 (Legendre's transformation).

¹¹This can be enforced in an actual experiment by loading the spring with an additional weight that acts along its axis and has a small moment of inertia about it (cf. Vol. I, Fig. 37). Thus the mass M that takes part in the torsional oscillation is increased and the frequency ω_T reduced. M_{red} and ω_B remain essentially unchanged, however.

oscillations are in *resonance* and the behavior of the spring becomes very sensitive to small changes of the parameters involved. Then the present theory is no longer sufficient: we have to take into account that the two modes of oscillation are coupled through the finite pitch of the spring which so far has been neglected.

For finite pitch h the slope α of the helix is given by

$$\sin \alpha = \frac{h}{2\pi R}.$$

This is also the angle of inclination that the cross-section of the wire forms with the vertical. The two loading moments PR and QR may then be decomposed as follows:

	normal to the cross-section	parallel to the cross-section
PR	$\cos \alpha \cdot PR$	$-\sin \alpha \cdot PR$
QR	$\sin \alpha \cdot QR$	$\cos \alpha \cdot QR$

The contributions to the torsional moment are on the left side, those to the bending moment on the right side, therefore

$$M_T = \cos \alpha PR + \sin \alpha QR, \quad M_B = \cos \alpha QR - \sin \alpha PR.$$

The total bending energy becomes

$$\begin{aligned} W &= W_T + W_B = \frac{M_T^2 l}{2\mu J_p} + \frac{M_B^2 l}{2EI} \\ (15a) \quad &= \frac{R^2 l}{2} \left(\frac{(\cos \alpha P + \sin \alpha Q)^2}{\mu J_p} + \frac{(\cos \alpha Q - \sin \alpha P)^2}{EI} \right), \end{aligned}$$

and the displacements can be determined according to the rule (11a):

$$\begin{aligned} y &= \frac{\partial W}{\partial P} = \frac{R^2 l}{\mu J_p} (\cos^2 \alpha P + \sin \alpha \cos \alpha Q) \\ &\quad + \frac{R^2 l}{EI} (-\sin \alpha \cos \alpha Q + \sin^2 \alpha P), \\ (15b) \quad x &= \frac{\partial W}{\partial Q} = \frac{R^2 l}{\mu J_p} (\sin \alpha \cos \alpha P + \sin^2 \alpha Q) \\ &\quad + \frac{R^2 l}{EI} (\cos^2 \alpha Q - \sin \alpha \cos \alpha P). \end{aligned}$$

These equations now replace Eqs. (11). Upon replacing the inertia forces (12) by P and Q , one obtains the following system of equations which describes the coupled oscillations of the spring:

$$(16) \quad \frac{d^2 y}{dt^2} + \omega_T^2 (y - kx) = 0, \quad \frac{d^2 x}{dt^2} + \omega_B^2 (x - hy) = 0$$

where ω_T , ω_B , k , and h are

$$(16a) \quad \omega_T^2 = \frac{\mu J_p}{MR^2 l} (1 + \nu \sin^2 \alpha), \quad \omega_B^2 = \frac{\mu J_p}{M_{rod} R^2 l} (1 + \nu \cos^2 \alpha),$$

$$(16b) \quad k = \frac{\nu \sin \alpha \cos \alpha}{1 + \nu \sin^2 \alpha}, \quad h = \frac{\nu \sin \alpha \cos \alpha}{1 + \nu \cos^2 \alpha}$$

and ν is Poisson's ratio. The coupling coefficients k and h vanish if $\alpha = 0$ so that the frequencies ω_T and ω_B reassume the previous values (14) and Eqs. (16) become identical with Eqs. (13).¹²

The further discussion of Eq. (16) is no longer a problem of theory of elasticity. For the case of resonance, $\omega_T = \omega_B$, the behavior of the spring has already been described in Vol. I 20: the energy passes back and forth between the originally excited mode and the mode that is excited consequential to it, to the extent that the two modes are alternately extinguished. The beat period N expressed in time units of single oscillations can be very accurately determined by counting the number of oscillations in a beat. It becomes a maximum in the case of resonance. The large number N_{\max} and the small angle α permit a precise determination¹³ of Poisson's ratio ν , as shown by the author.

The resonance phenomena discussed here have first been described and explained by Wilberforce,¹⁴ but his determination of Poisson's ratio is founded on the relations (14) rather than on the more elegant resonance method.

44. The Elastic Energy Content of a Rectangular Parallelepiped

In 14 we have studied elastic waves in an *infinitely extended* isotropic solid; in the following two articles we shall discuss the elastic oscillations in *finite* bodies, dealing first with a rectangular parallelepiped with sides a, b, c . Let us assume that the faces which are situated at $x = 0, a; y = 0, b;$

¹²In comparing the values of ω_B in (16a) and (14), use relation $J_p = 2I$ for circular cross-sections and relation (9.11), $E = 2\mu(1 + \nu)$, which has already been used in the transition from (15) to (16).

¹³Wüllner-Festschrift, Teubner, Leipzig 1905, p. 162.

¹⁴Phil. Mag. 38 (1894) 386.

$z = 0, c$, are free, in which case we must stipulate that the corresponding normal and shear stresses vanish. The oscillations possible under these conditions are called the *proper oscillations* of the body; they are executed without any *exchange of energy* with the surroundings.

The problem as it has just been outlined presents great mathematical difficulties.¹⁶ A particular case of the general problem, the vibrations of a rectangular plate, has withstood all attempts at a rigorous solution although Chladni's beautiful figures have been known for 150 years and are still a challenge for the best mathematicians. The most successful step so far was taken by Ritz;¹⁸ it does not, however, give a direct solution of the differential equations with their boundary conditions, but establishes a minimum principle by which a stepwise approximation of the solution becomes feasible.

It is, however, possible to prevent the exchange of energy with the surroundings by other sets of boundary conditions. Consider the work performed per unit of x -surface in the displacement with components ξ, η, ζ :

$$(1) \quad \delta A = \sigma_{xx}\xi + \sigma_{xy}\eta + \sigma_{xz}\zeta.$$

It is not only zero if

$$(2) \quad \sigma_{xx} = \sigma_{xy} = \sigma_{xz} = 0 \quad (\text{surface free of stress})$$

or if

$$(2a) \quad \xi = \eta = \zeta = 0 \quad (\text{surface kept immovable}),$$

but also if for example

$$(3) \quad \xi = 0, \quad \sigma_{xy} = \sigma_{xz} = 0$$

or

$$(3a) \quad \sigma_{xx} = 0, \quad \eta = \zeta = 0.$$

The assumption of *mixed* boundary conditions as in (3) or (3a) makes an elementary treatment of our problem possible as C. Somigliana¹⁷ showed in 1902 for the case of static loading; they are, on the other hand, equiva-

¹⁶The special case of the *cube* which is usually studied in similar problems of electromagnetic radiation is essentially not simpler than the more general case considered here. One can see that from the final result of Eq. (23), which refers only to the size of the body V , but not to its shape.

¹⁸W. Ritz, Theorie der Transversalschwingungen einer quadratischen Platte mit freien Rändern, Ann. Physik 28 (1909) 737. The circular plate can be directly integrated, as was shown by Kirchhoff.

¹⁷See the comprehensive article of O. Tedone in Encykl. d. Mathem. Wiss. Vol. IV, 4, Art. 25, No. 2.

lent to the uniform conditions (2) or (2a) as regards the physical applications which we have in mind.

We therefore base our calculation on the boundary conditions (3) and the corresponding conditions for y and z -surfaces, obtained from (3) by rotating the letters. Since the first Eq. (3) implies

$$\frac{\partial \xi}{\partial y} = \frac{\partial \xi}{\partial z} = 0, \quad 2\epsilon_{xy} = \frac{\partial \eta}{\partial x}, \quad 2\epsilon_{xz} = \frac{\partial \zeta}{\partial x},$$

the boundary conditions can be written:

$$(4) \quad \begin{aligned} \xi &= 0, \quad \frac{\partial \eta}{\partial x} = \frac{\partial \zeta}{\partial x} = 0 & \text{for } x &= \begin{cases} 0 \\ a \end{cases}, \\ \eta &= 0, \quad \frac{\partial \zeta}{\partial y} = \frac{\partial \xi}{\partial y} = 0 & \text{for } y &= \begin{cases} 0 \\ b \end{cases}, \\ \zeta &= 0, \quad \frac{\partial \xi}{\partial z} = \frac{\partial \eta}{\partial z} = 0 & \text{for } z &= \begin{cases} 0 \\ c \end{cases}. \end{aligned}$$

Our differential equations are the Eqs. (14.1b) which because of $\mathbf{F} = 0$ now read

$$(5) \quad \begin{aligned} \rho \frac{\partial^2 \xi}{\partial t^2} &= \mu \nabla^2 \xi + (\lambda + \mu) \frac{\partial \Theta}{\partial x}, \\ \rho \frac{\partial^2 \eta}{\partial t^2} &= \mu \nabla^2 \eta + (\lambda + \mu) \frac{\partial \Theta}{\partial y}, \\ \rho \frac{\partial^2 \zeta}{\partial t^2} &= \mu \nabla^2 \zeta + (\lambda + \mu) \frac{\partial \Theta}{\partial z}. \end{aligned}$$

Eqs. (4) can be satisfied by the following set of expressions for ξ , η , ζ :

$$(6) \quad \begin{aligned} \xi &= A \sin \frac{a\pi x}{a} \cos \frac{b\pi y}{b} \cos \frac{c\pi z}{c} e^{-i\omega t}, \\ \eta &= B \cos \frac{a\pi x}{a} \sin \frac{b\pi y}{b} \cos \frac{c\pi z}{c} e^{-i\omega t}, \\ \zeta &= C \cos \frac{a\pi x}{a} \cos \frac{b\pi y}{b} \sin \frac{c\pi z}{c} e^{-i\omega t}. \end{aligned}$$

where a, b, c are arbitrary integer numbers. A, B, C are constants whose ratios are to be determined; also the circular frequency ω must be found.

On introducing the expressions (6) in (5), there appear, in each of the three terms of the equations (5), the same trigonometrical factors as in ξ, η, ζ . One has for instance

$$\rho \frac{\partial^2 \xi}{\partial t^2} = -\rho \omega^2 A \sin \dots \cos \dots \cos \dots e^{-i\omega t},$$

$$\nabla^2 \xi = -A \left(\frac{a^2}{a^2} + \frac{b^2}{b^2} + \frac{c^2}{c^2} \right) \pi^2 \sin \dots \cos \dots \cos \dots e^{-i\omega t},$$

$$\frac{\partial \Theta}{\partial x} = - \left(A \frac{a^2}{a^2} + B \frac{ab}{ab} + C \frac{ac}{ac} \right) \pi^2 \sin \dots \cos \dots \cos \dots e^{-i\omega t}.$$

On omission of these factors, the differential equations (5) give the following linear system of equations for A, B, C

$$\begin{aligned} (7) \quad & A \left(\Omega + \frac{aa}{a^2} \right) + B \frac{ab}{ab} + C \frac{ac}{ac} = 0, \\ & A \frac{ba}{ba} + B \left(\Omega + \frac{bb}{b^2} \right) + C \frac{bc}{bc} = 0, \\ & A \frac{ca}{ca} + B \frac{cb}{cb} + C \left(\Omega + \frac{cc}{c^2} \right) = 0. \end{aligned}$$

Here Ω is defined by

$$(7a) \quad (\lambda + \mu) \Omega = \mu s - \frac{\rho \omega^2}{\pi^2}, \quad s = \frac{a^2}{a^2} + \frac{b^2}{b^2} + \frac{c^2}{c^2}.$$

The linear equations (7) have solutions different from zero only, if the determinant

$$(8) \quad \Delta = \begin{vmatrix} \Omega + \frac{aa}{a^2}, & \frac{ab}{ab}, & \frac{ac}{ac} \\ \frac{ba}{ba}, & \Omega + \frac{bb}{b^2}, & \frac{bc}{bc} \\ \frac{ca}{ca}, & \frac{cb}{cb}, & \Omega + \frac{cc}{c^2} \end{vmatrix} = 0$$

On expanding (8) in powers of Ω , one sees easily that the factors of Ω^0

and Ω^1 vanish while those of Ω^2 and Ω^3 are s and 1. Eq. (8) can thus be rewritten in the form

$$(9) \quad \Omega^3 + s\Omega^2 = \Omega^2(\Omega + s) = 0,$$

an equation that has the double root $\Omega_1 = \Omega_2 = 0$ and the simple root $\Omega_3 = -s$. From (7a) we obtain the corresponding frequency values

$$(10) \quad \omega_1^2 = \omega_2^2 = \pi^2 \frac{\mu}{\rho} s, \quad \omega_3^2 = \pi^2 \frac{\lambda + 2\mu}{\rho} s.$$

The ratios $A : B : C$ associated with these values of ω are found from (7) so that the set (6) has now been determined except for a common amplitude factor. Further arbitrary elements are the numbers a, b, c .

What is the physical meaning of this arbitrariness? By the numbers a, b, c the sides a, b, c are subdivided into segments which must be interpreted as wave lengths:

$$(11) \quad \lambda_a = \frac{a}{\alpha}, \quad \lambda_b = \frac{b}{\beta}, \quad \lambda_c = \frac{c}{\gamma}.$$

They just fit the boundaries of the parallelepiped. The associated wave numbers are

$$(11a) \quad k_a = \frac{2\pi}{\lambda_a} = 2\pi \frac{\alpha}{a}, \quad k_b = \frac{2\pi}{\lambda_b} = 2\pi \frac{\beta}{b}, \quad k_c = \frac{2\pi}{\lambda_c} = 2\pi \frac{\gamma}{c}.$$

With a view to Eqs. (6) and to Eqs. (11) we can write

$$(12) \quad \xi = A \sin \pi \frac{x}{\lambda_a} e^{-i\omega t}, \quad \eta = \zeta = 0,$$

if we consider a particular solution depending on x only. Eq. (12) represents a standing wave which has the boundaries $x = 0$ and $x = a = \alpha\lambda_a$ as nodal surfaces. Altogether, the Eqs. (6) represent the entirety of standing waves that can be accommodated by the parallelepiped. Unlike the example (12), however, they are in general not plane waves but are composed of waves in the three directions of the edges according to the particular rule set by Eqs. (6).

The structure of Eqs. (10) teaches further that the waves are partly of *transverse*, partly of *longitudinal* nature. According to Eqs. (14.6) and (14.3) we have

$$c_{\text{trans}} = \sqrt{\frac{\mu}{\rho}}, \quad c_{\text{long}} = \sqrt{\frac{\lambda + 2\mu}{\rho}},$$

where now c_{trans} and c_{long} stand for the previous notations b and a for

the sound velocities. If we further introduce a wave number k_r , resulting from the three wave numbers k_a, k_b, k_c , by

$$k_r = \sqrt{k_a^2 + k_b^2 + k_c^2},$$

we obtain from (11a) and (7a)

$$(13) \quad k_r = 2\pi \sqrt{\frac{a^2}{a^3} + \frac{b^2}{b^3} + \frac{c^2}{c^3}} = 2\pi \sqrt{s}.$$

Eqs. (10) are then simply

$$(14) \quad \omega_1 = \omega_2 = \frac{1}{2} c_{\text{trans}} k_r, \quad \omega_3 = \frac{1}{2} c_{\text{long}} k_r.$$

The fact that the transverse waves are counted twice points to the physical possibility of polarization in two mutually orthogonal directions.

We have thus found a system of infinitely many elastic waves which can be excited in an adiabatically insulated parallelepiped. The system is *complete*, that is, the *only* standing waves that obey our boundary conditions are those of the system (6). The proof of completeness consists in showing that an arbitrarily given initial state can be expanded in terms of the functions (6) for $t = 0$.¹⁸

Let us now determine the number z of all waves whose frequency is smaller than a given $\nu = \omega/2\pi$, which can be done by geometrical reasoning. We first count the longitudinal waves.

By marking in the rectangular system k_a, k_b, k_c all points that belong to integer values a, b, c , we obtain a three-dimensional orthorhombic lattice, whose elementary cell has according to (11a) the sides

$$\frac{2\pi}{a}, \quad \frac{2\pi}{b}, \quad \frac{2\pi}{c}.$$

Consider now the lattice points inside the spherical surface $k_r = \text{const}$, which corresponds to the frequency ν . According to (14) the radius of the sphere $k_r = 4\pi\nu/c_{\text{long}}$. Because of $a, b, c \geq 0$, we are only interested in the lattice points that lie in the positive octant, whose volume is

$$\frac{4\pi}{3} \frac{k_r^3}{8} = \frac{4\pi}{3} \left(\frac{2\pi\nu}{c_{\text{long}}} \right)^3.$$

¹⁸Cf. for such a proof and for a generalization to anisotropic bodies: R. Ortqvist, Ann. Physik. 42 (1913), 745. A treatment of the problem from the point of view of group theory was presented by H. Wierzejewski in his Breslau thesis suggested by E. Fues: Elastische Eigenschwingungen von Kristallen bei gemischten Randbedingungen, Z. f. Kristallographie, Vol. 101, 1939.

On dividing by the volume of the elementary cell

$$(15) \quad \frac{(2\pi)^3}{abc},$$

we obtain the number of elementary cells or the number of lattice points in the spherical octant which, at the same time, is the number of longitudinal waves with frequencies below ν :

$$(16) \quad \mathfrak{z}_{\text{long}} = \frac{4\pi}{3} \frac{abc\nu^3}{c_{\text{long}}^3}.$$

In exactly the same way one has for either state of polarization of the transversal waves

$$(16a) \quad \mathfrak{z}_{\text{trans}} = \frac{4\pi}{3} \frac{abc\nu^3}{c_{\text{trans}}^3};$$

thus the total number of vibrational states below ν becomes

$$(16b) \quad \mathfrak{z} = \mathfrak{z}_{\text{long}} + 2\mathfrak{z}_{\text{trans}} = \frac{4\pi}{3} abc\nu^3 \left(\frac{2}{c_{\text{trans}}^3} + \frac{1}{c_{\text{long}}^3} \right).$$

The number \mathfrak{z} just obtained is accurate except for an error which is due to the fact that the spherical surface and the boundaries of the enclosed elementary cells do not coincide. The error is of the order of magnitude $1/abc$ [cf. (15)] and thus negligible for a large parallelepiped. By differentiating (16b) with respect to ν we can now determine the number of vibrational states between ν and $\nu + d\nu$:

$$(17) \quad d\mathfrak{z} = 4\pi V \left(\frac{2}{c_{\text{trans}}^3} + \frac{1}{c_{\text{long}}^3} \right) \nu^2 d\nu$$

where V is the volume abc of the parallelepiped.

We are now ready to attack the problem which we formulated at the outset. We want to calculate *the energy content of the adiabatically insulated solid body*, which, according to the definition in the older literature, is *identical with the vibrational energy of its molecules*. It is preferable, however, to follow Debye¹⁹ who defines the energy content as that of

¹⁹P. Debye, Ann. Physik., 39 (1912) 789. In this fundamental paper Debye calculates the proper vibrations of a sufficiently large *sphere*, the surface of which is considered *free of stresses*, that is, he uses the boundary conditions corresponding to our equations (2). As the circular shape is the only case in which the plate problem can be directly integrated (cf. footnote, p. 315), so the sphere is the only elastic three-dimensional problem whose integration leads in the case of "uniform boundary conditions" to known functions (Bessel functions). But even in this case the solution is very involved and becomes only possible by the use of asymptotic approximations of Bessel functions for large argument and index that are due to Debye. The simplification that can be

the energy of the elastic vibrations of the body. The molecules are strongly coupled, hence it is impossible to excite oscillations of individual molecules; on the other hand, the waves considered in (6) are independent from each other and satisfy individually the differential equations of the elastic body.

Each of these vibrational states may therefore be quantized individually according to the quantum rules first established by Planck in the discovery of his radiation law:

$$(18) \quad \epsilon_n = nh\nu \begin{cases} n = \text{integer number} \\ h = \text{Planck's constant} \end{cases}$$

The quantum rules are here applied without further explanation; they will be discussed in Vol. V. Also the refinement of the rules due to modern quantum mechanics according to which the integer number n in (18) should be replaced by $n + \frac{1}{2}$ is here disregarded as irrelevant for our purpose.

In addition, we require for the following the Boltzmann factor which was introduced in (7.15c), though without proof. In the present case the Boltzmann factor has this physical meaning: Given N oscillating systems in thermodynamical equilibrium at the temperature T , the number N_n of those systems whose energy equals ϵ_n is then

$$(19) \quad N_n = A \exp\left(-\frac{\epsilon_n}{kT}\right) = A\alpha^n, \quad \alpha = \exp\left(-\frac{h\nu}{kT}\right);$$

the constant A can be determined, when the total number N of all oscillating systems is written as the sum of the N_n :

$$(20) \quad N = \sum_{n=0}^{\infty} N_n = A(1 + \alpha + \alpha^2 + \cdots) = \frac{A}{1 - \alpha}.$$

In our case, N is to be identified with the (large!) number d_3 from (17). We then obtain for A

$$(20a) \quad A = (1 - \alpha)d_3.$$

achieved by "mixed boundary conditions" was first stated by the author in a course on quantum theory in 1912 and then left to Mr. Ortqvist for further development and publication (cf. the preceding footnote). It should be noticed that Debye had to take the radius of the sphere sufficiently large to enforce independence of the distribution of the eigenfunctions from the shape of the body. For the same reason the dimensions of the parallelepiped in the present case must be sufficiently large as was already assumed in the text preceding Eq. (17) in order to make the "surface error" negligibly small.

Let us denote by dU that fraction of the total energy U which is contained in these $d\lambda$ oscillations. According to (19) and (20a), one has

$$(21) \quad dU = \sum_{n=0}^{\infty} N_n \epsilon_n = Ah\nu \sum n\alpha^n = (1 - \alpha)h\nu d\lambda \sum_{n=0}^{\infty} n\alpha^n.$$

The series occurring here can be summed easily (by differentiating the geometrical series in (20) with respect to α), and equals $\alpha/(1 - \alpha)^2$. Eq. (21) yields together with the definition of α in (19)

$$(22) \quad dU = h\nu \frac{\alpha}{1 - \alpha} d\lambda = \frac{h\nu}{\exp\left(\frac{h\nu}{kT}\right) - 1} d\lambda.$$

The denominator in this formula will reoccur in Planck's radiation law and, in a more general way, in the discussion of the Bose statistics in Vol. V.

We now substitute for $d\lambda$ according to (17) and integrate over ν from $\nu = 0$ up to an upper limit ν_s :

$$(23) \quad U = 4\pi Vh \left(\frac{2}{c_{\text{trans}}^3} + \frac{1}{c_{\text{long}}^3} \right) \int_0^{\nu_s} \frac{\nu^3 d\nu}{\exp\left(\frac{h\nu}{kT}\right) - 1}.$$

Our first task is the determination of the limit ν_s , which we find according to Debye by identifying the total number z_s of oscillations with frequencies smaller than ν_s with the *number of degrees of freedom of the body*. Since a single mass point has three degrees of freedom the number in question equals three times the number of molecules. If in particular the body is one mole of a uniform substance, the number of molecules, according to p. 53, is Loschmidt's number L . The number z_s thus equals $3L$. From Eq. (16b) we then obtain for the determination of the upper limit ν_s the relation

$$(24) \quad 3L = \frac{4\pi}{3} V_{\text{mol}} \nu_s^3 \left(\frac{2}{c_{\text{trans}}^3} + \frac{1}{c_{\text{long}}^3} \right),$$

where the molar volume V_{mol} has been written instead of abc . This equation that defines ν_s may also be used to simplify (23) which now takes the form

$$(25) \quad U_{\text{mol}} = \frac{9Lh}{\nu_s^3} \int_0^{\nu_s} \frac{\nu^3 d\nu}{\exp\left(\frac{h\nu}{kT}\right) - 1}.$$

With the abbreviations

$$(26) \quad y = \frac{h\nu}{kT}, \quad x = \frac{h\nu_0}{kT} = \frac{\Theta}{T}, \quad \Theta = \frac{h}{k} \nu_0,$$

we obtain finally

$$(27) \quad U_{\text{mol}} = 9Lk \frac{T^4}{\Theta^3} \int_0^x \frac{y^3 dy}{e^y - 1}.$$

The quantity Θ here introduced is known as *Debye's characteristic temperature*; for hard materials such as diamond and quartz it is approximately 100°K , for soft metals it amounts only to a few degrees. By and large, Eq. (27) is a good representation of the large number of data collected by Nernst and his co-workers. One can, of course, not expect that such details as depend on the specific structure of the crystal or the molecule should be covered by the general theory here developed.

We examine now Eq. (27) in the case of $T \gg \Theta$. This makes the upper limit $x \ll 1$, and the same is true for the integration variable y . Expanding the denominator

$$e^y - 1 = y \left(1 + \frac{y}{2} \dots \right),$$

we obtain for the integral in (27) with sufficient accuracy

$$\int_0^x y^3 dy = \frac{x^3}{3} = \frac{1}{3} \frac{\Theta^3}{T^3}.$$

From this we infer

$$(28) \quad U_{\text{mol}} = 3RT,$$

where the gas constant per mole, R , has been written for kL according to Eq. (7.15b).

Relation (28) contains the law of *Dulong-Petit*, since

$$(29) \quad c_{\text{mol}} = \frac{dU_{\text{mol}}}{dT} = 3R \cong 6 \text{ cal},$$

where c_{mol} denotes the specific heat per mole of the substance. Eq. (29) should be universally valid for all solids as an asymptotic law for high temperatures, provided one can disregard the relative vibrations of the components of the individual molecule. This restriction is necessary, since in counting the degrees of freedom we have assumed rigid molecules and disregarded the possible internal degrees of freedom. In fact, the rule of Dulong and Petit is particularly well satisfied for monatomic metals where the restriction is irrelevant. (In this case, c_{mol} is the gram atomic heat capacity).

The converse case, $T \ll \theta$, presents greater physical interest. The integral in (27) has now a very large upper limit ($x \gg 1$) and can be approximated by

$$(30) \quad \int_0^{\infty} \frac{y^3 e^{-y}}{1 - e^{-y}} dy = \int_0^{\infty} y^3 e^{-y} (1 + e^{-y} + e^{-2y} + \dots) dy.$$

Upon interchanging the order of summation and integration and introducing $z = ny$ in the n^{th} integral, one obtains instead of (30)

$$(30a) \quad \sum_{n=1}^{\infty} \frac{1}{n^4} \int_0^{\infty} z^3 e^{-z} dz = 3! \sum_{n=1}^{\infty} \frac{1}{n^4} = 3! \frac{\pi^4}{90}.$$

(The summation formula $\sum_{n=1}^{\infty} n^{-4} = \pi^4/90$ will be derived in Vol. VI in the chapter on Fourier series.)

With the use of the results (30) and (30a), Eq. (27) can be rewritten as

$$(31) \quad U_{\text{mol}} = \frac{3\pi^4}{5} \frac{RT^4}{\theta^3},$$

and differentiation with respect to T yields

$$(32) \quad c_{\text{mol}} = \frac{12\pi^4}{5} R \left(\frac{T}{\theta} \right)^3.$$

This is *Debye's third power law for the molar specific heat of a solid body at low temperature.*

Fig. 73 represents the general dependence of the specific heat on the temperature, as it is obtained by differentiation of Debye's equation (27); it also shows the two asymptotic laws for large T , i.e. the horizontal

FIG. 73. The specific heat per mole of a solid according to Debye, cf. Eq. (26) for the meaning of θ

straight line of the Dulong-Petit law, and for small T the T^3 -parabola of Debye. The latter law is a useful approximation only for extremely small values of T . Furthermore, there is a general deviation from this law in the proximity of absolute zero for metallic substances, which is caused by the degrees of freedom of the conduction electrons in this temperature region.

We do not want to leave this topic without mentioning the results that are obtained in the corresponding electromagnetic problem. In that case we are concerned with the energy confined within a cavity containing electromagnetic radiation but entirely devoid of matter. The free oscillations of such a cavity can be described and counted in a fashion similar to the case of the elastic parallelepiped. (Actually, the electromagnetic case is much simpler.) Methods to deal with this problem have been developed by Lord Rayleigh and Jeans, including the procedure of counting lattice points. These investigations have served as a pattern for the elastic theory developed in this article. In the electromagnetic case the result is equivalent to our Eq. (23) with the following simplifications:

1. Longitudinal waves do not occur in the electromagnetic field, so that the term $1/c^3_{\text{long}}$ does not occur.

2. Transverse waves travel with the velocity of light c ; hence the term $2/c^3_{\text{trans}}$ is simply $2/c^3$.

3. The number of degrees of freedom of the electromagnetic field is, as far as we know, unlimited (at least, it is not restricted by a molecular structure); ν_s becomes thus infinitely large.

4. The energy content per unit of volume (energy density) is obtained, if $V = 1$ in (23). In this case, one usually writes u instead of U and obtains from (23)

$$(33) \quad u = \frac{8\pi h}{c^3} \int_0^\infty \frac{\nu^3 d\nu}{\exp\left(\frac{h\nu}{kT}\right) - 1}.$$

Using again the substitution (26), and the formulas (30) and (30a), one has

$$(34) \quad u = \frac{8\pi h}{c^3} \frac{\pi^4}{15} \left(\frac{kT}{h}\right)^4 = \frac{8\pi^5}{15c^3} \frac{k^4}{h^3} T^4.$$

This is the law for the black body or cavity radiation in the definitive form due to Planck. *The T^4 -radiation law of Stefan and Boltzmann has the same physical origin as Debye's T^4 -law for the energy content of a solid and Debye's T^3 -law for the specific heat of a solid near absolute zero.*

45. The Surface Waves of the Elastic Half-Space.

We consider a homogeneous elastic solid having a plane boundary $y = 0$ and extending to infinity throughout the half-space $y > 0$, and want to study the simplest types of waves that can be propagated in the half-space. Along the boundary plane it is assumed that

$$(1) \quad \sigma_{yy} = \sigma_{yz} = \sigma_{yx} = 0;$$

then $y = 0$ is a stress-free boundary, as it would be if vacuum (or air) were on the other side.

A. Reflection of a Plane Transverse Spatial Wave

In the discussion of three-dimensional waves in 14 we distinguished between transverse and longitudinal waves; in the first case, the displacement vector is solenoidal (free of sources and sinks) and in the second case irrotational (cf. 20). Also the terms torsional and compressional waves are in use (cf. 14). The present discussion is restricted to the simplest case, that is, to *plane* waves of either sort.

Let us first consider a plane transverse wave whose direction of propagation forms the angle of incidence α with the positive y -axis and is "polarized" in the x, y -plane. This means that of the three displacements only ξ and η are different from zero. In complex notation such a wave is given in the following way:

$$(2) \quad \left. \begin{matrix} \xi_i \\ \eta_i \end{matrix} \right\} = \left. \begin{matrix} \cos \alpha \\ \sin \alpha \end{matrix} \right\} A \exp [ik(x \sin \alpha - y \cos \alpha)]$$

where the time-dependent factor $e^{-i\omega t}$ has been omitted for brevity [cf. the remarks to Eq. (13.15) and (13.15a)]; k is the wave number, and the subscript i characterizes the wave as incident. By Eq. (2) the condition of vanishing divergence is automatically fulfilled:

$$\Theta = \frac{\partial \xi_i}{\partial x} + \frac{\partial \eta_i}{\partial y} = 0.$$

Also, the planes of constant phase

$$(3) \quad x \sin \alpha - y \cos \alpha = \text{Const},$$

are normal to the direction of propagation defined by the angle α , as they have to be, and the displacement vector lies in this plane. The signs of the trigonometric functions in (2) follow from Fig. 74 and appear in the

first section of the following table, which gives the cosines of direction of the propagation and of the displacement vector relative to the positive x and y axes.

FIG. 74. A longitudinal wave is created in the reflexion of a transverse wave polarized in the plane of incidence.

	x	y	x	y	x	y

dir. of displ.	$\cos \alpha$	$\sin \alpha$	$\cos \alpha$	$-\sin \alpha$	$\sin \alpha_1$	$\cos \alpha_1$
	incid. transv.		refl. transv.		refl. longit.	

The differential equations of elasticity, which in the case of a transverse wave (because of $\Theta = 0$) have the simple form

$$(4) \quad \rho \frac{\partial^2 \xi}{\partial t^2} = \mu \nabla^2 \xi, \quad \rho \frac{\partial^2 \eta}{\partial t^2} = \mu \nabla^2 \eta,$$

are likewise satisfied by the set (2) provided that k for a given ω is determined from the well known equation

$$(5) \quad \frac{\omega^2}{k^2} = \frac{\mu}{\rho} = c_{\text{trans}}^2 = b^2$$

(b is the notation used for c_{trans} in 14).

The set (2) as it stands does not, of course, satisfy the boundary conditions (1). One might think that this can be achieved by superimposing a *reflected transversal* wave ξ_r, η_r

$$(6) \quad \left. \begin{array}{l} \xi_r \\ \eta_r \end{array} \right\} = \left. \begin{array}{l} \cos \alpha \\ -\sin \alpha \end{array} \right\} B \exp [ik(x \sin \alpha + y \cos \alpha)].$$

(the signs of the trigonometric functions now chosen as in the second section of the preceding table). This, however, cannot be done as we shall see now.

The quantities k and α in (6) must be identical with the corresponding quantities in (2). This follows for k from the differential equations (4), and for α as in elementary optics from the boundary conditions. For, the combination of an incident and a reflected wave

$$(7) \quad \xi = \xi_i + \xi_r, \quad \eta = \eta_i + \eta_r$$

is subject to the boundary conditions

$$\begin{aligned} 0 = \sigma_{yy} &= 2\mu\epsilon_{yy} = 2\mu \frac{\partial \eta}{\partial y} = -2\mu ik(A + B) \sin \alpha \cos \alpha e^{ikx \sin \alpha} \\ (8) \quad 0 = \sigma_{xy} &= 2\mu\epsilon_{xy} = \mu \left(\frac{\partial \xi}{\partial y} + \frac{\partial \eta}{\partial x} \right) = -\mu ik(A - B)(\cos^2 \alpha - \sin^2 \alpha) e^{ikx \sin \alpha} \end{aligned}$$

The third condition $\sigma_{yy} = 0$ is automatically fulfilled. But the two preceding conditions contradict each other, since the one requires $A = -B$ and the other $A = B$. Choosing another angle of reflexion ($\alpha_r \neq \alpha_i$) would make the contradiction even worse, since it would introduce an infinity of contradictory conditions instead of two, viz. a different one for every single x -value.

There is only one way to avoid the dilemma: assume that in the process of reflexion of a transverse wave there is generated a *longitudinal* wave in addition to the reflected transverse wave, so as to make available a further amplitude constant C . With a view to the third section of the table we put

$$(9) \quad \left. \begin{matrix} \xi_i \\ \eta_i \end{matrix} \right\} = \left. \begin{matrix} \sin \alpha_i \\ \cos \alpha_i \end{matrix} \right\} C e^{ik_i(x \sin \alpha_i + y \cos \alpha_i)}$$

where k_i is now *different* from the previous k . The elastic differential equations (14.1b) require in the present case, because of the term with $\text{grad } \theta$, that

$$(10) \quad \frac{\omega^2}{k_i^2} = \frac{2\mu + \lambda}{\rho} = c_{\text{long}}^2 = a^2,$$

where $a = c_{\text{long}}$ is the notation already used in 14; the prescribed ω is of course the same as in (5). From (5) and (10) we have

$$(11) \quad \frac{k_i}{k} = n,$$

where we have put

$$(11a) \quad n = \frac{b}{a} = \left(2 + \frac{\lambda}{\mu} \right)^{-1/2}$$

But the angle of reflexion α_i is now *different* from the previous angle of incidence α . In fact, the *reflected longitudinal* wave obeys a law of the same structure as the *refracted transversal* wave in elementary optics, namely

$$(12) \quad \sin \alpha = n \sin \alpha_i.$$

Let us call this the refraction formula, although it refers in the present case to a reflexion rather than to a refraction, and designate the coefficient n as an index of refraction in the same sense.

In order to prove (12), we first calculate from (9)

$$\Theta = \frac{\partial \xi_i}{\partial x} + \frac{\partial \eta_i}{\partial y} = ik_i C e^{ik_i x \sin \alpha_i}$$

for $y = 0$. In setting up the new boundary conditions the right member of the first equation (8) must be augmented by

$$(12a) \quad 2\mu \frac{\partial \eta_i}{\partial y} + \lambda \Theta = ik_i (2\mu \cos^2 \alpha_i + \lambda) C e^{ik_i x \sin \alpha_i},$$

and the second Eq. (8) by

$$(12b) \quad \mu \left(\frac{\partial \xi_i}{\partial y} + \frac{\partial \eta_i}{\partial x} \right) = ik_i 2\mu \sin \alpha_i \cos \alpha_i C e^{ik_i x \sin \alpha_i}.$$

The modified Eqs. (8) should now establish conditions for the A , B , C that are independent of x . This is possible only in the case that the same exponential function of x occurs in (8) and (12). *The law of refraction (12) must therefore be valid.*

Eqs. (8) modified according to (12) yield now the linear homogeneous system

$$(13) \quad \begin{aligned} -2\mu k \sin \alpha \cos \alpha (A + B) + k_i (2\mu \cos^2 \alpha_i + \lambda) C &= 0 \\ -\mu k (\cos^2 \alpha - \sin^2 \alpha) (A - B) + k_i 2\mu \sin \alpha_i \cos \alpha_i C &= 0 \end{aligned}$$

which determines in a unique way the ratios B/A and C/A , that is, the reflected fractions of the incident amplitude A ; the latter may, of course, be arbitrarily prescribed. One obtains from (13)

$$(14) \quad \begin{aligned} \frac{C}{A} &= \frac{n \sin 4\alpha}{\cos^2 2\alpha + n^2 \sin 2\alpha \sin 2\alpha_i}, \\ \frac{B}{A} &= \frac{\cos^2 2\alpha - n^2 \sin 2\alpha \sin 2\alpha_i}{\cos^2 2\alpha + n^2 \sin 2\alpha \sin 2\alpha_i}. \end{aligned}$$

This solves the problem of the reflexion of a transverse wave polarized in the plane of incidence. If the incident transverse wave is polarized normal to the plane of incidence, no longitudinal component occurs in addition to the regularly reflected wave. When, on the other hand, an incident longitudinal wave is reflected there appears beside the regularly reflected longitudinal wave a transverse wave which is polarized in the plane of incidence. This will be taken up in problem VIII.5.

In the present discussion we are not so much interested in the *elastic* but in the *optical* interpretation of the mathematical formalism. As is well known, the central idea of 19th century optics is an elastic ether that carries the optical phenomena; this is true for the period of development that leads from Fresnel and Fraunhofer to F. Neumann and ends with H. Hertz. We shall now briefly indicate why the endeavors of these men to build an elastic theory of light resulted in insurmountable contradictions.

Once the polarizability of light had been recognized, the only waves admissible in optics had to be transverse. It is true that Röntgen, under the influence of one of Helmholtz's last papers, was considering the possibility that his newly discovered X-rays might be longitudinal waves. However, experiments on polarization of X-rays, first carried out by Barkla, precluded this possibility.

Now we have seen that even the simplest process of reflexion is elastically impossible without the occurrence of longitudinal waves. Starting with purely *transverse waves*, we have found that *longitudinal waves*—essentially foreign to optics—are generated in the process of reflexion.

The root of this dilemma is in the last analysis an arithmetical one. To see that, let us consider the more general case of reflexion and refraction that occurs in the transition of a wave from a medium 1 into a medium 2. Here we have altogether *six* elastic boundary conditions: three equations for the stresses and three equations that express the continuity of the displacements ξ , η , ζ . For an incident transverse light wave, however, we have only four unknowns at our disposal, viz. two pairs of amplitude ratios for the two modes of polarization in the reflected and the refracted wave. This is a contradiction that can not be resolved.

When we now replace the elastic ether by the quasi-elastic ether of 15, a different set of conditions appears. The stress is no longer a symmetric but an antisymmetric tensor which can be represented by a vector. The quantities σ_{ii} are zero and the number of stress conditions to be fulfilled is reduced from 3 to 2; the same is true for the displacement conditions. We then arrive at boundary conditions that are identical with those of the *electromagnetic theory of light*, and the intrinsic difficulties of the elastic theory of light are most beautifully resolved.

B. Elastic Surface Waves

In dealing with this problem we follow closely the treatment of the analogous hydrodynamic problem in Chapter V. We therefore consider plane waves that progress in the positive x -direction with prescribed circular frequency ω ; the wave number k is to be determined. When speak-

ing of plane waves, we mean that the excitation is independent of the third coordinate z . The wave is composed of a longitudinal and a transversal component.

The longitudinal component is again *irrotational* as in hydrodynamics, and can be derived from a potential Φ . Accordingly we put

$$(15) \quad \xi_i = -\frac{\partial \Phi}{\partial x_i}, \quad \eta_i = -\frac{\partial \Phi}{\partial y_i}, \quad \zeta_i = 0,$$

but in the present case Φ does not satisfy the condition of incompressibility $\nabla^2 \Phi = 0$ as in hydrodynamics; Φ obeys, however, the relation

$$(16) \quad \rho \frac{\partial^2 \Phi}{\partial t^2} = (2\mu + \lambda) \nabla^2 \Phi,$$

which follows from the elastic differential equations for ξ and η . We try

$$(17) \quad \Phi = e^{i(kx - \omega t)} u(y)$$

and obtain from (16) for the unknown function u the equation

$$-\rho \omega^2 u = (2\mu + \lambda) \left(-k^2 u + \frac{d^2 u}{dy^2} \right),$$

or

$$(18) \quad \frac{d^2 u}{dy^2} = p^2 u, \quad \text{where} \quad p^2 = k^2 - \frac{\omega^2}{a^2},$$

$$a^2 = \frac{2\mu + \lambda}{\rho}.$$

Let us assume that p is real and take the positive sign of the square root in the determination of p . Of the two particular integrals of (18)

$$u = e^{-py} \quad \text{and} \quad u = e^{+py}$$

the second must be excluded because of its behavior at $y = \infty$. Thus (17) becomes (if the time-dependent term is omitted as usual)

$$\Phi = Ae^{ikx - py},$$

which yields by (15):

$$(19) \quad \xi_i = -ikAe^{ikx - py},$$

$$\eta_i = +pAe^{ikx - py}.$$

The transverse component of the wave to which we now turn is *free of divergence*. We may therefore introduce a function Ψ in analogy to the hydrodynamic stream function and put

$$(20) \quad \xi_i = -\frac{\partial \Psi}{\partial y}, \quad \eta_i = +\frac{\partial \Psi}{\partial x}.$$

The function Ψ satisfies the same differential equations as ξ_i and η_i , viz:

$$(21) \quad \rho \frac{\partial^2 \Psi}{\partial t^2} = \mu \nabla^2 \Psi.$$

Again we try

$$(22) \quad \Psi = B e^{i(kx - \omega t)} v(y)$$

and obtain from (21) the following differential equation for v :

$$(23) \quad \frac{d^2 v}{dy^2} = q^2 v \begin{cases} q^2 = k^2 - \frac{\omega^2}{b^2}, \\ b^2 = \frac{\mu}{\rho}. \end{cases}$$

With the only admissible solution

$$v = e^{-qv}$$

(where q is supposed to be real and positive) we have from (20) and (22)

$$(24) \quad \begin{aligned} \xi_i &= q B e^{i k x - q y}, \\ \eta_i &= i k B e^{i k x - q y}, \end{aligned}$$

where again the time-dependent term has been omitted. By superposition of (19) and (24) we obtain for the total displacement, ξ and η , expressions in which *two* constants are to be determined: the wave number k and the amplitude ratio A/B . They are to be found from the *two* boundary conditions (1) $\sigma_{yy} = \sigma_{xz} = 0$; the third condition (1) is automatically fulfilled because of the planeness of the wave. If one calculates the strains ϵ_{yy} , ϵ_{xy} and Θ from the displacements ξ , η , and the stresses σ_{yy} , σ_{xz} from the strains, the first two boundary conditions (1) can be written in the form

$$-2\mu(p^2 A + ikqB) + \lambda(k^2 - p^2)A = 0$$

$$2ikpA - (q^2 + k^2)B = 0.$$

If one substitutes for p and q by (18) and (23) and expresses the elastic constants λ and μ by the wave velocities a and b , one obtains

$$(25) \quad \left(2k^2 - \frac{\omega^2}{b^2}\right)A + 2ik \sqrt{k^2 - \frac{\omega^2}{b^2}} B = 0,$$

$$2ik \sqrt{k^2 - \frac{\omega^2}{a^2}} A - \left(2k^2 - \frac{\omega^2}{b^2}\right)B = 0.$$

The determinant of this homogeneous system must vanish, hence

$$(26) \quad \left(k^2 - \frac{\omega^2}{2b^2}\right)^2 = k^2 \sqrt{k^2 - \frac{\omega^2}{a^2}} \sqrt{k^2 - \frac{\omega^2}{b^2}},$$

which is a cubic equation for k^2 [the term containing k^6 cancels if (26) is squared]. The ratio A/B follows from (25), once (26) has been solved.

We wish to discuss (26) in some detail only in the limiting case $a \rightarrow \infty$, that is, in the case of an almost incompressible medium. Eq. (26) is then transformed into

$$(27) \quad (1 - x)^2 = \sqrt{1 - 2x}, \quad x = \frac{\omega^2}{2b^2 k^2}.$$

Here we are interested in the root close to $x = \frac{1}{2}$. Putting $x = \frac{1}{2} - \delta$, we obtain by expansion of (27)

$$(28) \quad \left(\frac{1}{2} + \delta\right)^2 = 2\delta, \quad \frac{1}{16} + \frac{4}{8}\delta + \dots = 2\delta, \quad \delta \cong \frac{1}{24}.$$

Hence the root x of (27) is approximately

$$(29) \quad x = \frac{\omega^2}{2b^2 k^2} = \frac{1}{2} \left(1 - \frac{1}{12}\right), \quad \frac{\omega}{k} = b \left(1 - \frac{1}{24}\right),$$

where ω/k is the velocity of propagation of the surface waves. It is slightly smaller than the velocity b of the transversal three-dimensional waves. According to our assumption, the velocity a of the longitudinal three-dimensional waves is much larger.

We finally ask for the depth at which the disturbance due to the surface waves is no longer noticeable. This question is answered by the exponential factors e^{-uy} in (24) and e^{-vy} in (19). Characterizing the attenuation in y -direction by the depth at which the amplitude decreases to $1/e$ of its surface value, we obtain the depths $y = 1/q$ resp. $y = 1/p$. From (23) and (29) we find for the first of these quantities

$$(30) \quad \frac{1}{q} = \frac{1}{k} \frac{1}{\sqrt{1 - 2x}} = \frac{\sqrt{12}}{k} = \frac{\sqrt{12}}{2\pi} l,$$

where l is the wave length; for the second we have from (18) with $a \rightarrow \infty$

$$(30a) \quad \frac{1}{p} = \frac{1}{k} = \frac{l}{2\pi}.$$

The depth of penetration is in either case only a fraction of the wave length l with which the wave progresses along the x -axis; l is, of course, the same for the two components of the wave since the boundary conditions require the same coordination of the two components everywhere along the surface. The penetrations of the two components are nevertheless different.

The results (30) and (30a) show that we deal here with an elastic process that is restricted to the proximity of the surface and is made possible only by the discontinuity of the elasticity constants at the surface. The particular value of the velocity of the surface waves should be interpreted in the same sense. The elastic reaction at the surface is milder, since yielding is easier than in the interior, whence the smaller velocity of the surface waves in comparison with the spatial waves. (The smaller velocity of the spatial transverse waves as compared with the spatial longitudinal waves can be understood along similar lines; in the second case the material is subject to compressive loading which raises stronger reactive forces than the shear loading that permits yielding in the transverse direction.)

In 1886, when the problem of elastic surface waves was first treated, Lord Rayleigh voiced the belief that they might play an important part in earthquakes. In the subsequent development of seismology, which is due in a large measure to the theoretical and experimental efforts of E. Wiechert, Lord Rayleigh's conjecture was fully confirmed. The relative importance of the two-dimensional waves that spread along the surface of the earth increases with increasing distance from the center of the disturbance in comparison with the spatial waves, the energy of which disperses in three dimensions through the interior of the earth. Hence the surface waves form the *principal part* of the observable seismic effect. Furthermore they are also temporally separate from the spatial waves, since they arrive at the point of observation somewhat later than the transverse spatial waves, partly because of their smaller velocity, partly because of their longer path (arc versus cord). The *longitudinal* spatial waves arrive at the seismograph still earlier than the transverse spatial waves, and form the first part of the *primary wave*.

The seismic signals bring us information not only about the average elastic behavior of the interior of the earth but also about its possible discontinuities. One knows that the analysis of these signals together with other geophysical and astronomical data led Wiechert to the idea of a

“solid” core of the earth that consists essentially of iron and is surrounded by lighter layers of sulfides and silicates. This theory is based not only on propagation processes but also on processes of reflexion along successive discontinuity surfaces in the interior of the earth, the simplest form of which has been studied in section A of this article.

PROBLEMS

Chapter I

I.1. *The definition of curl \mathbf{A} by a linear vector function compared with its definition by a differential operator.* Show that the two definitions of the curl

$$\mathbf{B} = \text{curl } \mathbf{A} \quad \text{in (2.6)}$$

and

$$2(\mathbf{A} - \mathbf{A}_0) = \mathbf{B} \times \mathbf{r} \quad \text{in (2.7a)}$$

are equivalent, provided that \mathbf{r} is considered infinitesimally small as in 1.—It will be noticed that the field vector \mathbf{A} of Eq. (2.7a) of the text vanishes for $\mathbf{r} = 0$ since it corresponds to the rotatory part ∇_1 of the general motion in 1. To avoid this restriction, we have written $\mathbf{A} - \mathbf{A}_0$ instead of \mathbf{A} , so that \mathbf{A}_0 is the value of the new field vector at $\mathbf{r} = 0$. Of course, \mathbf{A}_0 corresponds to a velocity \mathbf{v}_0 associated by $\mathbf{s}_0 = \mathbf{v}_0 \Delta t$ with the translatory part \mathbf{s}_0 of the general motion.

I.2. *The vector character of curl \mathbf{A} .* Investigate the vector character of the curl by applying the transformation formulas (2.2) to the differential definition

$$\mathbf{B} = \text{curl } \mathbf{A}$$

(Note that the components of \mathbf{A} and the “differential operators” $\partial/\partial x_i$ must be transformed.)

I.3. *A table of the most important vector analytic operations in polar coordinates.* Set up the expression for grad, div, curl, ∇^2 and D in cylindrical and spherical coordinates.

I.4. *The symbol $\nabla^2 \mathbf{A}$.* Calculate the expression

$$\text{grad div } \mathbf{A} - \text{curl curl } \mathbf{A}$$

in cylindrical coordinates and compare the result with what is obtained when the ∇^2 operator calculated in I.3 is formally applied to the components A_r , A_ϕ , A_z . The two results are identical only in the case of the “Cartesian” component A_z [cf. the remarks following Eq. (3.10).]

I.5. *Concerning the so-called second boundary value problem of potential theory.* Show that a potential problem in which $\partial U/\partial n$ instead of U is prescribed along the boundary of the region has a unique solution except for an additional constant.

I.6. *The geometrical meaning of the tensor invariants.* True geometrical properties of a geometrical object are those that do not change in an orthogonal transformation; conversely, an orthogonal invariant must always allow a geometrical interpretation. The geometrical correlative associated with the tensor concept is the tensor quadric which, for convenience, may be assumed as an ellipsoid; hence it must be possible to interpret the three tensor invariants (4.10) as geometrical quantities connected with that ellipsoid.

Interpret the three tensor invariants as geometrical properties of the tensor ellipsoid.

I.7. *Condition that a given pattern of field lines belongs to a potential field.* If the field vector \mathbf{F} is everywhere given, the condition for the existence of a potential U is $\text{curl } \mathbf{F} = 0$ according to Eq. (3.7), but if the field lines are given, we know only the ratios $F_x : F_y : F_z$, and a scalar multiplier λ is left undetermined. Is it possible to choose λ in such a way that \mathbf{F} has a potential? Show that this can not be done unless

$$\mathbf{F}_0 \perp \text{curl } \mathbf{F}_0,$$

which is therefore a necessary condition. Here \mathbf{F}_0 is any vector that satisfies the given ratio condition, e.g. a unit vector that is everywhere parallel to the field lines.

Chapter II

II.1. *The altitude of the polytropic atmosphere.* a) Determine the altitude h of the polytropic atmosphere for the following values of the polytropic exponent: $n = 1.4$ (adiabatic case), $n = 1.2$, and $n = 1$ (isothermal case). b) Find the pressure as a function of the distance from the surface of the earth, the surface being considered spherical rather than plane as in 7. Show that under this condition the pressure in the isothermal atmosphere does not vanish at any finite distance from the earth nor, contrary to what one might expect, at infinity.

II.2. *Separation of a gas mixture in a centrifugal field.* Determine the speed of revolution required to produce a pressure difference equivalent to a water column of 40cm height between the axis and the circumference of a rotating drum that has a diameter of 60cm and contains normal air at 0°C (21% O_2 and 79% N_2 by volume), and find the composition of the air at the circumference of the drum.

II.3. a) *The two-dimensional analogue to the flow in a capillary tube.* A fluid flows between two parallel plates at a distance $2h$ from each other, the straight streamlines being parallel to the x -axis as in Fig. 19. Determine the velocity profile in the x,y -plane and the pressure loss Π between

two cross-sections in the distance l . Determine also the force required to keep the plates at rest against the reactive forces of the flow.

b) *River in laminar flow* (cf. Fig. 19a and the remarks on p. 120 about the experimental realization). Show that the velocity profile is identical with the lower half of the velocity profile in part (a) of this problem. (Assume both river depth and angle of inclination α of the bottom constant, and consider the boundary condition at $y = 0$.) Here the external force of gravity replaces the driving pressure of case (a).

II.4. *Straight and cylindrical Couette-flow*. According to (16.14) the so-called Couette-flow in straight streamlines (cf. Fig. 19b) is characterized by the velocity law

$$(1) \quad u = \frac{y}{h} U, \quad v = w = 0.$$

The equilibrium conditions (10.8a, b) are fulfilled if $p = \text{const}$; no driving pressure is required since the upper plate is kept in motion by the force $\mu U/h$.

Likewise in the case of the Couette flow proper, which takes place between two coaxial cylinders of radii r_1 and r_2 , no driving pressure, but only the moments M_1 and M_2 are required, the one to maintain the motion of the external cylinder and the other to keep the internal cylinder at rest. Set up and integrate the differential equations of the flow and compare the result with Eq. (1) in the limiting case $r_2 \rightarrow \infty$. Calculate also the moments M_1 and M_2 and note that they are not equal.

II.5. *The problem of Boussinesq*. An elastic body bounded by a horizontal plane, but otherwise infinite, is subject to a vertical force P applied at a single point this plane, all other points of which are free of stress. Calculate the state of stress in the body, and in particular the hoop stresses, that is to say, the principal stresses which are tangential to the circles about the direction of P .

Chapter III

III.1. *The convective terms of the hydrodynamic equations in polar coordinates*. Show that there is a difference between the correct calculation of the convective terms according to (11.6) and the result obtained from the "misinterpreted" symbol $(\nabla \text{ grad})$. Take cylindrical coordinates as an example, where one might be tempted to give the following meaning to the symbol $(\nabla \text{ grad})$

$$v_r \frac{\partial}{\partial r}, \quad v_\varphi \frac{1}{r} \frac{\partial}{\partial \varphi}, \quad v_z \frac{\partial}{\partial z}.$$

Verify that such a difference occurs in the r - and φ -component but not in the z -component. Relate the missing terms to the *centripetal* and the *Coriolis accelerations*.

III.2. *Similarity considerations in pipe flow*. Let the connection between the pressure gradient per unit of length Π/l and the average velocity v be given by

$$(1) \quad \frac{\Pi}{l} = Cv^n.$$

For the laminar state we have $n = 1$, for the turbulent state $n = 1.722$ according to Reynolds, and $n = 1.75$ according to Hagen (cf. the schematic representation in Fig. 18).

The quantity C can depend on the density, the kinematic viscosity ν , and the radius of the pipe a .

a) Following Kármán [Physik. Z.12, (1911) 283], assume C proportional to a product of powers of these quantities and find the exponents by dimensional reasoning.

b) It must also be possible to represent the relation (1) by the dimensionless quantities R and S and the quotient l/a in the general form

$$(2) \quad S = f\left(\frac{l}{a}, R\right).$$

In particular, if the function f is again assumed as a product of powers and the exponent of l/a is taken as 1, one obtains instead of (2)

$$(3) \quad S = \lambda \cdot \frac{l}{a} R^\delta,$$

where λ is a dimensionless constant; δ can be easily expressed by the exponent n occurring in (1).

c) Show finally that the relation $S = \lambda R^{-1/4}$ in (16.13) is in accordance with Hagen's value $n = 1.75$.

III.3. *The free surface of a fluid in the presence of external forces*. Using the principle of virtual work, find the differential equation that determines the shape of the free surface of a liquid subject to capillary forces and external (body) forces that have a potential. The fact that the total volume of the liquid mass does not change in the displacement will have to be used.

III.4. *Rise of a liquid in a capillary tube*. The result of the foregoing problem can be applied to find the elevation (or depression) of a wetting (or non wetting) liquid in a narrow capillary tube. Consider for this purpose the surface of the liquid inside the tube as spherical; outside the tube the surface may be considered everywhere as plane with sufficient accuracy.

Chapter IV

IV.1. *Calculations in bipolar coordinates.* The bipolar coordinates ρ and φ have been defined by Eqs. (19.10a, b). Show that the line element in these coordinates has the form

$$(1) \quad ds^2 = g^2(d\rho^2 + d\varphi^2), \quad g = \frac{c}{\cosh \rho - \cos \varphi}.$$

Set up the expression for ∇^2 and the equation of the vibrating membrane (17.8) in these coordinates. Note that the latter is not separable in ρ and φ , that is, there is no solution of the form

$$(2) \quad u = f_1(\rho)f_2(\varphi).$$

IV.2. *The field of flow about two vortices of equal strength and opposite orientation.* Eq. (19.10), which is equivalent to Eq. (19.11), yields the velocity field

$$\mathbf{v} = -\text{grad } \Phi = A \text{ grad } \varphi, \quad v_\rho = 0, \quad v_\varphi = \frac{A}{g}$$

where the value of g is to be taken from Eq. (1) of the foregoing problem. Show by a geometrical argument that this representation of \mathbf{v} is equivalent to Eq. (19.14).

IV.3. *Calculations in elliptic coordinates.* Set up the line element ds and the operator ∇^2 in elliptic coordinates ξ, η . The equation of the vibrating membrane becomes separable in these coordinates, that is, a trial solution of the form (2) in problem IV.1

$$u = f_1(\xi)f_2(\eta)$$

makes the integration possible.

IV.4. *Transition from bipolar to toroidal and "spindle" coordinates.* By rotating the plane of the bipolar coordinates ρ and φ about the axis $\rho = 0$ (cf. Fig. 26) one obtains a system of toroidal coordinates; by rotation about the axis $\varphi = 0$ another spatial coordinate system results for which the name "spindle" coordinates seems appropriate. Find the line element in these coordinates, set up the operator ∇^2 , and discuss the question of separability.

Chapters V and VI

V.1. *The kinetic energy of water waves.* As a supplement to the topic of 26, p. 189, compute for gravity waves in deep water the kinetic energy contained in a column of cross-section $\Delta x \cdot \Delta y = \lambda \cdot 1$, bounded by the

bottom and the free surface; compare this with the amount of potential energy contained in the same column.

Carry out the computations of p. 189 and p. 190 for moderately deep water and show that the value of S/E agrees with the value of U/N in Eq. (26.13).

VI.1. *The drift current.* Winds blowing along the surface of the ocean generate water currents known as drift currents. The surface layer which is exposed to the immediate action of the wind imparts its motion to the adjacent layers by the friction pressures. Consider the ocean infinitely extended and its density and viscosity everywhere constant; introduce a coordinate system ξ, η, ζ rigidly connected with a surface point of the earth, the ξ and η axes being tangential to the meridian and the parallel, respectively, and the ζ axis coinciding with the outward surface normal, so that ξ, η, ζ form a right hand system and the ξ axis points south (cf. Fig. 49, Vol. I). The Navier-Stokes equations must now be augmented by the Coriolis terms of Vol. I. 30.2 or 30.5.¹ For an unlimited and homogeneous ocean the components v_ξ and v_η , as well as p are independent of ξ and η ; the component v_ζ can be neglected.

Investigate the steady state that results if one assumes the wind velocity vector constant in the ξ, η -system.

VI.2. *Instability of a plane discontinuity surface separating two flow fields with different velocities.* In 30 and 32, pp. 216, 232, it was pointed out that discontinuity surfaces are unstable since they curl into vortices under the influence of friction. However, this instability is also present *without friction*; this is to be shown for the simplest case of a plane discontinuity surface $y = 0$, the fluid being the same on both sides.

Assume the fluid flows in x -direction with the constant velocities U_1 and U_2 for $y > 0$ and for $y < 0$ respectively. The problem is thus restricted to two-dimensions and remains so if a disturbance of the surface is introduced in form of a sinusoidal cylinder with generatrices parallel to the z -axis. External forces may be neglected.

Use the velocity potentials

$$\left. \begin{array}{l} \Phi_1 = -U_1 x \\ \varphi_1 \end{array} \right\} y > 0 \quad \left. \begin{array}{l} \Phi_2 = -U_2 x \\ \varphi_2 \end{array} \right\} y < 0 \quad \begin{array}{l} \text{(principal motion)} \\ \text{(disturbance)} \end{array}$$

and apply Bernoulli's theorem in the form (11.15) valid for non-steady flow. The discussion of the equations of motion so obtained shows that the principal motion is unstable for all wave lengths of the disturbance, and, since every disturbance can be compounded from sinusoidal com-

¹Cf. Synge and Griffith, *op. cit.*, Sec. 12.3.

ponents according to the Fourier integral theorem, the flow is unstable for any disturbance.

According to Helmholtz (*Über atmosphärische Bewegungen*, Akad. Ber. Berlin, 1898 and 1899) the formation of high cirrocumulus clouds is connected with the instability of the boundary between two air currents of equal directions but different velocities. The clouds are generated by the condensation of water vapor in form of droplets or ice crystals in regions of diminished pressure.—The instability of the discontinuity surface to be shown here for incompressible fluids occurs doubtlessly in compressible fluids, too, as long as all velocities are small compared to the sound velocity (cf. appendix to 13).

VI.3. *Stability of a horizontal water surface for varying wind velocities.* Proceeding as in the foregoing problem, investigate the stability of a water surface at rest under the influence of an air current moving parallel to it. The density of the air must not be neglected as was done in Chap. V., although it is small relative to water (0.00129:1). Gravity must be considered in this problem.

Chapter VII

VII.1. *The shape of the free surface of a rotating liquid derived according to Lagrange's equations.* The free surface of an incompressible fluid rotating with constant angular velocity was determined in 6 p. 44 by the methods of statics and is now to be found by the use of Lagrange's equations. The axis of the drum is vertical as before.

VII.2. *Transition from Euler's to Lagrange's equations in the one-dimensional compressible case.* For the special case of a one-dimensional flow of a compressible fluid in the absence of external forces, derive Lagrange's form of the hydrodynamic equations directly from Euler's equations and the law of conservation of mass.

VII.3. *Simplified determination of the linear differential equations for Riemann's shock wave problem according to Hadamard.* The one-dimensional Lagrange equation derived in the preceding problem permits us, according to J. Hadamard (*Leçons sur la propagation des ondes*, Paris, 1903), to shorten the transition to the linear differential equation of second order in 37. Assume that the compressible fluid has initially constant density and use the Legendre transformation of Vol. I. Eq. (42.8), cf. also footnote 10 on p. 312.

VII.4. *Stokes' formula for a rotating sphere.* In analogy to the translatory motion of a sphere analyzed in 35, investigate the uniform rotation of a sphere of radius a . Assume again laminar motion and an incompressible fluid, and show that the moment $M = 8\pi\mu a^3\omega$ is required to maintain uniform rotation with angular velocity.

Chapter VIII

VIII.1. *The bending of a beam on two supports under a single load.* A beam of length $l = a + b$ rests with its ends A and B freely on two supports of equal height; a vertical force P acts at a distance a from A . Make a diagram of the shear force and the bending moment along the beam and determine the elastic line.

VIII.2. *The vibrations of a rod.* a) A vertically suspended prismatic rod is rigidly clamped at the upper end and carries at the lower end a mass M that is large compared with the mass of the rod m . The system is free to oscillate in the direction of the axis of the rod. Determine the circular frequency of the longitudinal oscillations neglecting m as small relative to M , and the elasticity of the body M as unimportant relative to that of the rod.

b) The system a) is now allowed to oscillate about the axis of the rod. In calculating the frequency of the torsional oscillations the weight of M that acts in the axis of the rod may be disregarded, since it is balanced by tensile stresses that are constant in time. The appropriate assumption is now that the moment of inertia Θ corresponding to the mass M is large compared to that of the rod.

c) We finally consider a horizontal rod that is either rigidly clamped at one end and loaded at the other end by a mass M , or supported at both ends A and B as in prob. VIII.1 and loaded at a distance a from A (respectively b from B) by a mass M . The equilibrium of the rod is disturbed by a vertical impulse. Determine the circular frequency of the oscillations normal to the axis of the rod (bending oscillations), if again $M \gg m$.

VIII.3. *Rod subject to an impulsive load.* Assume that the mass M of the rod of prob. VIII. 2a is not a steady load, but was put in contact with the rod at $t = 0$, and that at that instant the velocity of M was v_0 . Calculate the maximum displacement ξ_{\max} of the mass M and the maximum stress σ_{\max} at the end cross-section of the rod in general and show in particular:

a) for $v_0 = 0$, σ_{\max} is twice its static value.

b) for large values of v_0 , σ_{\max} increases with the kinetic energy of M at the instant of contact, and depends on the individual dimensions of the rod only through its volume.

VIII.4. *A supplement to the torsion problem for an elliptic rod.* Determine the torsional moment M and the angle of torsion φ , for a rod with elliptic cross-section by carrying out the integrations in (42.23), and compare the factor that expresses the influence of the geometry of the rod with the polar moment of inertia of the area of the ellipse.

VIII.5. *The reflexion of a plane transverse and plane longitudinal wave*

within an elastic solid having a plane boundary. As a supplement to 45 show that a transverse wave oscillating perpendicularly to the plane of incidence is reflected regularly at a plane surface that is free of forces, and no longitudinal wave is generated simultaneously. Show on the other hand, that a plane longitudinal wave generates, in addition to the regularly reflected longitudinal wave, a transverse wave that oscillates in the plane of incidence.

ANSWERS AND COMMENTS

I.1. a) Differentiate the z -component of

$$2(\mathbf{A} - \mathbf{A}_0) = \mathbf{B} \times \mathbf{r}$$

partially with respect to y , the y -component partially with respect to z and subtract the results. On disregarding all terms that vanish simultaneously with r , the usual expression for the x -component of

$$\mathbf{B} = \text{curl } \mathbf{A}$$

is obtained.

b) Note that the omitted terms have the form

$$(\mathbf{r} \text{ grad})\mathbf{B}_0 - x \text{ div } \mathbf{B}.$$

This points to the connection with the general formula

$$\text{curl}(\mathbf{a} \times \mathbf{b}) = (\mathbf{b} \text{ grad})\mathbf{a} - (\mathbf{a} \text{ grad})\mathbf{b} + \mathbf{a} \text{ div } \mathbf{b} - \mathbf{b} \text{ div } \mathbf{a},$$

valid for arbitrary vectors \mathbf{a} , \mathbf{b} but restricted to Cartesian components.

I.2. From (2.2) one has

$$x'_i = \sum_k \alpha_{ik} x_k, \quad x_k = \sum_i \alpha_{ik} x'_i, \quad A'_i = \sum_i \alpha_{ik} A_k$$

and finds by differentiation

$$\frac{\partial}{\partial x'_i} = \sum_k \frac{\partial x_k}{\partial x'_i} \frac{\partial}{\partial x_k} = \sum_k \alpha_{ik} \frac{\partial}{\partial x_k}, \quad \frac{\partial A'_l}{\partial x'_i} = \dots, \quad \frac{\partial A'_m}{\partial x'_i} = \dots$$

The difference of the derivatives $\partial A'_m / \partial x'_i - \partial A'_l / \partial x'_m$ gives the 1, 2, 3 components of $\text{curl}' A'$, when the pair (l, m) takes the values (2,3), (3,1), (1,2). Each derivative consists of 9 terms. When the difference is formed, 6 of the 18 terms cancel. The remaining 12 terms can be arranged in 6 pairs according to the 6 different $\partial A_k / \partial x_i$ and finally rearranged in 3 terms containing the three differences $\partial A_k / \partial x_i - \partial A_i / \partial x_k$. Hence each component of the transformed curl is a linear function of the components of the original curl; the coefficients are the cofactors of the elements of the transformation determinant as in (2.5). This points again to the axial vector character of the curl.

The treatment of this problem in Eqs. (2.10)-(2.15) of the text deserves preference.

I.3. It is, of course, possible to obtain the required expressions from

their definitions in Cartesian coordinates by applying the corresponding orthogonal transformations of coordinates, but this is a highly cumbersome procedure. A more efficient way is to specialize the general formulas (2.24), (2.25), (2.26), (3.9a), (3.9b) for the required type of coordinates. The results of this computation are collected for later use in the following table, which contains also the answers to problems I.4 and III.1 for cylindrical and spherical coordinates. As for the correct meaning of the symbols $\nabla^2 A$ and $(A \text{ grad})A$, the reader is again referred to Eqs. (3.10a) and (11.6).

It should be noticed that the sign of the curl depends on the orientation of the coordinate system. We have here assumed that the three coordinates in the sequence r, φ, z (and in the sequence r, ϑ, φ) form dexteral systems. Only under this condition the use of formula (2.26) is legitimate. In the case of spherical coordinates the usual definition of ϑ is such that ϑ increases from north to south. If this is adopted, φ runs contrary to the geographical longitude coordinate. If, however, φ is required to coincide with the geographical longitude, then the sign of the curl components would be reversed in accordance with Eq. (2.16), since the curl is an *axial* vector. The same thing happens when the order r, ϑ, φ is changed into r, φ, ϑ .

Cylindrical coordinates:

$$r, \varphi, z, \quad ds^2 = dr^2 + r^2 d\varphi^2 + dz^2$$

$$g_1 = 1, \quad g_2 = r, \quad g_3 = 1$$

$$\text{grad } U = \frac{\partial U}{\partial r}, \quad \frac{1}{r} \frac{\partial U}{\partial \varphi}, \quad \frac{\partial U}{\partial z}$$

$$\text{div } A = \frac{1}{r} \frac{\partial}{\partial r} (r A_r) + \frac{1}{r} \frac{\partial A_\varphi}{\partial \varphi} + \frac{\partial A_z}{\partial z}$$

$$\text{curl}_r A = \frac{1}{r} \frac{\partial A_z}{\partial \varphi} - \frac{\partial A_\varphi}{\partial z}$$

$$\text{curl}_\varphi A = \frac{\partial A_r}{\partial z} - \frac{\partial A_z}{\partial r}$$

$$\text{curl}_z A = \frac{1}{r} \frac{\partial (r A_\varphi)}{\partial r} - \frac{1}{r} \frac{\partial A_r}{\partial \varphi}$$

$$\nabla^2 U = \frac{1}{r} \left\{ \frac{\partial}{\partial r} \left(r \frac{\partial U}{\partial r} \right) + \frac{\partial}{\partial \varphi} \left(\frac{1}{r} \frac{\partial U}{\partial \varphi} \right) + \frac{\partial}{\partial z} \left(r \frac{\partial U}{\partial z} \right) \right\}$$

$$= \frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial U}{\partial r} \right) + \frac{1}{r^2} \frac{\partial^2 U}{\partial \varphi^2} + \frac{\partial^2 U}{\partial z^2}$$

$$= \frac{\partial^2 U}{\partial r^2} + \frac{1}{r} \frac{\partial U}{\partial r} + \frac{1}{r^2} \frac{\partial^2 U}{\partial \varphi^2} + \frac{\partial^2 U}{\partial z^2}$$

$$DU = \left(\frac{\partial U}{\partial r} \right)^2 + \frac{1}{r^2} \left(\frac{\partial U}{\partial \varphi} \right)^2 + \left(\frac{\partial U}{\partial z} \right)^2,$$

$$(\mathbf{A} \cdot \text{grad}) \mathbf{A} = \begin{cases} \mathbf{A} \cdot \text{grad } A_r - \frac{A_\varphi^2}{r} \\ \mathbf{A} \cdot \text{grad } A_\varphi + \frac{A_r A_\varphi}{r} \\ \mathbf{A} \cdot \text{grad } A_z \end{cases}$$

$$\nabla^2 \mathbf{A} = \begin{cases} \nabla^2 A_r - \frac{A_r}{r^2} - \frac{2}{r^2} \frac{\partial A_\varphi}{\partial \varphi} \\ \nabla^2 A_\varphi - \frac{A_\varphi}{r^2} + \frac{2}{r^2} \frac{\partial A_r}{\partial \varphi} \\ \nabla^2 A_z \end{cases}$$

Spherical coordinates:

$$r, \vartheta, \varphi, \quad ds^2 = dr^2 + r^2 d\vartheta^2 + r^2 \sin^2 \vartheta d\varphi^2$$

$$g_1 = 1, \quad g_2 = r, \quad g_3 = r \sin \vartheta$$

$$\text{grad } U = \frac{\partial U}{\partial r}, \quad \frac{1}{r} \frac{\partial U}{\partial \vartheta}, \quad \frac{1}{r \sin \vartheta} \frac{\partial U}{\partial \varphi}$$

$$\text{div } \mathbf{A} = \frac{1}{r^2} \frac{\partial}{\partial r} (r^2 A_r) + \frac{1}{r \sin \vartheta} \frac{\partial}{\partial \vartheta} (\sin \vartheta A_\vartheta) + \frac{1}{r \sin \vartheta} \frac{\partial A_\varphi}{\partial \varphi}$$

$$\text{curl}_r \mathbf{A} = \frac{1}{r \sin \vartheta} \left(\frac{\partial (\sin \vartheta A_\varphi)}{\partial \vartheta} - \frac{\partial A_\vartheta}{\partial \varphi} \right)$$

$$\text{curl}_\vartheta \mathbf{A} = \frac{1}{r \sin \vartheta} \frac{\partial A_r}{\partial \varphi} - \frac{1}{r} \frac{\partial (r A_\varphi)}{\partial r}$$

$$\text{curl}_\varphi \mathbf{A} = \frac{1}{r} \left(\frac{\partial (r A_\vartheta)}{\partial r} - \frac{\partial A_r}{\partial \vartheta} \right)$$

$$\begin{aligned}
\nabla^2 U &= \frac{1}{r^2 \sin \vartheta} \left\{ \frac{\partial}{\partial r} \left(r^2 \sin \vartheta \frac{\partial U}{\partial r} \right) + \frac{\partial}{\partial \vartheta} \left(\sin \vartheta \frac{\partial U}{\partial \vartheta} \right) + \frac{\partial}{\partial \varphi} \left(\frac{1}{\sin \vartheta} \frac{\partial U}{\partial \varphi} \right) \right\} \\
&= \frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial U}{\partial r} \right) + \frac{1}{r^2 \sin \vartheta} \frac{\partial}{\partial \vartheta} \left(\sin \vartheta \frac{\partial U}{\partial \vartheta} \right) + \frac{1}{r^2 \sin^2 \vartheta} \frac{\partial^2 U}{\partial \varphi^2} \\
&= \frac{\partial^2 U}{\partial r^2} + \frac{2}{r} \frac{\partial U}{\partial r} + \frac{1}{r^2} \frac{\partial^2 U}{\partial \vartheta^2} + \frac{1}{r^2} \operatorname{ctg} \vartheta \cdot \frac{\partial U}{\partial \vartheta} + \frac{1}{r^2 \sin^2 \vartheta} \frac{\partial^2 U}{\partial \varphi^2} \\
DU &= \left(\frac{\partial U}{\partial r} \right)^2 + \frac{1}{r^2} \left(\frac{\partial U}{\partial \vartheta} \right)^2 + \frac{1}{r^2 \sin^2 \vartheta} \left(\frac{\partial U}{\partial \varphi} \right)^2
\end{aligned}$$

$$(\mathbf{A} \operatorname{grad}) \mathbf{A} = \begin{cases} \nabla^2 A_r - \frac{2}{r^2} \left[A_r + \frac{1}{\sin \vartheta} \frac{\partial}{\partial \vartheta} (\sin \vartheta A_\vartheta) + \frac{1}{\sin \vartheta} \frac{\partial A_\varphi}{\partial \varphi} \right] \\ \nabla^2 A_\vartheta + \frac{2}{r^2} \left[\frac{\partial A_r}{\partial \vartheta} - \frac{A_\vartheta}{2 \sin^2 \vartheta} - \frac{\operatorname{ctg} \vartheta}{\sin \vartheta} \frac{\partial A_\varphi}{\partial \varphi} \right] \\ \nabla^2 A_\varphi + \frac{2}{r^2 \sin \vartheta} \left[\frac{\partial A_r}{\partial \varphi} + \operatorname{ctg} \vartheta \frac{\partial A_\vartheta}{\partial \varphi} - \frac{A_\varphi}{2 \sin \vartheta} \right] \end{cases}$$

I.4. The r -component of $\operatorname{curl} \operatorname{curl} \mathbf{A}$ is according to the preceding table

$$\begin{aligned}
\operatorname{curl}_r \operatorname{curl} \mathbf{A} &= \frac{1}{r} \frac{\partial}{\partial \varphi} \operatorname{curl}_\vartheta \mathbf{A} - \frac{\partial}{\partial z} \operatorname{curl}_\varphi \mathbf{A} \\
&= \frac{1}{r^2} \frac{\partial}{\partial r} r \frac{\partial A_\varphi}{\partial \varphi} - \frac{1}{r^2} \frac{\partial^2 A_r}{\partial \varphi^2} - \frac{\partial^2 A_r}{\partial z^2} + \frac{\partial^2 A_z}{\partial r \partial z},
\end{aligned}$$

and, likewise,

$$\operatorname{grad}_r \operatorname{div} \mathbf{A} = \frac{\partial^2 A_r}{\partial r^2} + \frac{\partial}{\partial r} \frac{A_r}{r} + \frac{1}{r} \frac{\partial^2 A_\varphi}{\partial r \partial \varphi} - \frac{1}{r^2} \frac{\partial A_\varphi}{\partial \varphi} + \frac{\partial^2 A_z}{\partial r \partial z}.$$

We obtain therefore for the difference

$$\operatorname{grad}_r \operatorname{div} \mathbf{A} - \operatorname{curl}_r \operatorname{curl} \mathbf{A} = \dots - \frac{A_r}{r^2} - \frac{2}{r^2} \frac{\partial A_\varphi}{\partial \varphi}.$$

The terms fully written on the right hand side are those that are missed if the expression $\nabla^2 A_r$ is calculated by a schematical application of the ∇^2 -expression in cylindrical coordinates. One finds in the same way

$$\operatorname{grad}_\vartheta \operatorname{div} \mathbf{A} - \operatorname{curl}_\vartheta \operatorname{curl} \mathbf{A} = \dots - \frac{A_\vartheta}{r^2} + \frac{2}{r^2} \frac{\partial A_r}{\partial \varphi}.$$

I.5. For the difference $U = U_2 - U_1$ of two solutions U_1 and U_2 the Laplacian $\nabla^2 U$ vanishes in the interior, and the normal derivative $\partial U / \partial n$ vanishes on the boundary. From Green's theorem (3.16a) it follows that $U = \text{const}$ as in the first boundary value problem so that $U_2 = U_1 + \text{const}$. To conclude that $U_2 = U_1$ is, of course, no longer possible.

I.6. Let the strain ellipsoid with the semi-axes a, b, c be given by the equation

$$(1) \quad \sum \epsilon_{ik} x_i x_k = 1,$$

referred to a system x_1, x_2, x_3 which is connected with the system of principal axes by some rotation.

a) $\Theta = \Theta'$: For $x_2 = x_3 = 0$ we obtain $\epsilon_{11} = 1/\bar{x}_1^2$ where $|\bar{x}_1|$ is the radius vector from O to the point at which the x_1 -axis cuts the ellipsoid. The lengths $|\bar{x}_2|$ and $|\bar{x}_3|$ being correspondingly defined, we obtain for Θ

$$(2) \quad \Theta = \frac{1}{\bar{x}_1^2} + \frac{1}{\bar{x}_2^2} + \frac{1}{\bar{x}_3^2}.$$

The invariance of Θ permits the following geometric interpretation. *If an ellipsoid is cut by an orthogonal triad whose apex coincides with the center of the ellipsoid, the sum of the reciprocal squares of the intercepts is independent of the position of the triad; in particular, it is equal to*

$$\Theta' = \frac{1}{a^2} + \frac{1}{b^2} + \frac{1}{c^2}.$$

b) $\Delta = \Delta'$: The plane $x_3 = 0$ intersects the ellipsoid (1) in the ellipse

$$\epsilon_{11}x_1^2 + 2\epsilon_{12}x_1x_2 + \epsilon_{22}x_2^2 = 1,$$

whose principal semi-axes are $1/\sqrt{\lambda_1}$ and $1/\sqrt{\lambda_2}$, λ_1 and λ_2 being the roots of the equation

$$(3) \quad \begin{vmatrix} \epsilon_{11} - \lambda & \epsilon_{12} \\ \epsilon_{21} & \epsilon_{22} - \lambda \end{vmatrix} = 0.$$

The area of the ellipse is

$$(4) \quad F_2 = \frac{\pi}{\sqrt{\lambda_1 \lambda_2}}.$$

From (3) and (4) we conclude

$$\lambda_1 \lambda_2 = \epsilon_{11}\epsilon_{22} - \epsilon_{12}^2 = \frac{\pi^2}{F_2^2},$$

and, therefore, (F_1 , F_2 are defined correspondingly)

$$(5) \quad \Delta = \pi^2 \left(\frac{1}{F_1^2} + \frac{1}{F_2^2} + \frac{1}{F_3^2} \right).$$

Hence, if an ellipsoid is cut by an orthogonal trihedron whose apex coincides with the center of the ellipsoid, the sum of the reciprocal squares of the areas cut out by the trihedron is independent of its position; in particular it is equal to

$$\Delta' = \frac{1}{b^2 c^2} + \frac{1}{c^2 a^2} + \frac{1}{a^2 b^2}.$$

c) $D = D'$: The volume of an ellipsoid with the semi-axes a , b , c is given by

$$(6) \quad V = \frac{4\pi}{3} abc.$$

When the determinant (4.7) is set up in principal coordinates, it reduces to the product of the terms $1/a^2$, $1/b^2$, $1/c^2$ in the main diagonal so that

$$(7) \quad D' = \frac{1}{a^2 b^2 c^2} = \frac{16\pi^2}{9V^2}.$$

On the other hand, by an orthogonal transformation D' is transformed into D [cf. (4.7)]. We have therefore once more

$$(8) \quad D = \frac{16\pi^2}{9V^2}.$$

The invariance of D has its geometrical equivalent in the independence of the volume V from the coordinate system.

I.7. The relation $\mathbf{F} = \lambda \mathbf{F}_0$ implies

$$\text{curl } \mathbf{F} = \lambda \text{curl } \mathbf{F}_0 + \text{grad } \lambda \times \mathbf{F}_0.$$

By scalar multiplication with \mathbf{F}_0 and application of the vector formula

$$\mathbf{A} \cdot (\mathbf{B} \times \mathbf{C}) = \mathbf{B} \cdot (\mathbf{C} \times \mathbf{A}),$$

one obtains an equation from which one concludes that $\mathbf{F}_0 \perp \text{curl } \mathbf{F}_0$, provided $\text{curl } \mathbf{F} = 0$.

If U is a potential function that belongs to the pattern of field lines given by \mathbf{F}_0 so that $\lambda \mathbf{F}_0 = \text{grad } U$, then any function V of U is also a potential and the associated multiplier $\lambda' = \lambda dV/dU$. Thus the problem under consideration has an infinity of solutions, if it has a solution at all.

II.1. a) With the values of p_0 and ρ_0 of p. 99 one obtains from (7.9b) the values of h for $n = 1.4$, 1.2 and 1 , given on p. 52. The last value is in

accordance with the fact that the exponential function in (7.14) vanishes only for $z = \infty$.

In the adiabatic case ($n = 1.4$) the lapse rate of the temperature can be determined from Eq. (7.11). If we assume a ground temperature of $0^\circ\text{C} = 273^\circ\text{K}$, the lapse rate is just about 1°C per 100m. This same adiabatic lapse rate for dry air is also found in the descending air current of a foehn² between two points of *the same stream line*, while in vertical direction, that is, in the transition to a different streamline, only half this value is found (corresponding to the average temperature gradient in the atmosphere).

b) We substitute in the second equation (7.7)

$$V = - \frac{GM}{r},$$

where G = constant of Newton's law of gravitation, M = mass of the earth, r = distance from the center of the earth. The constant in (7.7) is determined by the condition: $p = p_0$ for $r = R$, R being the radius of the earth. In this way one obtains from (6a) and (7)

$$(1) \quad p = p_0 \left[1 - \frac{n-1}{n} \frac{\rho_0}{p_0} GM \left(\frac{1}{R} - \frac{1}{r} \right) \right]^{n/(n-1)}.$$

At the surface of the earth we have

$$(2) \quad \frac{GM}{R^2} = g.$$

The limit of the atmosphere is obtained if we let $p = 0$; with $r = R + h$ we obtain from (1)

$$(3) \quad 1 = \frac{n-1}{n} \frac{\rho_0}{p_0} gh \frac{R}{R+h},$$

in accordance with (7.9b), provided $h \ll R$ and $n > 1$.

For the isothermal case, $n = 1$, the two results no longer agree. If we substitute $G = R^2 g / M$ in (1) and pass to the limit $n \rightarrow 1$ we obtain

$$(4) \quad p = p_0 \exp \left[- \frac{\rho_0}{p_0} \cdot g R \left(1 - \frac{R}{r} \right) \right], \quad r > R.$$

In this case there is no upper limit of the atmosphere that would be definable by $p = 0$: for $r \rightarrow \infty$ we have the paradoxical result of a small but finite pressure value

²This is a not uncommon meteorological phenomenon in the European Alps, its characteristic feature being the sliding down of air masses along mountain slopes.

$$(5) \quad p = p_0 \exp \left(- \frac{\rho_0}{p_0} gR \right).$$

II.2. The partial pressures of N_2 and O_2 are originally ($\omega = 0$)

$$(1) \quad p_{01} = p_0 \frac{21}{100}, \quad p_{02} = p_0 \frac{79}{100}, \quad \text{with } p_0 = 1033 \times 981 \frac{\text{gr}}{\text{cm sec}^2}.$$

From (7.18) we have the partial pressures at the circumference r

$$(2) \quad \begin{aligned} p_1 &= p_{01} \exp \left(\frac{\mu_1}{2} \frac{r^2 \omega^2}{RT} \right) \cdots \mu_1 = 32, \\ p_2 &= p_{02} \exp \left(\frac{\mu_2}{2} \frac{r^2 \omega^2}{RT} \right) \cdots \mu_2 = 28. \end{aligned}$$

The pressure difference $(p_1 + p_2) - p_0$ is prescribed as $40 \times 981 \text{ gr cm}^{-1} \text{ sec}^{-2}$ and equals by (1) and (2)

$$p_1 + p_2 - p_0 = p_{01} \left[\exp \left(\frac{\mu_1}{2} \frac{r^2 \omega^2}{RT} \right) - 1 \right] + p_{02} \left[\exp \left(\frac{\mu_2}{2} \frac{r^2 \omega^2}{RT} \right) - 1 \right].$$

The arguments of the exponentials being small, we obtain a good approximation by expanding the exponentials and retaining the linear terms. With $R = 8.31 \times 10^7 \text{ erg/grad}$ and $T = 273^\circ \text{ K}$, this leads to

$$40 = 10.33(21 \times 32 + 79 \times 28) \frac{30^2 \omega^2}{2 \times 8.31 \times 10^7 \times 273},$$

whence $\omega = 260 \text{ sec}^{-1}$ and $n = 30 \omega / \pi = 2480 \text{ rpm}$. The pressure (or density) ratio at the circumference is found as

$$\frac{p_1}{p_2} = \frac{\rho_1}{\rho_2} = \frac{p_{01}}{p_{02}} \cdot \frac{1 + \frac{\mu_1}{2} \frac{r^2 \omega^2}{RT}}{1 + \frac{\mu_2}{2} \frac{r^2 \omega^2}{RT}} = \frac{21}{79} \cdot \frac{1.043}{1.038},$$

or only 0.5% larger than at the center, hence the centrifuge is not an efficient means to separate mixtures of gases or isotopes. Even the ultracentrifuge mentioned on p. 55 separates only aggregates of colloids or, at best, the giant molecules of protein mixtures.

II.3. a) In close analogy with Eqs. (10.11) to (10.17) one obtains

$$(1) \quad u = \frac{A}{2\mu} (h^2 - y^2) \quad u_m = \frac{Q}{2h} = A \frac{h^2}{3\mu} \quad \Pi = Al = 3\mu l \frac{u_m}{h^2},$$

that is, a parabolic velocity profile as in Fig. 14 and a pressure loss proportional to the first power of the average velocity and to the minus

second power of the half width h , which corresponds to the radius in Eq. (10.17). The reactive force acting on the upper or lower plate in the direction of the flow is $3\mu u_m/h$ per unit of area.

b) The component of gravity in the direction of the x -axis of Fig. 19a equals

$$(2) \quad F_x = \rho g \sin \alpha;$$

the component directed toward the bottom $y = -h$ need not concern us here. At the free surface the pressure equals the atmospheric pressure ($p = 0$); no pressure gradient in x -direction is required since its role is taken over by the body force (2). The differential equation (10.8a) reads under these conditions

$$-\mu \frac{\partial^2 u}{\partial y^2} = \rho g \sin \alpha.$$

The boundary conditions at $y = 0$ require both $p = 0$ and $p_{,yy} = -\mu \partial u / \partial y = 0$, but these conditions are satisfied in (a) because of the symmetry of the flow relative to the plane $y = 0$. The velocity profile in the present case is therefore identical with the lower half of the profile in a), the constant A being modified as required.

II.4. We refer to the formulas for cylindrical coordinates developed in the answer to problem I.3 and put

$$v = v_\varphi, \quad v_r = v_z = 0.$$

The condition of incompressibility

$$\dots \frac{1}{r} \frac{\partial v}{\partial \varphi} + \dots = 0$$

requires that v be independent of φ , so that $v = v(r)$. The same is true for the pressure p .

The expression for $\nabla^2 v$, which we find again in the table I.3, yields the differential equation

$$\frac{d^2 v}{dr^2} + \frac{1}{r} \frac{dv}{dr} - \frac{v}{r^2} = 0.$$

The general solution is a linear combination of the particular integrals $v = r$ and $v = 1/r$; the coefficients follow from the boundary conditions

$$v = 0 \quad \text{for} \quad r = r_i, \quad v = U \quad \text{for} \quad r = r_e.$$

In this way we obtain the solution

$$v = U \frac{r_e}{r} \frac{r^2 - r_i^2}{r_e^2 - r_i^2}$$

which becomes identical with the solution (16.14) for the straight Couette flow if we pass to the limit infinity with r_i and use the notations $r_o = r_i + h$ and $r = r_i + y$.

The reactive moments (per unit of length of the cylinder axis) are given by

$$M_o = 2\pi\mu Ur_o \frac{r_o^2 + r_i^2}{r_o^2 - r_i^2}, \quad M_i = 2\pi\mu Ur_o \frac{2r_i^2}{r_o^2 - r_i^2}.$$

Their difference per unit of circumferential length of the external cylinder equals μU ; the dimension of this quantity is that of a torque per unit of area. It is in fact equal to the torque per unit of area which acts in the case of the straight Couette flow upon the two boundary plates (stress $\mu U/h \times \text{arm } h$).

II.5. This problem shows in a typical way how the fundamental equations of elasticity are applied. The solution requires a somewhat lengthy calculation, the single phases of which we shall clearly indicate. It is left to the reader to supply the connecting steps.

Let the direction of the force P coincide with the z -axis and its point of application be the origin of a system of cylindrical coordinates r, φ, z . On denoting the components of the displacement vector by

$$\rho = \sqrt{\xi^2 + \eta^2}, \quad 0, \quad \zeta,$$

the dilatation Θ is obtained according to the table I.3 in the form

$$(1) \quad \Theta = \frac{1}{r} \frac{\partial}{\partial r} (r\rho) + \frac{\partial \zeta}{\partial z}$$

since the problem is symmetrical about the z -axis.

a) The differential equation for Θ is found from (9.18) similarly as in (14.2):

$$(2) \quad \nabla^2 \Theta = 0.$$

Solutions that have the required symmetry are to be chosen from the following (cf. p. 248):

$$(3) \quad \Theta = \frac{1}{R}, \frac{\partial}{\partial z} \frac{1}{R}, \frac{\partial^2}{\partial z^2} \frac{1}{R}, \dots \quad R^2 = r^2 + z^2.$$

We select the second solution and put therefore

$$(4) \quad \Theta = -A \frac{\partial}{\partial z} \frac{1}{R} = A \frac{z}{R^3}.$$

b) The differential equation for the Cartesian component ζ is according to (9.18) and the table I.3

$$(5) \quad \frac{\partial^2 \zeta}{\partial r^2} + \frac{1}{r} \frac{\partial \zeta}{\partial r} + \frac{\partial^2 \zeta}{\partial z^2} = - \frac{\mu + \lambda}{\mu} A \left(\frac{1}{R^3} - \frac{3z^2}{R^5} \right).$$

A particular solution of this equation is

$$(6) \quad \zeta = B \frac{z^2}{R^3}, \quad B = - \frac{\mu + \lambda}{\mu} \frac{A}{2},$$

to which we may add solutions of the form (3). Choosing the first solution (3), we assume ζ in the more general form

$$(7) \quad \zeta = \frac{C}{R} - \frac{\mu + \lambda}{\mu} \frac{A}{2} \frac{z^2}{R^3}.$$

c) The differential equation for ρ follows easily from Eq. (1), viz.

$$(8) \quad \frac{1}{r} \frac{\partial}{\partial r} (r\rho) = \Theta - \frac{\partial \zeta}{\partial z} = A \frac{z}{R^3} + C \frac{z}{R^3} + \frac{\mu + \lambda}{\mu} A \frac{z}{R^3} \left(1 - \frac{3}{2} \frac{z^2}{R^2} \right).$$

This may be transformed into

$$(9) \quad \frac{\partial}{\partial r} (r\rho) = - \left(\frac{2\mu + \lambda}{\mu} A + C \right) z \frac{\partial}{\partial r} \frac{1}{R} + \frac{\mu + \lambda}{\mu} \cdot \frac{A}{2} z^3 \frac{\partial}{\partial r} \frac{1}{R^3}$$

and can be integrated to give

$$(10) \quad r\rho = - \left(\frac{2\mu + \lambda}{\mu} A + C \right) \frac{z}{R} + \frac{\mu + \lambda}{\mu} \frac{A}{2} \frac{z^3}{R^3} + f(z),$$

where $f(z)$ is the integration constant. For $r = 0$ and all positive values of z we must require $r\rho = 0$; since then $R = z$, we have

$$f(z) = C + \frac{3\mu + \lambda}{\mu} \frac{A}{2},$$

and Eq. (10) yields

$$(11) \quad \rho = \left(C + \frac{3\mu + \lambda}{\mu} \frac{A}{2} \right) \frac{1}{r} - \left(C + \frac{2\mu + \lambda}{\mu} A \right) \frac{z}{rR} + \frac{\mu + \lambda}{\mu} \frac{A}{2} \frac{z^3}{rR^3}.$$

d) The boundary conditions at the surface $z = 0$ are for $r > 0$

$$(12) \quad \sigma_{rr} = 0, \quad \sigma_{rz} = 0, \quad \sigma_{zz} = 0.$$

The first condition requires that

$$(13) \quad \frac{\partial \zeta}{\partial r} + \frac{\partial \rho}{\partial z} = 0.$$

The second condition is automatically fulfilled for reasons of symmetry,

not only at the surface $z = 0$, but everywhere inside the elastic body (see below under *f*). The third condition is equivalent to

$$\frac{\partial \zeta}{\partial z} = 0$$

since $\Theta = 0$ for $z = 0$ and $r > 0$; according to (7) it is also automatically fulfilled. We now substitute in (13) according to (7) and (11) for $z = 0$

$$\frac{\partial \zeta}{\partial r} = -\frac{C}{r^2}, \quad \frac{\partial \rho}{\partial z} = -\left(C + \frac{2\mu + \lambda}{\mu} A\right) \frac{1}{r^2}$$

and obtain

$$(14) \quad C = -\frac{2\mu + \lambda}{\mu} \frac{A}{2}.$$

e) The state of deformation can thus be described by the following relations

$$(15) \quad \Theta = A \frac{z}{R^3}, \quad \zeta = -\frac{A}{2} \left(\frac{2\mu + \lambda}{\mu} \frac{1}{R} + \frac{\mu + \lambda}{\mu} \frac{z^2}{R^3} \right)$$

$$\rho = \frac{A}{2r} \left(1 - \frac{2\mu + \lambda}{\mu} \frac{z}{R} + \frac{\mu + \lambda}{\mu} \frac{z^3}{R^3} \right).$$

It follows that

$$(16) \quad \sigma_{zz} = 2\mu \frac{\partial \zeta}{\partial z} + \lambda \Theta = A(\mu + \lambda) \frac{3z^3}{R^5}.$$

Only the integration constant A remains to be determined; this must be done by relating it to the external force P . If the body is cut in two at an arbitrary depth z_0 along the plane $z = z_0$, the following condition of equilibrium must hold:

$$(17) \quad P = -2\pi \int_{r=0}^{\infty} \sigma_{zz} r dr \quad \text{when} \quad z = z_0.$$

On substituting for σ_{zz} according to (16) and observing that

$$\int_{r=0}^{\infty} \frac{r dr}{R^5} = -\frac{1}{3R^3} \Big|_{r=0}^{\infty} = \frac{1}{3z^3},$$

one obtains

$$(18) \quad P = -2\pi A(\mu + \lambda).$$

f) Of the three shear stresses $\sigma_{r\theta}$, $\sigma_{\theta z}$, σ_{rz} the first two obviously vanish everywhere within the elastic body. This implies that the normal

stress $\sigma_{\varphi\varphi}$ belonging to any point of the surface $\varphi = \text{const}$ is a *principal stress* usually called the *hoop stress*. The associated stress trajectories are circles about the axis given by the forces P . In every torus or hoop of infinitesimal cross-section whose axis is a circular stress trajectory, there acts a definite stress $\sigma_{\varphi\varphi}$ that is characteristic of the hoop. The same hoop stresses occur in pipes and boilers subject to internal pressure, and their magnitude is the determining factor for the safety of the construction. In the present case the action of the external force P on the "hoops", of which the semi infinite body can be thought to consist, may be compared with that of an internal pressure. Since ρ denotes the increment of the hoop radius, the change of its length is $2\pi\rho$ and its extension $2\pi\rho/2\pi r = \rho/r$. It follows therefore that

$$(19) \quad \epsilon_{\varphi\varphi} = \frac{\rho}{r}, \quad \sigma_{\varphi\varphi} = 2\mu\epsilon_{\varphi\varphi} + \lambda\theta = 2\mu\frac{\rho}{r} + \lambda A \frac{z}{R^3},$$

or, because of (15),

$$\sigma_{\varphi\varphi} = \frac{A}{r^3} \left(\mu - (2\mu + \lambda) \frac{z}{R} + (\mu + \lambda) \frac{z^3}{R^3} \right) + \lambda A \frac{z}{R^3}.$$

This may be rewritten in the following form

$$(20) \quad \sigma_{\varphi\varphi} = \frac{A\mu}{r^3} \left(1 - 2 \frac{z}{R} + \frac{z^3}{R^3} \right).$$

The expression stays finite for $r = 0$ since the factor in parentheses vanishes.

The justification for the use of the particular solutions (4) and (7) must be seen in the fact that they can be made to fit all continuity requirements and boundary conditions of the problem. The vanishing of the displacements and stresses at infinity should also be counted among the boundary conditions. It can be verified directly from Eqs. (15), (16), and (20).

The assumption of a load concentrated at one point is physically not justifiable, but greatly simplifies the mathematics of the problem. The general case of a prescribed load distribution along the surface $z = 0$ can be easily constructed from the foregoing formulas by integration.

Boussinesq published his solution in 1879 and gave a complete representation of it in his book "Applications des potentiels directes, inverses, logarithmiques" Paris 1885.

III.1. The misinterpretation of the operator ($\nabla \text{ grad}$) would lead to the following expression for the r component

$$(1) \quad (\nabla \text{ grad})v_r = v_r \frac{\partial v_r}{\partial r} + \frac{v_\varphi}{r} \frac{\partial v_r}{\partial \varphi} + v_z \frac{\partial v_r}{\partial z}.$$

Instead of this one obtains by (11.6)

$$v_r \frac{\partial v_r}{\partial r} + v_\varphi \frac{\partial v_\varphi}{\partial r} + v_z \frac{\partial v_z}{\partial r} - v_\varphi \operatorname{curl}_\varphi v + v_z \operatorname{curl}_z v.$$

With the values for $\operatorname{curl}_\varphi A$ and $\operatorname{curl}_z A$ according to table I.3, the last equation yields after cancellation of two pairs of terms

$$(2) \quad v_r \frac{\partial v_r}{\partial r} + \frac{v_\varphi}{r} \frac{\partial v_r}{\partial \varphi} + v_z \frac{\partial v_r}{\partial z} - \frac{v_\varphi^2}{r}.$$

The last term is the *centripetal acceleration* [missing in (1)]. The corresponding computation for the φ -component of $(\nabla \operatorname{grad}) v$ gives the additional term

$$\frac{v_r v_\varphi}{r} = v_r \omega, \quad \omega = \frac{v_\varphi}{r}.$$

When we here interpret ω as the amount of the axial vector ω parallel to the z -axis that represents the angular velocity associated with the linear velocity v_φ , then the term $v_r \omega = (\omega \times \mathbf{v})_\varphi$ becomes one half of a *Coriolis acceleration* [cf. Vol. I Eq. (29.4a)]. One finds, however, that the two results are identical in the case of the z -component. The formulas have already been tabulated in I.3 for cylindrical and spherical coordinates.

III.2 a) We put in Eq. (1) of the problem

$$C = A \rho^\alpha v^\beta a^\gamma,$$

where the α, β, γ are to be determined and A is dimensionless. (On substituting the dimensions of $v, \rho, \Pi/l$ and v , the following dimensional identity is obtained

$$\text{gr cm}^{-2} \text{ sec}^{-2} = \text{gr}^\alpha \text{ cm}^{-3\alpha+2\beta+\gamma+n} \text{ sec}^{-\beta-n},$$

which yields $\alpha = 1, \beta = 2 - n$, and $\gamma = n - 3$, whence

$$C = A \rho v^{2-n} a^{n-3}.$$

b) On substituting in Eq. (3) of the problem the expressions (16.9) and (16.8) for S and R , one obtains

$$\frac{\Pi}{\rho v^3} = \lambda \frac{l}{a} \left(\frac{va}{v} \right)^\delta.$$

v must occur here in the n^{th} power since this relation should be equivalent to Eq. (1) of the problem. It follows that $\delta = n - 2$ and therefore

$$\Pi = \lambda \rho \frac{l}{a} v^2 R^{n-2}.$$

c) On using Hagen's value $n = 1.75$ in this equation, one obtains

$$\Pi = \lambda \rho \frac{l}{a} v^2 R^{-1/4},$$

which agrees with the first form of Eq. (16.13), the exponent κ having Blasius's value of $\frac{1}{4}$.

III.3. Let the virtual displacement of the liquid be a motion of the surface elements dF in the direction of their normals by δn . Since the volume is conserved both positive and negative displacements δn (outward and inward displacements) must occur. The virtual work is composed of the work of the capillary forces and that of the external forces; the first contribution follows from (17.11) by multiplication with δn and integration over the surface, and the second contribution equals $\int U \delta n dF$ where U is the potential energy per unit of volume.

The constancy of the volume τ as a whole requires that the variation $\delta\tau$ vanish:

$$(1) \quad \delta\tau = \int \delta n dF = 0.$$

This restriction on δn can be taken care of by a Lagrangian multiplier λ , that is, by adding the term $\lambda \delta\tau$ to the left side of the virtual work and setting the total equal to zero.

The displacements δn being now arbitrary, one obtains

$$(2) \quad T \left(\frac{1}{R_1} + \frac{1}{R_2} \right) + U + \lambda = 0.$$

If the mean curvature is here replaced by the appropriate expressions from differential geometry, one has in (2) a partial differential equation for the determination of the shape of the surface. The hitherto unknown multiplier λ is fixed by requiring the surface to pass through a given point with given mean curvature (cf. the next problem).

III.4. Let the z -axis coincide with the axis of the vertical capillary tube and count z positive upward from the external liquid level. Then

$$(1) \quad U = \rho g z.$$

For a wetting liquid the radius of the concave spherical surface is negative. Eq. (2) of the preceding problem then gives

$$(2) \quad -T \frac{2}{R} + \rho g z + \lambda = 0.$$

Since for the external surface $z = 0$ and the radius $R = \infty$, the multiplier

λ must be set equal to zero. The radius of the sphere R can be expressed by the radius of the tube r if the angle of contact is known:

$$(3) \quad R = r / \cos \vartheta.$$

Defining the elevation h by a suitably chosen mean value of the z -ordinates of the meniscus, one obtains from (2) and (3)

$$(4) \quad h = \frac{2T}{\rho g r} \cos \vartheta$$

where the value of $\cos \vartheta$ for wetting liquids is nearly 1. For non-wetting liquids R is positive and the right member in Eq. (4) takes therefore a minus sign; h denotes now the capillary depression.

IV.1. From (19.10a, b) one calculates $z = x + iy$ as a function of $\rho + i\varphi$ and obtains by differentiation the differential $dx + idy$ in terms of $d\rho + i d\varphi$. The square of the line element ds^2 is found as the absolute value of $dx + idy$ which leads directly to relation (1).

The fact that the factors of $d\rho^2$ and $d\varphi^2$ [denoted by g_1^2 and g_2^2 in (2.22)] are here equal means that the network of the two families of curves $\rho = \text{const}$, and $\varphi = \text{const}$ consists of infinitesimal squares (provided the increments $d\rho$ and $d\varphi$ are equal). In other words, the bipolar coordinates are isometric in the sense of p. 139. Note that the same can be achieved with polar coordinates in the plane if one replaces $z = re^{i\varphi}$ by $z = e^{\rho+i\varphi}$, where $\rho = \log r$.

In setting up the operator ∇^2 the three dimensional scheme (3.9b) must be specialized for *two* coordinates $p_1 = \rho$, $p_2 = \varphi$ which amounts to putting

$$g_1 = g_2 = g, \quad g_3 = 1, \quad \frac{\partial}{\partial p_3} = 0.$$

In the case of the *potential equation* $\nabla^2 U = 0$ the additional factor $1/g^3$ is immaterial, but its presence destroys the separability in the case of the *wave equation*. With the assumption of a periodic time dependence $U = u e^{-i\omega t}$ the wave equation $\nabla^2 U + k^2 U = 0$ reads

$$\frac{\partial^2 u}{\partial \rho^2} + \frac{\partial^2 u}{\partial \varphi^2} + k^2 g^2 u = 0, \quad k = \frac{\omega}{c}.$$

On substituting here the trial solution (2) and dividing by $f_1 f_2$, one is led to a contradiction if one differentiates once more with respect to ρ or φ .

IV.2. We start from Eq. (19.11) which yields

$$\mathbf{v} = A \text{ grad } \varphi.$$

For an arbitrary function of the bipolar coordinates $f(\rho, \varphi)$ we have

$$\text{grad}_\rho f = \frac{1}{g} \frac{df}{d\rho}, \quad \text{grad}_\varphi f = \frac{1}{g} \frac{df}{d\varphi}.$$

If in particular $f = \varphi$, then $v_\rho = 0$ and $v_\varphi = 1/g$, as already mentioned in the text of the problem. With $A = \mu/\pi$ as in Eq. (19.8a) we have therefore

$$(1) \quad |\mathbf{v}| = v_\varphi = \frac{\mu}{\pi c} (\cosh \rho - \cos \varphi).$$

This should be compared with the value of $|\mathbf{v}|$ that follows from (19.14)

$$(2) \quad |\mathbf{v}| = \frac{\mu}{\pi} \left| \frac{\hat{\mathbf{e}}_1}{r_1} - \frac{\hat{\mathbf{e}}_2}{r_2} \right|.$$

The vector φ_1/r_1 (φ_2/r_2) has the amount $1/r_1$ ($1/r_2$) and is perpendicular to the radius vector from $z = +c$ ($z = -c$) to the field point. The angle subtended by the two radius vectors $\mathbf{r}_1, \mathbf{r}_2$ is therefore $\varphi = \varphi_1 - \varphi_2$. Vectorial addition then yields

$$\begin{aligned} \sqrt{\frac{1}{r_1^2} + \frac{1}{r_2^2} - \frac{2}{r_1 r_2} \cos \varphi} &= \sqrt{\frac{2}{r_1 r_2}} \sqrt{\frac{1}{2} \left(\frac{r_2}{r_1} + \frac{r_1}{r_2} \right) - \cos \varphi} \\ &= \sqrt{\frac{2}{r_1 r_2}} \sqrt{\cosh \rho - \cos \varphi}. \end{aligned}$$

Relations (1) and (2) are equivalent when

$$\frac{1}{c} \sqrt{\cosh \rho - \cos \varphi} = \sqrt{\frac{2}{r_1 r_2}},$$

which is in fact the case, as one sees by applying the law of cosines to the triangle whose corners are $z = \pm c$ and the field point.

IV.3. From the definition of elliptic coordinates in (19.15) we derive similarly as in problem IV.1

$$ds^2 = g^2(d\xi^2 + d\eta^2), \quad g = \frac{c}{\sqrt{2}} \sqrt{\cosh 2\xi - \cos 2\eta}.$$

The equation of the vibrating membrane has the same form as in IV.1, but the meaning of g is different:

$$(1) \quad \frac{\partial^2 u}{\partial \xi^2} + \frac{\partial^2 u}{\partial \eta^2} + k^2 g^2 u = 0.$$

Substitution of the trial solution and division by $f_1 f_2$ leads to

$$(2) \quad \frac{f_1''}{f_1} + \frac{c^2 k^2}{2} \cosh 2\xi = -\frac{f_2''}{f_2} + \frac{c^2 k^2}{2} \cos 2\eta = \lambda.$$

Now the quantity λ (the "separation parameter") is independent of ξ and η ; to show this differentiate (2) with respect to η or ξ . (In other words, λ is a function of ξ alone according to the first, and of η alone according to the second member of Eq. (2) and is therefore constant.) The partial differential equation (2) then yields two ordinary differential equations

$$(3) \quad f_1'' = \left(\lambda - \frac{c^2 k^2}{2} \cosh 2\xi \right) f_1, \quad f_2'' = \left(-\lambda + \frac{c^2 k^2}{2} \cos 2\eta \right) f_2.$$

The solutions of (3) are called Mathieu's functions.

IV.4a. Toroidal coordinates first occur in a posthumous paper of Riemann "About the potential of a torus", Ges. Werke XXIV, p. 431. We introduce the notations ρ, φ, ψ and restrict the ranges as follows:

$$(1) \quad 0 \leq \rho < \infty, \quad 0 \leq \varphi < 2\pi, \quad 0 \leq \psi < 2\pi.$$

The geometrical meaning of ρ and φ follows from Fig. 26, the right half of which need only be considered (ρ positive). The angle ψ is the angle of rotation about the axis $\rho = 0$ (azimuth); the surfaces $\psi = \text{const}$ are half planes containing this axis. In the rotation the circles $\rho = \text{const}$ yield a system of coaxial tori about the axis $\rho = 0$, and the circular arcs $\varphi = \text{const}$ yield spherical segments.

Let us now change the notation of the complex variable z of Eq. (19.10a) into $\bar{z} = \bar{x} + i\bar{y}$; then by (19.10a, b)

$$(2) \quad \bar{x} = -\frac{c \sinh \rho}{\cosh \rho - \cos \varphi}, \quad \bar{y} = \frac{c \sin \varphi}{\cosh \rho - \cos \varphi}.$$

If we introduce a spatial Cartesian system x, y, z such that the z -axis coincides with $\rho = 0$, the origin with the center of Fig. 26, and the positive x -axis has the azimuth $\psi = 0$, the following relations hold between the coordinates x, y, z and the coordinates \bar{x}, \bar{y}, ψ of the same point:

$$(3) \quad x = \bar{x} \cos \psi, \quad y = \bar{x} \sin \psi, \quad z = \bar{y}.$$

The square of the line element follows now by differentiation (cf. prob. IV.1),

$$(4) \quad ds^2 = dx^2 + dy^2 + dz^2 = g^2(d\rho^2 + d\varphi^2) + g_3^2 d\psi^2,$$

where

$$(5) \quad g = g_1 = g_2 = \frac{c}{\cosh \rho - \cos \varphi}, \quad g_3 = -\bar{x} = \frac{c \sinh \rho}{\cosh \rho - \cos \varphi}.$$

The Laplacian operator follows by (3.9b):

$$(6) \quad \nabla^2 U = \frac{1}{g^2 g_3} \left\{ \frac{\partial}{\partial \rho} \left(g_3 \frac{\partial U}{\partial \rho} \right) + \frac{\partial}{\partial \varphi} \left(g_3 \frac{\partial U}{\partial \varphi} \right) + \frac{g^2}{g_3} \frac{\partial^2 U}{\partial \psi^2} \right\}.$$

One assumes U in the form

$$(7) \quad U = \sqrt{\cosh \rho - \cos \varphi} V(\rho, \varphi) e^{im\psi},$$

and obtains the following form of $\nabla^2 U$ after several steps

$$(8) \quad c^2 \nabla^2 U = (\cosh \rho - \cos \varphi)^{5/2} \cdot \left\{ \frac{\partial^2 V}{\partial \rho^2} + \coth \rho \frac{\partial V}{\partial \rho} + \frac{\partial^2 V}{\partial \varphi^2} + \left(\frac{1}{4} - \frac{m^2}{\sinh^2 \rho} \right) V \right\} e^{im\psi}.$$

When we are interested in the potential equation $\nabla^2 U = 0$, the resulting differential equation for V can be separated by setting

$$(9) \quad V = f(\rho) e^{in\varphi}.$$

The ordinary differential equation that results for f is

$$(10) \quad f'' + \coth \rho f' + \left(\frac{1}{4} - n^2 - \frac{m^2}{\sinh^2 \rho} \right) f = 0,$$

the solutions of which are generalized spherical harmonics.

In the case of the wave equation, however, the differential equation for V , obtained from (7), is

$$(11) \quad \frac{\partial^2 V}{\partial \rho^2} + \coth \rho \frac{\partial V}{\partial \rho} + \frac{\partial^2 V}{\partial \varphi^2} + \left(\frac{1}{4} - \frac{m^2}{\sinh^2 \rho} + \frac{k^2 c^2}{(\cosh \rho - \cos \varphi)^{3/2}} \right) V = 0.$$

It is not separable in the coordinates ρ and φ .

IV.4b. If the diagram in Fig. 26 is made to rotate about the axis $\varphi = 0$ rather than $\rho = 0$, the circles $\rho = \text{const}$ generate spheres and the circular arcs $\varphi = \text{const}$ generate "spindles" (the latter name is appropriate only for the surfaces $\varphi < \pi/2$). The third coordinate is the angle of rotation ψ about the axis, hence the surfaces $\psi = \text{const}$ are half-planes as before. The ranges for the coordinates are now

$$(1') \quad -\infty < \rho < +\infty, \quad 0 \leq \varphi < \pi, \quad 0 \leq \psi < 2\pi.$$

Introduce again Cartesian coordinates x, y, z , so that the z -axis coincides with the axis of rotation and the origin with the center of Fig. 26.

With \bar{x} and \bar{y} having the same meaning as before, we have now instead of (3)

$$(3') \quad x = \bar{y} \cos \psi, \quad y = \bar{y} \sin \psi, \quad z = \bar{x}.$$

By differentiation, a line element of the same form and also with the same value of g as in (4) is obtained, but the value of g_3 is now

$$(5') \quad g_3 = \bar{y} = \frac{c \sin \varphi}{\cosh \rho - \cos \varphi}.$$

The expression (6) for $\nabla^2 U$, which is still correct, yields when the form (7) of U and the present value of g_3 are used

$$(8') \quad c^2 \nabla^2 U = (\cosh \rho - \cos \varphi)^{5/2} \cdot \left\{ \frac{\partial^2 V}{\partial \rho^2} + \cot \varphi \frac{\partial V}{\partial \varphi} + \frac{\partial^2 V}{\partial \varphi^2} - \left(\frac{1}{4} + \frac{m^2}{\sin^2 \varphi} \right) V \right\} e^{im\psi}.$$

When we are interested in the potential equation $\nabla^2 U = 0$, the resulting differential equation for V becomes separable if one puts

$$(9') \quad V = f(\varphi) e^{im\psi}.$$

The equation for f is

$$(10') \quad f'' + \cot \varphi f' - \left(\frac{1}{4} - \alpha^2 + \frac{m^2}{\sin^2 \varphi} \right) f = 0,$$

which can be solved by generalized spherical harmonics like (10).

The wave equation $\nabla^2 U + k^2 U = 0$, however, is also not separable in these coordinates.

V.1. The kinetic energy to be computed is given by

$$(1) \quad E_{kin} = \frac{\rho}{2} \int_0^\lambda dx \int_\eta^\infty dy \left\{ \left(\frac{\partial \Phi}{\partial x} \right)^2 + \left(\frac{\partial \Phi}{\partial y} \right)^2 + \left(\frac{\partial \Phi}{\partial z} \right)^2 \right\}.$$

On substituting for Φ according to (26.6) one obtains without difficulty

$$(2) \quad E_{kin} = \rho k \pi A^2 \int_\eta^\infty e^{-2ky} dy = \frac{\rho}{2} \pi A^2 e^{-2k\eta}.$$

This agrees with the expression (26.7a) for E_{pot} , since the amplitude A , which occurs in the expression for η [cf. Eq. (26.6)], is considered as a first order infinitesimal, and $e^{-2k\eta}$ may therefore be replaced by 1. Since E_{kin} is zero if the fluid is at rest, the expression (2) is at the same time the difference in kinetic energy between states of motion and rest for the spatial domain in question.

In the second part of the problem

$$\Phi = C \cos(kx - \omega t) \cosh k(h - y),$$

and one has by (24.3) and (24.8)

$$\eta = -\frac{\omega}{g} \sin(kx - \omega t) \cosh kh;$$

this yields

$$S = \frac{\rho}{4} \pi C^2 (\sinh 2kh + 2kh), \quad E_{kin} = E_{pot} = \frac{\rho}{4} \pi C^2 \sinh 2kh.$$

VI.1. The Navier-Stokes equations (10.8a, b) augmented by the Coriolis term read

$$(1) \quad 2\rho \mathbf{v} \times \boldsymbol{\omega} + \mu \nabla^2 \mathbf{v} - \text{grad } p + \mathbf{F} = 0.$$

With the simplification indicated in the problem text the ξ and η components of Eq. (1) yield for a point on the northern hemisphere

$$(2) \quad \begin{aligned} 2\omega \sin \varphi v_\eta + \nu \frac{d^2 v_\xi}{d\zeta^2} &= 0, \\ -2\omega \sin \varphi v_\xi + \nu \frac{d^2 v_\eta}{d\zeta^2} &= 0, \end{aligned}$$

where φ is the geographical latitude. (Note that the gravity vector \mathbf{F} is perpendicular to ξ and η .) Since $v_\zeta = 0$ and the vertical component of the Coriolis acceleration is negligibly small in comparison with g , the ζ -component of Eq. (1) gives simply the hydrostatic pressure gradient in ζ direction

$$-\frac{dp}{d\zeta} = \rho g.$$

With the simplifications introduced, the condition of incompressibility is automatically fulfilled. The two Eqs. (2) can be conveniently written as one complex equation, similarly as in the theory of Foucault's pendulum (cf. Vol. I. 31.5). We put

$$V = v_\xi + i v_\eta$$

and obtain instead of (2)

$$(3) \quad \frac{d^2 V}{d\zeta^2} - 2i\lambda^2 V = 0, \quad \lambda^2 = \frac{\omega}{\nu} \sin \varphi.$$

The integration yields

$$(4) \quad V = Ae^{\lambda(1+i)z},$$

if due regard is given to the orientation of ζ . The constant A must be determined from the excitation due to the wind pressure, whose components have to balance the friction pressures $p_{\tau\tau}$ and $p_{\tau\eta}$ everywhere on the surface $\zeta = 0$. If one introduces a complex friction pressure P by

$$P = p_{\tau\tau} + ip_{\tau\eta} = -\mu \left(\frac{dv_{\tau}}{d\zeta} + i \frac{dv_{\eta}}{d\zeta} \right) = -\mu \frac{dV}{d\zeta},$$

where v_{τ} has again been neglected, one obtains from (4) for $\zeta = 0$

$$(5) \quad -P_0 = \mu A \lambda (1 + i).$$

This is the value of the wind pressure on the surface $\zeta = 0$ in complex notation; it must be considered as a known vector. We introduce the notations

$$P_0 = |P_0| e^{i\delta}, \quad v_0 = -\frac{|P_0|}{\mu \lambda \sqrt{2}}, \quad \zeta = -z,$$

and obtain the velocities v_{τ} and v_{η} when we take A from (5), substitute it in (4), and separate real and imaginary parts:

$$(6) \quad \begin{aligned} v_{\tau} &= v_0 e^{-\lambda z} \cos \left(\lambda z + \frac{\pi}{4} - \delta \right), \\ v_{\eta} &= -v_0 e^{-\lambda z} \sin \left(\lambda z + \frac{\pi}{4} - \delta \right). \end{aligned}$$

This result permits the following interpretation: *The drift current on the surface makes an angle of -45° with the wind direction. The velocity of the current $|v|$ attenuates with increasing depth and changes its direction in such a way that at the depth*

$$(7) \quad z_E = \frac{\pi}{\lambda} = \frac{\pi}{\sqrt{\frac{\omega}{\nu}} \sin \varphi}$$

the current is opposite to the surface current. At that depth $|v|$ is equal to $v_0 \cdot e^{-\pi}$ (Ekman's friction-depth).

For a justification of our simplifying assumptions and for further discussion see: V. W. Ekman, "Dynamische Gesetze der Meeresströmungen" in the Innsbruck lectures quoted on p. 242. The fact that the actual motion is properly a turbulent one can be accounted for by giving

μ a larger value than usual; this takes care of the increased internal friction due to turbulence.

VI.2. When higher powers of φ_1 and φ_2 are neglected and the constant terms $U_1^2/2$ and $U_2^2/2$ of Bernoulli's equation are absorbed in the constants C_1 and C_2 , the following equations are obtained from (11.15) for the disturbance potentials φ_1 and φ_2

$$\frac{p_1}{\rho} = \frac{\partial \varphi_1}{\partial t} + U_1 \frac{\partial \varphi_1}{\partial x} - C_1 \cdots y > 0,$$

$$\frac{p_2}{\rho} = \frac{\partial \varphi_2}{\partial t} + U_2 \frac{\partial \varphi_2}{\partial x} - C_2 \cdots y < 0.$$

Since the pressure on both sides of the discontinuity surface ($y = 0$) must be the same, one obtains

$$(1) \quad \frac{\partial \varphi_1}{\partial t} + U_1 \frac{\partial \varphi_1}{\partial x} = \frac{\partial \varphi_2}{\partial t} + U_2 \frac{\partial \varphi_2}{\partial x} + c \cdots y = 0,$$

and the constant $c = C_1 - C_2$ must be zero because of the assumed periodicity of φ_1 and φ_2 .

We write the sinusoidal disturbance of the surface in the convenient complex form

$$(2) \quad \eta = Ae^{ikx}, \quad k = \frac{2\pi}{\lambda}, \quad A = \text{function of } t$$

The y -velocity $-\partial\varphi_1/\partial y$ of a particle close to the discontinuity surface is, except for second order terms, given by

$$\frac{d\eta}{dt} = \frac{\partial \eta}{\partial t} + U_1 \frac{\partial \eta}{\partial x}.$$

We obtain therefore

$$(3) \quad \frac{\partial \eta}{\partial t} + U_1 \frac{\partial \eta}{\partial x} = - \frac{\partial \varphi_1}{\partial y}$$

and, correspondingly,

$$(4) \quad \frac{\partial \eta}{\partial t} + U_2 \frac{\partial \eta}{\partial x} = - \frac{\partial \varphi_2}{\partial y}.$$

Since the problem is two-dimensional, we put

$$(5) \quad \varphi_1 = A_1 e^{ik(x+iy)}, \quad \varphi_2 = A_2 e^{ik(x-iy)}, \quad \left. \begin{matrix} A_1 \\ A_2 \end{matrix} \right\} = \text{functions of } t$$

Note that (5) fulfills the condition of incompressibility and φ_1 (φ_2) stays finite for $y = +\infty$ ($y = -\infty$). The problem has a solution only if the wave number k in (5) has the same value as in (2).

Upon substituting (2) and (5) in Eqs. (1), (3), and (4) the amplitudes A , A_1 , A_2 are found to obey the following linear system of differential equations

$$(6) \quad \frac{dA_1}{dt} + ikU_1A_1 = \frac{dA_2}{dt} + ikU_2A_2$$

$$(7) \quad \frac{dA}{dt} + ikU_1A = kA_1$$

$$(8) \quad \frac{dA}{dt} + ikU_2A = -kA_2.$$

The solution can be set up in the form

$$(9) \quad A = ae^{\alpha t}, \quad A_1 = a_1e^{\alpha t}, \quad A_2 = a_2e^{\alpha t}.$$

If one substitutes for A_1 and A_2 according to (9), one can compute a_1 and a_2 from (7) and (8), and obtains a quadratic equation for α by introducing these values into (6). The two roots are

$$(10) \quad \alpha = \frac{k}{2} [\pm(U_1 - U_2) - i(U_1 + U_2)].$$

Unless U_1 equals U_2 , one of the two roots has a positive real part which implies a continual increase of the amplitudes A , A_1 , A_2 . At any wave number k there are thus sinusoidal initial disturbances that will grow in the course of time.

VI.3. In the first pair of equations of VI.2, replace U_1 by U (wind velocity) and set $U_2 = 0$ (water at rest), add the action of gravity $-g\eta$ (η positive upward), and introduce the two densities ρ_1 and ρ_2 instead of ρ . With $s = \rho_1/\rho_2$ and $c = 0$ as before, these equations yield

$$(1') \quad s\left(\frac{\partial\varphi_1}{\partial t} - g\eta + U\frac{\partial\varphi_1}{\partial x}\right) = \frac{\partial\varphi_2}{\partial t} - g\eta.$$

Eqs. (2) and (5) of VI.2 remain unchanged, and so do (3) and (4) except for the specified values of U_1 and U_2 . One then has the same form of a solution as (9) for the differential equations that correspond to Eqs. (6), (7), (8) in VI.2, and expresses again a_1 and a_2 by a . In this way one obtains for α the quadratic equation

$$(10') \quad s(\alpha + ikU)^2 + \alpha^2 = -gk(1 - s).$$

One of the two roots has a positive real part if

$$(11') \quad U^2 > \frac{g}{k} \frac{1-s^2}{s}.$$

Now, $\sqrt{g/k}$ is, according to (23.16), the phase velocity V of the deep water waves if the inertia of the air is neglected (the value of V is only insignificantly smaller if the inertia of the air is considered, as can be shown by suitably expanding the calculations of 23); hence the condition of instability (11') can be written as

$$U > V \sqrt{\frac{1-s^2}{s}}.$$

In order to excite disturbances of wave length λ , the wind velocity U must be considerably larger than the phase velocity V associated with this wave length. The plane water surface is therefore stable with regard to this wave length for all wind velocities

$$U < \frac{V}{\sqrt{0.0013}} = 28V.$$

If in addition to gravity capillarity is considered, the stabilizing tendency of gravity is strengthened and the plane water surface is seen to be absolutely stable for all wave lengths as long as

$$U < 28 V_{\min}; \quad V_{\min} = 23.2 \text{ cm/sec.}$$

The phase velocity V_{\min} belongs to the wave length $\lambda_{\min} = 1.73 \text{ cm}$ as calculated on p. 184. A wind velocity smaller than $28 \times 23.2 \text{ cm/sec} \sim 6.5 \text{ m/sec}$ (wind strength 2-3 Beaufort) would not be able to disturb the plane surface of the water. This result assumes perfect homogeneity of the wind, which in reality is always turbulent.

VII.1. Let a, b, c be the coordinates of a fluid element at the time $t = 0$; in cylindrical coordinates r, φ, z

$$(1) \quad \begin{aligned} a &= x_0 = r \cos \varphi, \\ b &= y_0 = r \sin \varphi, \\ c &= z_0. \end{aligned}$$

Because of the uniform rotation the coordinates of the same element at the time t are obtained if we replace φ by $\varphi + \omega t$, where $\omega =$ angular velocity. Hence

$$\begin{aligned}
 x &= a \cos \omega t - b \sin \omega t, \\
 (2) \quad y &= b \cos \omega t + a \sin \omega t, \\
 z &= c.
 \end{aligned}$$

It is easy to verify that the condition of incompressibility (34.3) is fulfilled. Lagrange's equations (34.1) give in the present case (gravity being the only external force, and the z -axis being counted positive downward as in Fig. 7)

$$\begin{aligned}
 (3) \quad & \frac{\partial^2 x}{\partial t^2} \cos \omega t + \frac{\partial^2 y}{\partial t^2} \sin \omega t + \frac{1}{\rho} \frac{\partial p}{\partial a} = 0, \\
 & -\frac{\partial^2 x}{\partial t^2} \sin \omega t + \frac{\partial^2 y}{\partial t^2} \cos \omega t + \frac{1}{\rho} \frac{\partial p}{\partial b} = 0, \\
 & \frac{\partial^2 z}{\partial t^2} - g + \frac{1}{\rho} \frac{\partial p}{\partial c} = 0.
 \end{aligned}$$

If the accelerations in (3) are computed according to (2), one obtains for p the system of differential equations

$$(4) \quad \frac{1}{\rho} \frac{\partial p}{\partial a} = \omega^2 a, \quad \frac{1}{\rho} \frac{\partial p}{\partial b} = \omega^2 b, \quad \frac{1}{\rho} \frac{\partial p}{\partial c} = g.$$

The value of p obtained by integration of the system (4) is identical with Eq. (6.10) if (2) is taken into account.

To carry out the same calculation for a compressible gas is quite instructive; the continuity equation gives in this case $\partial \rho / \partial t = 0$ and the equation of motion becomes $\mathcal{O} = gz + r^2 \omega^2 / 2$, which becomes identical with Eq. (7.19) by applying (7.18) (the orientation of the z -axis is now different).

VII.2. One starts from the one-dimensional Euler equation (13.1) (no external force)

$$(1) \quad \frac{du}{dt} = -\frac{1}{\rho} \frac{\partial p}{\partial x}$$

and introduces t and a as independent variables, where $a = x_0$ is the initial coordinate of a volume element whose coordinate at any later time is $x(t)$. The mass contained in this volume element equals

$$\text{for } t = 0 : \rho_0 da, \quad \text{for } t > 0 : \rho dx = \rho \frac{\partial x}{\partial a} da.$$

Conservation of mass demands

$$(2) \quad \rho \frac{\partial x}{\partial a} = \rho_0.$$

It follows that

$$(3) \quad \frac{\partial}{\partial t} \left(\rho \frac{\partial x}{\partial a} \right) = 0,$$

which is identical with Eq. (34.3b).

According to the remarks preceding Eq. (34.1), we can express the material acceleration in (1) by

$$(4) \quad u = \frac{\partial x}{\partial t} \quad \text{as} \quad \frac{du}{dt} = \frac{\partial^2 x}{\partial t^2};$$

the pressure gradient may be written

$$(5) \quad \frac{\partial p}{\partial x} = \frac{\partial p}{\partial a} \frac{\partial a}{\partial x} = \frac{\partial p}{\partial a} / \frac{\partial x}{\partial a}.$$

Substitution of these derivatives in (1) yields

$$(6) \quad \frac{\partial^2 x}{\partial t^2} \frac{\partial x}{\partial a} = - \frac{1}{\rho} \frac{\partial p}{\partial a}.$$

This agrees with (34.1) if and only if one takes into account the modification of Lagrange's equations for compressible fluids stated in (34.3a).

VII.3. If the compressible fluid has initially the constant density ρ_0 one concludes from Eq. (2) of answer VII.2 by differentiation with respect to the independent variable a

$$(1) \quad \frac{\partial}{\partial a} \left(\rho \frac{\partial x}{\partial a} \right) = 0,$$

or

$$(2) \quad \frac{1}{\rho} \frac{\partial \rho}{\partial a} = - \frac{1}{\omega} \frac{\partial^2 x}{\partial a^2},$$

where we have used Hadamard's abbreviation

$$(3) \quad \omega = \frac{\partial x}{\partial a}.$$

If now a p, ρ -relation $p = \varphi(\rho)$ is assumed one obtains, using (2),

$$(4) \quad \frac{1}{\rho} \frac{\partial p}{\partial a} = \frac{\varphi'(\rho)}{\rho} \frac{\partial \rho}{\partial a} = - \frac{\varphi'(\rho)}{\omega} \frac{\partial^2 x}{\partial a^2}.$$

Eq. (6) of the preceding answer then takes the form

$$(5) \quad \frac{\partial^2 x}{\partial t^2} = \Omega \frac{\partial^2 x}{\partial a^2}, \quad \Omega = \frac{\varphi'(\rho)}{\omega^2}.$$

The quantity Ω is a function of ω alone since, by Eq. (2) of the preceding answer, ρ is inversely proportional to ω . This suggests the introduction of ω as an *independent variable*. A second independent variable, suited for our purpose, is

$$(6) \quad u = \frac{\partial x}{\partial t}.$$

By (3) and (6), one finds

$$(7) \quad dx = \omega da + u dt.$$

If one introduces in accordance with the rule of Legendre's transformation the dependent variable

$$(8) \quad z(u, \omega) = ut + \omega a - x(t, a)$$

and forms its total differential, then one finds

$$(9) \quad dz = t du + a d\omega.$$

From (8) and (9) one has

$$(10) \quad \frac{\partial^2 x}{\partial a^2} = \omega_a, \quad \frac{\partial^2 x}{\partial t^2} = u_t;$$

$$(11) \quad \frac{\partial^2 z}{\partial \omega^2} = a_{\omega}, \quad \frac{\partial^2 z}{\partial u^2} = t_u,$$

and from (5) and (10) follows

$$(12) \quad u_t = \Omega \omega_a.$$

Using a well known transformation rule we conclude from (12)

$$(13) \quad a_{\omega} = \Omega t_u.$$

Because of (11) this is a *linear differential equation of second order* for z since the coefficient Ω depends only on the *independent variable* ω . Writing (13) in the variable z , we have

$$(14) \quad \frac{\partial^2 z}{\partial \omega^2} = \Omega \frac{\partial^2 z}{\partial u^2},$$

which is the basis of Hadamard's discussion of Riemann's shock waves. The fact that Eq. (14) is not identical with (37.11) is of course due to the different meanings of the new dependent and independent variables.

VII.4. Introduce spherical coordinates r, ϑ, φ , so that $r = 0$ coincides with the center of the sphere and $\vartheta = 0$ with the axis of rotation; let the constant angular velocity be $\dot{\vartheta} = \omega$. Assume that the fluid moves in circular streamlines about the axis in the sense of increasing φ , and show that this very simple assumption is permissible.—The first two of the velocity components $v_r, v_\vartheta, v_\varphi = v$ vanish and, because of the assumed incompressibility,

$$\frac{\partial v}{\partial \varphi} = 0,$$

while $\partial v / \partial \vartheta$ and $\partial v / \partial r$ are different from zero. Eq. (35.6) is again our starting point; developing the expressions for curl curl with the aid of answer I.3 we obtain

$$(1) \quad \text{curl}_r \text{curl} \mathbf{v} = \text{curl}_\vartheta \text{curl} \mathbf{v} = 0$$

$$(2) \quad \text{curl}_\vartheta \text{curl} \mathbf{v} = -\frac{1}{r} \frac{\partial^3(rv)}{\partial r^3} - \frac{1}{r} \frac{\partial}{\partial \vartheta} \frac{1}{r \sin \vartheta} \frac{\partial(\sin \vartheta v)}{\partial \vartheta}.$$

From (35.6) and (1) we conclude first

$$\text{grad}_r p = \text{grad}_\vartheta p = 0,$$

and since for reasons of symmetry $\text{grad}_\varphi p = 0$, we have altogether

$$(3) \quad p = \text{const.}$$

From (2), the differential equation for v is obtained:

$$(4) \quad \frac{\partial^3 v}{\partial r^3} + \frac{2}{r} \frac{\partial v}{\partial r} + \frac{1}{r^2} \left(\frac{\partial^3 v}{\partial \vartheta^3} + \cot \vartheta \frac{\partial v}{\partial \vartheta} - \frac{v}{\sin^2 \vartheta} \right) = 0.$$

On substituting $v = C \cdot f(r)g(\vartheta)$, one obtains the two equations

$$(5) \quad f'' + \frac{2}{r} f' - \frac{\lambda}{r^2} f = 0, \quad g'' + \cot \vartheta g' + \left(\lambda - \frac{1}{\sin^2 \vartheta} \right) g = 0,$$

λ being the parameter of separation. A solution² of this equation that vanishes at infinity and remains finite for all values $0 < \vartheta < \pi$ is

$$(6) \quad f = \frac{1}{r^2}, \quad g = \sin \vartheta, \quad \lambda = 2.$$

²A more general solution is

$$f = \frac{1}{r^n}, \quad g = P_n^1(\cos \vartheta), \quad \lambda = n(n+1)$$

where P_n^1 is Legendre's associated function of the first kind, cf. Vol. VI, Chap. IV.

The velocity law is obtained as

$$(7) \quad v = \omega \frac{a^3}{r^3} \sin \vartheta$$

where the factor C was chosen so as to make $v = \omega a \sin \vartheta$ on the surface of the sphere. Thus, since we can fulfill the boundary conditions, the special choice $\lambda = 2$ in (6) is justified, and it is seen that the more general solutions mentioned in the footnote would be unsuited for our problem.

In order to pass from (7) to the friction pressures, one calculates similarly as on p. 36 from (4.26) and (4.28) with $\delta \dot{q}_1 = \delta \dot{q}_2 = 0$, $\delta \dot{q}_3 = v = \omega \sin \vartheta a^3/r^3$:

$$\dot{e}_{rr} = \dot{e}_{\vartheta\vartheta} = \dot{e}_{\varphi\varphi} = \dot{e}_{r\varphi} = \dot{e}_{r\vartheta} = 0$$

$$\dot{e}_{r\varphi} = \frac{1}{2g_1} \frac{\partial v}{\partial r} - \frac{1}{2g_3 g_1} v \frac{\partial g_3}{\partial r} = \frac{\omega}{2} \sin \vartheta \left(-2 \frac{a^3}{r^3} - \frac{a^3}{r^3} \right) = -\frac{3}{2} \omega \sin \vartheta \frac{a^3}{r^3}.$$

Hence all friction pressures vanish except

$$(8) \quad p_{r\varphi} = -2\mu \dot{e}_{r\varphi} = 3\mu\omega \frac{a^3}{r^3} \sin \vartheta.$$

The moment can now be computed:

$$(9) \quad -M = 2\pi a^3 \int p_{r\varphi} \sin^2 \vartheta d\vartheta = 6\pi\mu\omega a^3 \int_0^\pi \sin^3 \vartheta d\vartheta = 8\pi\mu\omega a^3$$

in agreement with (35.21). The moment required for the maintenance of uniform rotation is opposite to the moment of the friction pressures and acts therefore in the positive φ -direction as expected.

Kirchhoff treats the same problem in a more elegant though less concise manner using Cartesian coordinates, cf. footnote on p. 251.

VIII.1. We denote the reactions at the points A and B by these same letters and have

$$A = P \frac{b}{l}, \quad B = P \frac{a}{l}.$$

These reactions determine the shear force introduced in the context of Eq. (41.12) in the regions I (between A and P) and II (between P and B) as

$$(1) \quad S_I = A, \quad S_{II} = -B, \text{ respectively}$$

Note that the positive x -direction is from A to B and that both shears S_{II} and S_I refer to positive x -surfaces in the sense of Fig. 6. The shear force is constant throughout either one of the regions I and II, but jumps at the load point by the amount P ; this discontinuity is, of course, due

to the unrealistic assumption of a concentrated load. In a cross-section at a distance x from A (region I) the bending moment equals

$$(2) \quad M_I = Ax = P \frac{b}{l} x.$$

For the region II, in a cross-section at a distance ξ from B , the bending moment is

$$(3) \quad M_{II} = B\xi = P \frac{a}{l} \xi.$$

M_{II} refers to a positive ξ -surface which evidently is equivalent to a negative x -surface. A graph of M consists therefore of two straight lines that intersect at $x = a$ (or $\xi = b$). At this point, $M = M_{\max} = Pab/l$ according to both (2) and (3).

The deflection of y_I is found for the region I from

$$(4) \quad \frac{d^2 y_I}{dx^2} = \frac{P}{EJ} \frac{b}{l} x,$$

and for the region II from

$$(5) \quad \frac{d^2 y_{II}}{d\xi^2} = \frac{P}{EJ} \frac{a}{l} \xi.$$

The constants occurring in the solutions of (4) and (5) must be determined from the following boundary and continuity conditions:

- a) The deflection y_I must vanish at A , and y_{II} at B .
- b) At the point of application of the load both curves must join continuously and with common tangent. These conditions yield

$$(6) \quad \begin{aligned} y_I &= \frac{P}{EJ} \frac{a^2 b^2}{6l} \left(\frac{x^3}{a^2 b} - 2 \frac{x}{a} - \frac{x}{b} \right), \\ y_{II} &= \frac{P}{EJ} \frac{a^2 b^2}{6l} \left(\frac{\xi^3}{ab^2} - 2 \frac{\xi}{b} - \frac{\xi}{a} \right). \end{aligned}$$

The deflection at the load point is found from both equations as

$$(7) \quad y = y_{\max} = \frac{P}{EJ} \frac{a^2 b^2}{3l}.$$

The shear forces (1) and the bending moments (2) and (3) are always interconnected by the relation

$$(8) \quad S = \frac{dM}{dx}.$$

If the beam is loaded by several vertical forces at given points, shear force, bending moment, and deflection can be easily obtained by superposition of the corresponding expressions for single loads.

VIII.2. a) Let F be the cross-section of the rod, and count the displacement ξ of M (which is also that of the lower end cross-section) positive downward. M is subject to the downward action of gravity and the elastic force of the rod $\sigma \cdot F = FE \cdot \xi/l$ that acts upward. The equation for the displacement ξ reads

$$(1) \quad M\ddot{\xi} = Mg - k\xi, \quad k = \frac{FE}{l},$$

and gives, when integrated,

$$(2) \quad \xi = \frac{g}{\omega_0^2} + A \cos \omega_0 t + B \sin \omega_0 t,$$

where

$$(3) \quad \omega_0 = \sqrt{\frac{k}{M}} = \sqrt{\frac{EF}{Ml}};$$

the constants A and B are to be found from the given initial conditions. One sees that ξ oscillates about the constant value $\xi_0 = g/\omega_0^2$ which is nothing else but the static extension obtained from (1) for $\xi = 0$.

b) With the notations J_p = polar moment of inertia of the cross-section of the rod (assumed as circular), μ = torsion modulus, φ = angle of torsion of the mass M about the axis of the rod, we have by (42.6)

$$(5) \quad \Theta \ddot{\varphi} = \frac{-\mu J_p}{l} \varphi,$$

and

$$(6) \quad \omega_0 = \sqrt{\frac{\mu J_p}{\Theta l}}.$$

c) The motion of M can be described in good approximation as a vertical displacement (it is exactly that for a rod on two supports if $a = b = l/2$), hence Eq. (1) may be used again, but ξ means now the transverse displacement of M .

The "spring constant" k is

for the rod clamped at one end: $k = 3 EI/l^3$

for the rod supported at both ends: $k = 3 EI/l^3$

where I is the equatorial moment of inertia of the cross-section. This leads to the frequencies

$$(7) \quad \omega_0 = \sqrt{\frac{3EI}{Ml^3}}, \quad (8) \quad \omega_0 = \sqrt{\frac{3EI}{Ma^3b^3}} \quad \text{respectively.}$$

In a more accurate theory of extensional, torsional, and bending oscillations the mass of the rod itself would have to be considered; this would lead to partial differential equations of second order in place of the ordinary equations (1) and (5). In addition to the fundamental oscillation of frequency ω , which was determined in the foregoing, one would obtain an infinite sequence of harmonic oscillations according to the infinitely many degrees of freedom of the elastic rod that are now active.

VIII.3. For $t = 0$, one has $\xi = 0$, $\dot{\xi} = v_0$; then, according to Eq. (2) of the preceding answer, one obtains

$$(1) \quad \xi = \frac{g}{\omega_0^2} (1 - \cos \omega_0 t) + \frac{v_0}{\omega_0} \sin \omega_0 t,$$

hence

$$(2) \quad \xi_{\max} = \frac{g}{\omega_0^2} + \sqrt{\left(\frac{g}{\omega_0^2}\right)^2 + \left(\frac{v_0}{\omega_0}\right)^2}.$$

The maximum tension is found according to Hooke's law as

$$(3) \quad \sigma_{\max} = \frac{E}{l} \xi_{\max}.$$

Assume now

a) $v_0 = 0$,

then

$$\xi_{\max} = 2 \frac{g}{\omega_0^2} = \frac{2gMl}{EF}, \quad \sigma_{\max} = 2 \frac{gM}{F};$$

b) for large v_0

$$\xi_{\max} = \frac{v_0}{\omega_0} = \sqrt{\frac{Mv_0^2 l}{EF}}, \quad \sigma_{\max} = \sqrt{\frac{Mv_0^2 E}{Fl}}.$$

Both results verify the statements a) and b) made in the text of the problem.

VIII.4. The equations

$$y = a \cos u, \quad z = b \sin u, \quad 0 < u < 2\pi;$$

constitute a parametric representation of the elliptic circumference of the cross-section; a family of similar concentric ellipses is given by

$$y = a\lambda \cos u, \quad z = b\lambda \sin u, \quad 0 < \lambda < 1.$$

The parameters λ and u occurring here are suitable coordinates for the calculation of the integral (42.23). The Jacobian of the transformation $y, z \rightarrow \lambda, u$ is

$$D = \begin{vmatrix} \frac{\partial y}{\partial \lambda} & \frac{\partial y}{\partial u} \\ \frac{\partial z}{\partial \lambda} & \frac{\partial z}{\partial u} \end{vmatrix} = ab\lambda.$$

One obtains therefore

$$M = \mu\alpha \frac{\pi a^3 b^3}{a^2 + b^2}, \quad \varphi_1 = \alpha l = \frac{Ml}{\mu} \frac{a^2 + b^2}{\pi a^3 b^3}.$$

On the other hand, the polar moment of inertia J_z of the area of the ellipse is conveniently calculated by adding the two equatorial moments of inertia I_x and I_y , which, in turn, can be obtained from the equatorial moment of inertia of a circular area of radius a , $I = a^2\pi/4$, by "homogeneous compression". This means that I_x and I_y take up the factors b^3/a^3 and b/a respectively. The resulting polar moment of inertia is

$$J_z = \left(\frac{b^3}{a^3} + \frac{b}{a}\right)I = \frac{\pi}{4} ab(a^2 + b^2).$$

It is different from the geometrical factor occurring in M and φ_1 , viz.

$$\frac{\pi a^3 b^3}{a^2 + b^2},$$

the two factors being identical only for a circular cross-section where $a = b$.

VIII.5. Let the plane of incidence be the x, y -plane as in 45. Polarization perpendicular to this plane means that of the three displacements ξ, η, ζ , only ζ is excited. According to the table on p. 327 a *transverse wave* incident at the angle α_1 and reflected at the angle α_2 , is given by

$$\zeta_i = A \exp [ik(x \sin \alpha_1 - y \cos \alpha_1)],$$

$$\zeta_r = B \exp [ik(x \sin \alpha_2 + y \cos \alpha_2)].$$

Since the frequency ω of both waves is the same this is also true for the wave number k , cf. (45.5). The three conditions (45.1) (boundary $y = 0$ free of forces) reduce to one condition

$$\sigma_{yz} = 2\mu e_{yz} = \mu \frac{\partial \zeta}{\partial y} = \mu \left(\frac{\partial \zeta_i}{\partial y} + \frac{\partial \zeta_r}{\partial y} \right) = 0,$$

which can be fulfilled, without assuming an additional longitudinal wave, simply by setting

$$(1) \quad \alpha_1 = \alpha_2 \quad \text{and} \quad B = A.$$

This is a regular reflexion with constant amplitude.

If on the other hand, a *longitudinal* wave strikes at the angle α_1 and is reflected at the angle α_2 , we have to deal with the two components ξ, η given by

$$(2) \quad \left. \begin{matrix} \xi_i \\ \eta_i \end{matrix} \right\} = \left. \begin{matrix} \sin \alpha_1 \\ -\cos \alpha_1 \end{matrix} \right\} A \exp [ik(x \sin \alpha_1 - y \cos \alpha_1)],$$

$$(3) \quad \left. \begin{matrix} \xi_r \\ \eta_r \end{matrix} \right\} = \left. \begin{matrix} \sin \alpha_2 \\ \cos \alpha_2 \end{matrix} \right\} B \exp [ik(x \sin \alpha_2 + y \cos \alpha_2)].$$

Since ω is again the same for both waves [it is given by (45.10)], the wave number is the same too.

Of the three conditions (45.1) only $\sigma_{xx} = 0$ is now identically fulfilled. The two others

$$(4) \quad \sigma_{xx} = 0, \quad \sigma_{xy} = 0$$

call again for regular reflexion, that is, $\alpha_2 = \alpha_1 = \alpha$, but they cannot be satisfied by adjusting the one available constant B/A . Again a reflected *transverse* wave polarized parallel to the plane of incidence must be added; this wave can be written according to the central column of the table on p. 327 in the following form

$$(5) \quad \left. \begin{matrix} \xi_t \\ \eta_t \end{matrix} \right\} = \left. \begin{matrix} \cos \alpha_t \\ -\sin \alpha_t \end{matrix} \right\} C \exp [ik_t(x \sin \alpha_t + y \cos \alpha_t)],$$

The two angles α_t and α are connected by the "law of refraction" (45.12)

$$\sin \alpha = n \sin \alpha_t, \quad n = \frac{k_t}{k} = \left(2 + \frac{\lambda}{\mu}\right)^{1/2}.$$

One computes from (2), (3), and (5) the total displacements.

$$\xi = \xi_i + \xi_r + \xi_t, \quad \eta = \eta_i + \eta_r + \eta_t$$

and finds from the two equations (4) two conditions for the two ratios $A : B : C$ [cf. the similar equations (45.13) and (45.14)].

THE COMPONENTS OF THE THREE-DIMENSIONAL STRAIN TENSOR IN ORTHOGONAL CURVILINEAR COORDINATES

The formulas (4.26) and (4.28) for the strains ϵ_{ii} and ϵ_{ik} simplify considerably if instead of the displacements δq , which have the dimensions of a length, the associated variations of the coordinates δp are introduced; the latter do not, in general, have uniform dimensions; e.g. in the case of polar coordinates, the quantities δp are (in part) angular changes. On substituting in (4.26) and (4.28) for the δp_k according to Eq. (4.19) $\delta q_k = g_k \delta p_k$ and carrying out the differentiations $\partial \delta q_i / \partial p_i$ one obtains directly

$$(1) \quad \epsilon_{ii} = \frac{\partial \delta p_i}{\partial p_i} + \frac{\delta p_\alpha}{g_i} \frac{\partial g_i}{\partial p_\alpha},$$

$$(2) \quad 2\epsilon_{ik} = \frac{g_i}{g_k} \frac{\partial \delta p_i}{\partial p_k} + \frac{g_k}{g_i} \frac{\partial \delta p_k}{\partial p_i}.$$

The second term in the right member of Eq. (1) symbolizes the sum of the terms that are obtained by putting $\alpha = 1, 2, \dots, n$, in accordance with the following summation convention introduced by Einstein: a Greek¹ character that occurs twice in one term is to be considered as a summation index. Since we operate in three-dimensional space, the second term on the right side of Eq. (1) stands for

$$\sum_{\alpha=1}^3 \frac{\delta p_\alpha}{g_i} \frac{\partial g_i}{\partial p_\alpha}.$$

To simplify the notation further we shall denote the variation of the coordinate, δp_i , by ξ^i . This we do in accordance with the general conventions of tensor calculus, where superscripts indicate contravariant and subscripts covariant components of a vector. With these changes Eq. (1) reads

$$(1a) \quad \epsilon_{ii} = \frac{\partial \xi^i}{\partial p_i} + \frac{\xi^\alpha}{g_i} \frac{\partial g_i}{\partial p_\alpha} = \xi^i_{;i}.$$

¹By restricting the indices of summation or dummy indices to Greek letters one avoids confusing ϵ_{ii} or the later occurring $\xi^i_{;i}$ with the first scalar or spur of the corresponding tensors. Without this or a similar restriction the notations of tensor calculus are likely to mislead the student, however concise or convenient they may be.

The *subscript* that occurs here in the symbol $\xi^i_{;}$ is used to denote the *covariant derivative* of the contravariant vector ξ^i with respect to the coordinate p_i (note that the position of the subscript indicating the differentiation is shifted to the right; in this way a definite order of the indices is established). Vector components are called *contravariant*² if they transform in the same way as the coordinate differentials dp_i ; covariant vector components transform conversely to the differentials in the sense that the matrix of the transformation $\xi^i \rightarrow \xi_i$ is the inverse of the matrix of the transformation $dp_i \rightarrow dp'_i$. The differential quotients of a scalar point function with respect to the coordinates form examples of covariant vector components (gradient of a scalar). The same is *not* true for the differential quotients of a vector like $\partial \xi^i / \partial p_i$. The latter quantity must be augmented by the sum over α that appears in (1a) in order to become a covariant derivative.

We shall first verify that the factor that goes with ξ^α in (1a) is a special case of what is generally called a Christoffel symbol³ (of the second kind).

The general definition of this symbol (for arbitrary coordinates x_1, x_2, x_3) is

$$(3) \quad \{\mu\nu, \sigma\} = \frac{1}{2} g^{\sigma\lambda} \left(\frac{\partial g_{\mu\lambda}}{\partial x_\nu} + \frac{\partial g_{\nu\lambda}}{\partial x_\mu} - \frac{\partial g_{\mu\nu}}{\partial x_\lambda} \right),$$

where $g_{\alpha\lambda}$ are the covariant components of the metric tensor. In the case of orthogonal coordinates to which we restrict ourselves in the following, we have

$$g_{ik} = \delta_{ik} g_i g_k, \quad g^{ik} = \frac{\delta_{ik}}{g_i g_k}$$

(for the definition of δ_{ik} cf. p. 10). It is now easy to verify that in this case

$$(3a) \quad \{\alpha i, i\} = \frac{1}{g_i} \frac{\partial g_i}{\partial p_\alpha},$$

²The terms contravariant and covariant were introduced by Einstein to replace the terms *cogredient* and *contragredient* (respectively) which had been used before. It will be noticed that for reasons of consistency the coordinates and their differentials should also be written with superscripts, that is, p_i and dp_i should be replaced by p^i and dp^i respectively; this notation has actually been adopted by some authors.---The differential operation $\xi^i_{;}$ is covariant in the sense defined before, but we shall not prove that here, nor shall we prove formula (4) or the rule concerning the raising or lowering of indices. For these matters the reader is referred to the very careful although condensed representation by A. S. Eddington in his *Mathematical Theory of Relativity*, (Cambridge, 1923) and to *The absolute differential Calculus* by T. Levi-Civita, (engl. transl. London, 1927). Our Eqs. (3b) and (4) are derived in 20, Eq. (4) of Eddington's book.

³Instead of $\{\mu\nu, \sigma\}$ one often finds $\left\{ \begin{smallmatrix} \mu\nu \\ \sigma \end{smallmatrix} \right\}$; note also Einstein's symbol $\Gamma^{\sigma}_{\mu\nu}$.

which permits us to write instead of (1a)

$$(3b) \quad \xi^i_{;i} = \frac{\partial \xi^i}{\partial p_i} + \{\alpha i, i\} \xi^\alpha.$$

We supplement this by the general expression for the covariant derivative

$$(4) \quad \xi^i_{;k} = \frac{\partial \xi^i}{\partial p_k} + \{\alpha k, i\} \xi^\alpha.$$

In the present case $\{\alpha k, i\}$ is only different from zero for $\alpha = i$ and $\alpha = k$, therefore

$$(5) \quad \xi^i_{;k} = \frac{\partial \xi^i}{\partial p_k} + \frac{1}{g_i} \frac{\partial g_i}{\partial p_k} \xi^i - \frac{g_k}{g_i^2} \frac{\partial g_k}{\partial p_i} \xi^k.$$

One might think that the last expression represents the strain ϵ_{ik} [Eq. (2)], but this cannot be correct, since it is not symmetrical in the indices i and k . To satisfy the symmetry condition we have to consider the covariant vector ξ_i and its contravariant derivative $\xi^{i;k}$. The latter is obtained by lowering the superscript i and raising the subscript k in $\xi^i_{;k}$. In the case of an orthogonal line element these operations require only a multiplication by g_i^2 and division by g_k^2 . In this way we obtain from (5)

$$\xi^{i;k} = \frac{g_i^2}{g_k^2} \frac{\partial \xi^i}{\partial p_k} + \frac{g_i}{g_k^2} \frac{\partial g_i}{\partial p_k} \xi^i - \frac{1}{g_k} \frac{\partial g_k}{\partial p_i} \xi^k.$$

We finally interchange i and k , which is entirely a matter of notation, and obtain,

$$(6) \quad \xi^{k;i} = \frac{g_k^2}{g_i^2} \frac{\partial \xi^k}{\partial p_i} + \frac{g_k}{g_i^2} \frac{\partial g_k}{\partial p_i} \xi^k - \frac{1}{g_i} \frac{\partial g_i}{\partial p_k} \xi^i.$$

The last two terms in (6) are opposite in sign to the corresponding terms in (5), hence we obtain by adding (5) and (6)

$$\xi^i_{;k} + \xi^{k;i} = \frac{\partial \xi^i}{\partial p_k} + \frac{g_k^2}{g_i^2} \frac{\partial \xi^k}{\partial p_i}$$

or, after multiplication with g_i/g_k ,

$$(7) \quad \frac{g_i}{g_k} (\xi^i_{;k} + \xi^{k;i}) = \frac{g_i}{g_k} \frac{\partial \xi^i}{\partial p_k} + \frac{g_k}{g_i} \frac{\partial \xi^k}{\partial p_i}.$$

The right member of this equation agrees with the right member of (2) if one returns to the original notation $\delta p_i = \xi^i$, $\delta p_k = \xi^k$. In the notation of tensor calculus the strains are thus given by the representation

$$(8) \quad 2\epsilon_{ik} = \frac{g_i}{g_k} (\xi^i_{;k} + \xi^{k;i}),$$

which includes the representation (1a) when $i = k$:

$$(8a) \quad \epsilon_{ii} = \xi^i_{,i}$$

Note that the last two equations are in complete analogy with the original representation (1.11) in rectangular coordinates. This is in accordance with the general aim of tensor calculus in which one tries to introduce symbols and operational rules of such a nature that the equations written in curvilinear coordinates correspond as closely as possible to those written in Cartesian coordinates.

APPENDIX II

THE CONVECTIVE TERMS OF THE ACCELERATION VECTOR IN TENSOR NOTATION

From the contravariant displacement vector $\delta p_i = \xi^i$ (Appendix I) we pass now to the contravariant velocity vector $\delta p_i = v^i$; the general form of the contravariant vector of the material acceleration is

$$(1) \quad \frac{dv^i}{dt} = \frac{\partial v^i}{\partial t} + v^\alpha v^i_{,\alpha},$$

where the Greek index again indicates the summation with respect to α . This formula corresponds to the elementary vector equation

$$(2) \quad \frac{d\mathbf{v}}{dt} = \frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \text{ grad})\mathbf{v};$$

but (2) is only correct in Cartesian coordinates, while (1) is correct for any form of the line element and yields automatically the additional inertia terms that were computed in Problem III.1 in an indirect way for the case of cylindrical coordinates.

Let us take up this example once more to examine the structure of the convective terms $v^\alpha v^i_{,\alpha}$ for $i = 1, 2, 3$. With $p_1 = r$, $p_2 = \varphi$, $p_3 = z$ and $g_1 = 1$, $g_2 = r$, $g_3 = 1$ we have

$$(3) \quad v^1 = \frac{dr}{dt} = v_r, \quad v^2 = \frac{d\varphi}{dt} = \frac{v_\varphi}{r}, \quad v^3 = \frac{dz}{dt} = v_z.$$

According to Eqs. (3a, b) of Appendix I we calculate the first line and according to Eq. (5) the second and the third lines of the following table:

$$\begin{aligned}
 v^1_{,1} &= \frac{\partial v_r}{\partial r}, & v^2_{,2} &= \frac{\partial}{\partial \varphi} \frac{v_\varphi}{r} + \frac{v_r}{r}, & v^3_{,3} &= \frac{\partial v_z}{\partial z}, \\
 (4) \quad v^1_{,2} &= \frac{\partial v_r}{\partial \varphi} - v_\varphi, & v^2_{,1} &= \frac{\partial}{\partial r} \frac{v_\varphi}{r} + \frac{v_\varphi}{r^2}, & v^3_{,1} &= \frac{\partial v_z}{\partial r}, \\
 v^1_{,3} &= \frac{\partial v_r}{\partial z}, & v^2_{,3} &= \frac{\partial}{\partial z} \frac{v_\varphi}{r}, & v^3_{,2} &= \frac{\partial v_z}{\partial \varphi}.
 \end{aligned}$$

Multiplication of the terms of the $1^{st}(2^d, 3^d)$ column with those terms of (3) that have the same index α , and summation over α yield the $1^{st}(2^d, 3^d)$ component of the convective acceleration:

$$(5) \quad v^\alpha v^\alpha_{,\alpha} = \begin{cases} v_r \frac{\partial v_r}{\partial r} + v_\varphi \frac{\partial v_r}{r \partial \varphi} + v_z \frac{\partial v_r}{\partial z} - \frac{v_\varphi^2}{r} \\ \frac{1}{r} \left(v_r \frac{\partial v_\varphi}{\partial r} + v_\varphi \frac{\partial v_\varphi}{r \partial \varphi} + v_z \frac{\partial v_\varphi}{\partial z} + \frac{v_r v_\varphi}{r} \right) \\ v_r \frac{\partial v_z}{\partial r} + v_\varphi \frac{\partial v_z}{r \partial \varphi} + v_z \frac{\partial v_z}{\partial z} + * \end{cases}$$

In the second line the common denominator of all terms, $1/r$, has been factored out in preparation for the final equation of motion in Appendix IV.

Note again the "inertia terms" that have been placed in the fourth column:

$$-\frac{v_\varphi^2}{r}, \quad \frac{v_r v_\varphi}{r}, \quad *;$$

they are identical with those of Prob. III.1.

While only the first three terms are correctly obtained by applying the pseudo-vectorial operation $(\nabla \text{ grad})\nabla$ (cf. also the table on p. 347 where these terms have been indicated in the form $\mathbf{A} \cdot \text{grad } \mathbf{A}$, etc.), the present computation yields all four terms at once without discrimination. The correspondence between the "additional" terms on the one hand, the centripetal and half of the Coriolis acceleration on the other hand, was already pointed out.

If the same calculation is made in spherical coordinates r, ϑ, φ where $g_1 = 1, g_2 = r, g_3 = r \sin \vartheta$, one obtains instead of (3), (4), (5)

$$(3a) \quad v^1 = \frac{dr}{dt} = v_r, \quad v^2 = \frac{d\vartheta}{dt} = \frac{v_\vartheta}{r}, \quad v^3 = \frac{d\varphi}{dt} = \frac{v_\varphi}{r \sin \vartheta},$$

$$(4a) \quad \begin{cases} v^1_{,1} = \frac{\partial v_r}{\partial r}, & v^2_{,2} = \frac{\partial v_\vartheta}{r \partial \vartheta} + \frac{v_r}{r}, & v^3_{,3} = \frac{\partial v_\varphi}{r \sin \vartheta \partial \varphi} + \frac{v_r}{r} + \frac{\cos \vartheta v_\vartheta}{r \sin \vartheta} \\ v^1_{,2} = \frac{\partial v_r}{\partial \vartheta} - v_\vartheta, & v^2_{,1} = \frac{\partial v_\vartheta}{r \partial r}, & v^3_{,1} = \frac{\partial v_\varphi}{r \sin \vartheta \partial r}, \\ v^1_{,3} = \frac{\partial v_r}{\partial \varphi} - \sin \vartheta v_\varphi, & v^2_{,3} = \frac{\partial v_\varphi}{r \partial \varphi} - \frac{\cos \vartheta}{r} v_\vartheta, & v^3_{,2} = \frac{\partial v_\varphi}{r \sin \vartheta \partial \vartheta}. \end{cases}$$

$$(5a) \quad v^\alpha v_{;\alpha} = \begin{cases} \mathbf{v} \cdot \text{grad } v_r = \frac{v_\vartheta^2}{r} - \frac{v_\varphi^2}{r} \\ \frac{1}{r} \left\{ \mathbf{v} \cdot \text{grad } v_\vartheta + \frac{v_r v_\vartheta}{r} - \frac{\cos \vartheta}{r \sin \vartheta} \frac{v_\varphi^2}{r} \right\} \\ \frac{1}{r \sin \vartheta} \left\{ \mathbf{v} \cdot \text{grad } v_\varphi + \frac{v_r v_\varphi}{r} + \frac{\cos \vartheta v_\vartheta v_\varphi}{r \sin \vartheta} \right\}. \end{cases}$$

With $1/r$ and $1/r \sin \vartheta$ factored out (in the second and third line), the result shows the presence of the terms corresponding to the elementary vector formula $\mathbf{v} \cdot \text{grad } \mathbf{v}$. Let us again consider the additional "inertia terms": in the first line we find the ordinary centripetal accelerations $-v_\vartheta^2/r$ and $-v_\varphi^2/r$. The full value of the latter term that corresponds to the motion along the parallel of radius $r \sin \vartheta$ is $-v_\varphi^2/r \sin \vartheta$, but the component in r -direction is obtained by multiplying with $\sin \vartheta$ so that this factor cancels. In the second line we find the other component, which has the factor $\cos \vartheta$. We further recognize in the middle term of the second line and also in the last two terms of the third line one half of a Coriolis acceleration. We need not attempt to visualize these terms in a direct kinematic way, nor do we need the geometrical arguments that single out the components, since we trust the validity of the general formulations of tensor calculus.—It is, of course, possible to obtain the same result by vector analytic methods (cf. the table on p. 348).

APPENDIX III

THE TENSOR OF FRICTION PRESSURES AND ITS DIVERGENCE

The connection between the tensor of the friction pressure and the rate of strain is given by Eq. (10.2), $p_{ik} = 2\mu \dot{\epsilon}_{ik}$, when we restrict our

argument to incompressible fluids. To obtain i_{ik} , we differentiate Eq. (8) of Appendix I with respect to t and obtain

$$(1) \quad i_k = -\mu \frac{g_i}{g_k} (v_{,k}^i + v_k^i).$$

This equation expresses the friction pressure in terms of general tensor analysis (Eqs. (4) and (4a) of Appendix II can again be used for the particular cases of cyl. and sph. coordinates). In the equations of motion, however, the friction pressures do not occur individually, but as arguments of the "vector divergence" [cf. Eq. (10.5)]. In Cartesian coordinates, the latter could be transformed into the pseudo-vector $-\mu \nabla^2 \mathbf{v}$ of Eq. (10.8) (see problem I.4 for the correct form of $\nabla^2 \mathbf{v}$ in cylindrical coordinates). In order to carry out the corresponding computation in terms of general tensor calculus, we have to replace $\nabla^2 \mathbf{v}$ by the differentiation and subsequent contraction of the tensor $v_{,k}^i + v_k^i$ of Eq. (1), in other words, we have to carry out the operation

$$(2) \quad v_{,a}^{i;a} + v_a^{i;a}.$$

The dummy index α indicates here the summation as well as contravariant differentiation. The second term in (2) vanishes, however, when the summation is carried out as a consequence of the assumed incompressibility. The i^{th} component of the vector so obtained (we denote it in the following simply by $\text{Div}^i p$) is therefore

$$(3) \quad \text{Div}^i p = -\mu v_{,a}^{i;a}.$$

This calculation requires the contravariant differentiation of a tensor⁴ rather than a vector, which is dealt with in Eddington's book, loc. cit. §30. In the case of cylindrical coordinates one obtains on the basis of Eq. (4) Appendix II

$$(4) \quad v_{,a}^{i;a} = \frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial v_r^i}{\partial r} \right) + \frac{1}{r^2} \frac{\partial^2 v_r^i}{\partial \varphi^2} + \frac{\partial^2 v_r^i}{\partial z^2} - \frac{v_r^i}{r^2} - 2 \frac{\partial v_r^i}{r^2 \partial \varphi}.$$

The first three terms of the right member represent the ordinary Laplacian of Prob. I.3, p. 346f applied to v_r and may be denoted by $\nabla^2 v_r$;

⁴The formula in question is

$$v_{,kl}^i = \frac{Dv_{,k}^i}{Dx_l} = \frac{\partial v_{,k}^i}{\partial x_l} - \{kl, \beta\} v_{,\beta}^i + \{\beta l, i\} v_{,\beta}^i,$$

and, of course, $v_{,k}^{i;k} = g^{ik} v_{,k}^i$.

the last two terms are due to the fact that v_r is not a scalar but a vector component. *These terms and the corresponding terms in $v_{,a}^{1;\alpha}$ agree with those of Prob. I.4 as expected.* In the "Cartesian" component $v_{,a}^{3;\alpha}$ no such terms occur. Applying the same ∇^2 -operator to the other components we can write the result as

$$(5) \quad \begin{aligned} v_{,a}^{1;\alpha} &= \nabla^2 v_r - \frac{v_r}{r^2} - 2 \frac{\partial v_\varphi}{r^2 \partial \varphi}, & v_{,a}^{2;\alpha} &= \frac{1}{r} \left(\nabla^2 v_\varphi - \frac{v_\varphi}{r^2} + 2 \frac{\partial v_r}{r^2 \partial \varphi} \right), \\ v_{,a}^{3;\alpha} &= \nabla^2 v_z. \end{aligned}$$

Note that in the second equation $1/r$ has been factored out as in Appendix II.

In the case of spherical coordinates one obtains in the same way instead of (4)

$$(4a) \quad \begin{aligned} v_{,a}^{1;\alpha} &= \frac{1}{r^3} \frac{\partial}{\partial r} \left(r^2 \frac{\partial v_r}{\partial r} \right) + \frac{1}{r^3 \sin \vartheta} \frac{\partial}{\partial \vartheta} \left(\sin \vartheta \frac{\partial v_r}{\partial \vartheta} \right) + \frac{1}{r^3 \sin^2 \vartheta} \frac{\partial^2 v_r}{\partial \varphi^2} \\ &\quad - \frac{2}{r^3} \left(v_r + \frac{1}{\sin \vartheta} \frac{\partial}{\partial \vartheta} (\sin \vartheta v_\vartheta) + \frac{1}{\sin \vartheta} \frac{\partial v_\varphi}{\partial \varphi} \right). \end{aligned}$$

The first line is again the Laplacian $\nabla^2 v_r$ in the form valid for the present coordinates. The additional terms in the second line can be reduced if the condition of incompressibility is used. Giving $\nabla^2 v_\vartheta$ and $\nabla^2 v_\varphi$ the appropriate meaning and factoring out $1/r$ and $1/r \sin \vartheta$ as in Appendix II, Eq. (5a), we obtain

$$(5a) \quad \begin{aligned} v_{,a}^{1;\alpha} &= \nabla^2 v_r + \frac{2}{r^3} \frac{\partial}{\partial r} (r v_r), \\ v_{,a}^{2;\alpha} &= \frac{1}{r} \left[\nabla^2 v_\vartheta + \frac{1}{r^2} \left(2 \frac{\partial v_r}{\partial \vartheta} - \frac{v_\vartheta}{\sin^2 \vartheta} - \frac{2 \cos \vartheta}{\sin^2 \vartheta} \frac{\partial v_\varphi}{\partial \varphi} \right) \right], \\ v_{,a}^{3;\alpha} &= \frac{1}{r \sin \vartheta} \left[\nabla^2 v_\varphi + \frac{1}{r^2 \sin \vartheta} \left(2 \frac{\partial v_r}{\partial \varphi} - \frac{v_\varphi}{\sin \vartheta} + 2 \frac{\cos \vartheta}{\sin^2 \vartheta} \frac{\partial v_\vartheta}{\partial \varphi} \right) \right]. \end{aligned}$$

APPENDIX IV

THE EQUATIONS OF MOTION OF A VISCOUS INCOMPRESSIBLE FLUID IN CYLINDRICAL AND SPHERICAL COORDINATES

The general form of the Navier-Stokes equations for arbitrary coordinates is:

$$(1) \quad \rho \left(\frac{\partial v^i}{\partial t} + v^\alpha v_{;\alpha}^i \right) - \mu v_{;\alpha}^{i;\alpha} + (p + V)^i = 0.$$

The individual terms correspond exactly to the vector equation (16.1), provided we write the external force \mathbf{F} as the negative gradient of the potential energy V and collect the latter together with the pressure in one term. The notation $(p + V)^i$ in (1) means contravariant differentiation with respect to the i^{th} coordinate.

Eq. (1) presents an opportunity to point out a homogeneity law of tensor calculus that refers to the degree in which the individual indices occur. One sees that all terms of Eq. (1) are of degree $+1$ in the index i and of degree 0 in the index α , provided we count the occurrence of a certain index positive, if it is a superscript and negative if it is a subscript. It is this circumstance that requires the last term in (1) to be a contravariant differentiation, and is responsible for the factor $1/g_i$ that will occur later, when we pass over to the ordinary gradient operation. (Remember here that the derivative of a *scalar* with respect to x_i is in itself a covariant vector, as pointed out in Appendix I.) It should be kept in mind that v^i is the rate of change of the i^{th} coordinate, but not of the corresponding component of the path; likewise $\partial v^i / \partial t$ is the local acceleration of the coordinate which differs from the corresponding acceleration along the path by the factor $1/g_i$. The condition of incompressibility, $\text{div } \mathbf{v} = 0$, appears now in the form $v_{;\alpha}^\alpha = 0$; it has already been used in setting up the friction term in (1), cf. the simplification of Eq. (2) in Appendix III.

Eq. (1) is perfectly general and does not presume an orthogonal system of coordinates; the simplicity is lost, however, when Eq. (1) is spelled out for any particular system of non-Cartesian coordinates. Even if we assume an orthogonal line element, we should have to introduce the quantities g_i on which the Christoffel symbols depend that are implicitly present in (1). Thus it is hardly worthwhile to develop Eq. (1) in terms of general

orthogonal coordinates, and we shall give only the results for our two special cases:

Cylindrical coordinates.

We substitute expressions (5) of Appendix II for the convective terms and expressions (4) of Appendix III for the friction terms, and multiply the second component of Eq. (1) with the factor r that appears in the denominators of the second line of III.4 and II.5. The first and third terms in the second component of Eq. (1), viz.

$$\frac{\partial v^2}{\partial t} = \frac{\partial}{\partial t} \frac{v_\varphi}{r} \quad \text{and} \quad (p + V)^2 = \frac{1}{r^2} \frac{\partial(p + V)}{\partial \varphi}$$

are then transformed into the ordinary acceleration and the ordinary φ component of the gradient

$$\frac{\partial v_\varphi}{\partial t} \quad \text{and} \quad \frac{\partial(p + V)}{r \partial \varphi}.$$

Using again the appropriate (scalar) ∇^2 operating on the components of \mathbf{v} and the notation $\mathbf{v} \cdot \text{grad } v_i$ we obtain

$$\begin{aligned} & \rho \left(\frac{\partial v_r}{\partial t} + \mathbf{v} \cdot \text{grad } v_r - \frac{v_\varphi^2}{r} \right) \\ & - \mu \left(\nabla^2 v_r - \frac{v_r}{r^2} - 2 \frac{\partial v_\varphi}{r \partial \varphi} \right) + \frac{\partial(p + V)}{\partial r} = 0, \\ (2) \quad & \rho \left(\frac{\partial v_\varphi}{\partial t} + \mathbf{v} \cdot \text{grad } v_\varphi + \frac{v_r v_\varphi}{r} \right) \\ & - \mu \left(\nabla^2 v_\varphi - \frac{v_\varphi}{r^2} + 2 \frac{\partial v_r}{r \partial \varphi} \right) + \frac{\partial(p + V)}{r \partial \varphi} = 0, \\ & \rho \left(\frac{\partial v_z}{\partial t} + \mathbf{v} \cdot \text{grad } v_z \right) - \mu \nabla^2 v_z + \frac{\partial(p + V)}{\partial z} = 0. \end{aligned}$$

This must be supplemented by the condition of incompressibility $v_{,a}^a = 0$, viz.

$$(3) \quad \frac{1}{r} \frac{\partial}{\partial r} (r v_r) + \frac{\partial v_\varphi}{r \partial \varphi} + \frac{\partial v_z}{\partial z} = 0.$$

The corresponding calculation in *spherical coordinates* uses (II.5a) and (III.4a). We again have to multiply with the denominators factored out

in the second and third lines of these equations and obtain with the symbols ∇^2 and $\mathbf{v} \cdot \text{grad } v_i$, the meaning of which is now different, the following relation:

$$\begin{aligned} & \rho \left(\frac{\partial v_r}{\partial t} + \mathbf{v} \cdot \text{grad } v_r - \frac{v_\vartheta^2}{r} - \frac{v_\varphi^2}{r} \right) \\ & \quad - \mu \left(\nabla^2 v_r + \frac{2}{r^2} \frac{\partial}{\partial r} (rv_r) \right) + \frac{\partial(p+V)}{\partial r} = 0, \\ (2a) \quad & \rho \left(\frac{\partial v_\vartheta}{\partial t} + \mathbf{v} \cdot \text{grad } v_\vartheta + \frac{v_r v_\vartheta}{r} - \frac{\cos \vartheta}{r \sin \vartheta} \frac{v_\varphi^2}{r} \right) \\ & \quad - \mu \left(\nabla^2 v_\vartheta + \frac{2}{r^2} \left[\frac{\partial v_r}{\partial \vartheta} - \frac{v_\vartheta}{2 \sin^2 \vartheta} - \frac{\cos \vartheta}{\sin^2 \vartheta} \frac{\partial v_\varphi}{\partial \varphi} \right] \right) + \frac{\partial(p+V)}{r \partial \vartheta} = 0, \\ & \rho \left(\frac{\partial v_\varphi}{\partial t} + \mathbf{v} \cdot \text{grad } v_\varphi + \frac{v_r v_\varphi}{r} + \frac{\cos \vartheta}{r \sin \vartheta} \frac{v_\vartheta v_\varphi}{r} \right) \\ & \quad - \mu \left(\nabla^2 v_\varphi + \frac{2}{r^2 \sin \vartheta} \left[\frac{\partial v_r}{\partial \varphi} + \frac{\cos \vartheta}{\sin \vartheta} \frac{\partial v_\vartheta}{\partial \varphi} - \frac{v_\varphi}{2 \sin \vartheta} \right] \right) + \frac{\partial(p+V)}{r \sin \vartheta \partial \varphi} = 0. \end{aligned}$$

We add the condition of incompressibility $v^a_{;a} = 0$, viz.

$$(3a) \quad \frac{1}{r^2} \frac{\partial}{\partial r} (r^2 v_r) + \frac{1}{r \sin \vartheta} \frac{\partial}{\partial \vartheta} (\sin \vartheta v_\vartheta) + \frac{1}{r \sin \vartheta} \frac{\partial v_\varphi}{\partial \varphi} = 0.$$

The appearance of these equations is rather unsymmetric, although we have tried to write the inertia terms that accompany the ∇^2 expressions as uniformly as possible. The only perfectly symmetric form that can compete with the form of the Stokes-Navier equations in Cartesian coordinates is Eq. (1) itself.—It cannot be denied that the calculation of the foregoing results by tensor methods is rather involved; the elementary, vector methods of Prob. I.4 and III.1 yield the same results more quickly. In more general cases, however, such as the oblique four-dimensional coordinates indispensable in the general theory of relativity, there is no other method available but that of tensor calculus.

PREFACE

Heinrich Hertz's great paper on the "Fundamental Equations of Electrodynamics for Bodies at Rest" has served as model for my lectures on electrodynamics ever since my student days (see §1). Following this example I proceed in Part I from Maxwell's equations as an axiomatic basis, expressed not as with Hertz, in the coordinates and in differential form, but in vectorial integral form. In Part II the several classes of phenomena, in static, stationary, quasistationary, and rapidly variable fields, are derived from these equations, as in Hertz's paper. After I had heard Hermann Minkowski's lecture on "Space and Time" in 1909 in Cologne, I carefully developed the four-dimensional form of electrodynamics as an apotheosis of Maxwell's theory and at the same time as the simplest introduction to the theory of relativity; in return, this has always met with an enthusiastic reception on the part of my audience. This four-dimensional electrodynamics is presented in Part III. Its title "Theory of Relativity and Electron Theory" requires the comment that it is limited to the *special* theory of relativity on the one hand and to the theory of the *individual* electron on the other. The statistics of electrons in metals and electrons in insulators belong in Vols. IV* and V* of the Lectures. Schwarzschild's principle of action, which establishes the fundamental relationship between Maxwell's theory and the dynamics of the individual electron (or individual electrons), is presented at the end of Part III with certain modifications which appear necessary from our point of view. In Part IV is developed the electrodynamics of moving media, again following Minkowski rather closely. As the most important application the fields of unipolar induction are discussed and are calculated as an exercise for a particularly simple example.

Part II constitutes the main portion of the Lectures. I distinguish between summation and boundary-value problems in electrostatics and magnetostatics. The computation of the electric potential for given charge distribution and the calculation of the magnetic potential for given magnetization are examples of the first; the theory of the permanent magnet, insofar as it falls within the competence of Maxwell's theory rather than atomic theory, becomes simple and clear from this standpoint. On the other hand, the solution of the electric and magnetic boundary-value problems properly belongs in Vol. VI; only the most important cases are treated in the present volume. The calculation of stationary fields for a given distribution of the current density, either by the method of the vector potential in §15 or that of the magnetic shell in §16, is also a simple summation prob-

* See p. xii for list of *Lectures on Theoretical Physics*.

lem. Among the rapidly variable fields those of the wire-wave type are treated with some completeness. The principal wave on a single wire in §22 (symmetric electrical type) serves as primary example; however, because of their recent practical applications (theory of wave guides in §24) and their utilization in the theory of the Lecher system, the magnetic type and the asymmetric secondary waves as well as wire waves on nonconductors are also dealt with in §23. As conclusion of Part II the Lecher system is treated fully for arbitrary separation and dimensions of the two parallel wires, employing bipolar coordinates for the exterior of the wires and ordinary polar coordinates for their interior. It is only assumed that the two wires are rather good conductors.

The dimensional character of the field entities is taken seriously throughout. We do not accept Planck's position, according to which the question of the real dimension of a physical entity is meaningless; Planck states in §7 of his *Lectures on Electrodynamics* that this question has no more meaning than that of the "real" name of an object. Instead, we derive from the basic Maxwell equations the fundamental distinction between entities of *intensity* and entities of *quantity*, which has heretofore been applied consistently in the excellent textbooks of G. Mie. The Faraday-Maxwell induction equation shows that the magnetic induction \mathbf{B} is an entity of intensity along with the electric field strength \mathbf{E} ; \mathbf{B} , rather than \mathbf{H} , deserves the name *magnetic field strength*. \mathbf{H} , like \mathbf{D} , is best designated as "excitation." $\text{div } \mathbf{H}$ represents the magnetic density, just as $\text{div } \mathbf{D}$ represents the electric charge density. Hertz's distinction between "true" and "free" electricity becomes pointless, since $\text{div } \mathbf{E}$ is, dimensionally, not a charge, but a divergence of lines of force. The same applies to the distinction between "true" and "free" magnetism, particularly since $\text{div } \mathbf{B}$ is everywhere zero. The current density \mathbf{J} , the electric polarization \mathbf{P} , and the magnetization \mathbf{M} , are entities of quantity like \mathbf{H} and \mathbf{D} . Energy quantities always take the form of products of an entity of quantity and an entity of intensity, e.g. $\frac{1}{2}\mathbf{D} \cdot \mathbf{E}$, $\frac{1}{2}\mathbf{H} \cdot \mathbf{B}$, $\mathbf{J} \cdot \mathbf{E}$, $\mathbf{E} \times \mathbf{H}$. The fact that \mathbf{B} and \mathbf{E} , and \mathbf{H} and \mathbf{D} , belong together follows unambiguously from the theory of relativity, in which the quantities $c\mathbf{B}$ and $-i\mathbf{E}$, and \mathbf{H} and $-ic\mathbf{D}$, respectively, are coupled together in a six-vector (antisymmetric tensor). We call the first the field tensor F , the second, the excitation tensor f .

The introduction of a *fourth electric unit*, independent of the mechanical units, is decisive for the fruitfulness of these dimensional considerations. We choose for this the unit of charge Q , which, as a matter of convenience we may identify with the coulomb if we wish. In this manner we avoid the "bed of Procrustes" of the cgs-units, in which the electromagnetic quantities are forced to take on the well known unnatural dimensions. Since we must definitely give up the hope of a mechanical interpretation of electrical quantities, we must regard the charge as a basic, irreducible entity which can claim a dimension of its own. We shall refer to the "electrostatically"

or "electromagnetically" measured charge only in passing, and exclusively for historical reasons. With the particular unit of charge $Q = 1$ coulomb the electric current has the customary unit amperes $= Q/\text{sec}$.

As mechanical units, following the suggestion of G. Giorgi, we shall employ the units meter M , kilogram (mass) K , and second S . The unit of energy then becomes 1 joule (without a power of ten as factor!) and that of power 1 joule $S^{-1} = 1$ watt. Furthermore, the powers of ten disappear also for the electric units volt, ohm, farad, and henry; we have 1 volt $= 1 \text{ joule}/Q$, 1 ohm $= 1 \text{ joule } S/Q^2$, 1 farad $= 1 Q^2/\text{joule}$ and 1 henry $= 1 \text{ joule } S^2/Q^2$.

On the other hand powers of ten must appear as factors when the units of the magnetic field strength B and the magnetic excitation H are expressed in terms of the gauss and the oersted, respectively, which as we shall see in §8, have been adapted to the cgs-system. As expected, the unit Q automatically drops out of the energy densities $\frac{1}{2}D \cdot E$, $\frac{1}{2}H \cdot B$, and $J \cdot E$ referred to above; their dimension becomes joule/ M^3 directly, whereas that of the energy flux $E \times H$ is joule/(M^2S).

With our dimensional differentiation between entities of intensity and entities of quantity the dielectric constant and the permeability evidently become *dimensional* quantities and therefore cannot be set equal to 1 in vacuum. Their choice, in which we accept electrical engineering practice, happily permits us to meet the demand for "rational units" without difficulty. It is only necessary to set,

$$\mu_0 = 4\pi \cdot 10^{-7} \frac{QS}{M}$$

in accord with international conventions, and to derive ϵ_0 from the relation $\epsilon_0\mu_0 = 1/c^2$, verified by Hertz's experiments. With this choice the 4π 's disappear wherever they do not belong, as in Poisson's equation and the energy expressions in Poynting's theorem, and appear where they belong, as in Coulomb's law and for the spherical condenser. We thus avoid the desperate expedient by which Lorentz achieves rationalization in his articles in the Enzyklopaedie, namely the introduction of the factor $\sqrt{4\pi}$ in the definition of the charge and of magnetism.

At the same time, with this choice of ϵ_0 and μ_0 , the square root of the ratio of μ_0 and ϵ_0 evidently becomes a resistance, namely the so-called "wave resistance of vacuum." This quantity occurs in Part II as a factor wherever the wave fields E and H enter into formulas of the same dimensions. It occurs again in the theory of relativity in the relation between the excitation tensor f and the field tensor F , which in vacuum assumes the simple form for all six components

$$f = \sqrt{\frac{\mu_0}{\epsilon_0}} F.$$

These questions of units, dimensions, and rationalization, often discussed to excess in recent years, are disposed of as briefly as possible in the lectures; however, the reader is repeatedly urged in them to convince himself of the dimensional logic of formulas. In numerical computations our MKSQ system of units is found convenient throughout since it is adapted to the practical and legal units, volt, ampere, etc. We leave the question open as to whether it is also appropriate for atomic physics. So as to permit an effortless transition to the Gaussian system ($\epsilon_0 = \mu_0 = 1$), which is customary in this case, we explain Cohn's system in §9, which in our interpretation is based on the five units MKSQP (P = magnetic unit pole).

The wonderful simplicity and beauty of the Maxwell equations, which is most striking in their relativistic formulation for vacuum, lead to the conviction that these equations, along with the equations of gravitation (§38), are the demonstration of an all-inclusive world geometry. Approaches to this by no means resolved problem are summarily discussed in §37. The amazingly simple representation of the general theory of relativity in §38 is based on a derivation of Schwarzschild's line element kindly made available to me by W. Lenz. In this manner the three tests of the theory open to astronomical observation may be treated without tensor calculus.

This volume is based on lecture notes prepared by H. Welker in the winter semester of 1933/34, at which time I first abandoned the cgs system and passed over to the more general system of the four units. In the final formulation of Parts I and II I have had the benefit of the constant advice of Professor J. Jaumann, whose electrotechnical experience and point of view have been of great advantage to this volume. I am grateful to Messrs. P. Mann and E. Gora and to my colleague F. Bopp for critical remarks and suggestions for improvements. Dr. W. Becker has kindly assisted me in reading the proof of this, as of preceding volumes.

Munich, April 1948

Arnold Sommerfeld

TRANSLATOR'S NOTE

A minimum number of changes has been made in this translation of Sommerfeld's "Elektrodynamik" (the third volume of the Lectures on Theoretical Physics) to adapt it for use in English-speaking countries. As far as possible, the same conventions regarding notation are employed as in G. Kuerti's translation of Volume II, "Mechanics of Deformable Bodies." Thus vectors are represented by bold-face letters, vector components and scalars (as well as tensors and their components) by italics; this in spite of the fact that the Gothic letters employed in the original text for both vectors and vector components were used even in Maxwell's Treatise. To avoid confusion a few additional changes of symbols were required in consequence of this major change.

E. G. R.

PART I

FUNDAMENTALS AND BASIC PRINCIPLES OF MAXWELL'S ELECTRODYNAMICS

§1. *Historical Review. Action at a Distance and Action by a Field*

I can best give you an idea of the sweeping changes in viewpoint brought about by the theory of Faraday and Maxwell by telling you of the time I spent as a student, 1887-1891.

My native city, Königsberg, was the earliest fountainhead of mathematical physics in Germany, thanks to the activity of the revered Franz Neumann, 1798-1894. At the University of Königsberg he taught, in addition to crystallography, theoretical physics which was not at the time given elsewhere in Germany. His students, of whom Gustav Kirchhoff of Königsberg was the most prominent, spread the teachings of the master to the other German universities. Through the seminar in mathematical physics, founded by him and C. G. J. Jacobi, he also saw to it that the East Prussian secondary-school teachers received a particularly thorough preparation. This may bear some relation to the fact that the Gymnasium in the Altstadt graduated the mathematician Hermann Minkowski and the physicists Max and Willy Wien shortly before my final examination, while at the same time the only slightly older David Hilbert and Emil Wiechert were attending other Königsberg schools. Neumann's greatest successes in research were achieved in the elastic theory of light and in the physics of crystals; his mathematical formulation of the induction currents discovered by Faraday will be discussed in §15. Simultaneously with Neumann and Jacobi, and almost outshining them, F. W. Bessel taught in Königsberg.

My time of study coincided with the period of Hertz's experiments. At first, however, electrodynamics was still presented to us in the old manner—in addition to Coulomb and Biot-Savart, Ampère's law of the mutual action of two elements of current and its competitors, the laws of Grassmann, Gauss, Riemann, and Clausius, and as a culmination the law of Wilhelm Weber, all of which were based on the Newtonian concept of action at a distance. The total picture of electrodynamics thus presented to us was awkward, incoherent, and by no means self-contained. Teachers and students made a great effort to familiarize themselves with Hertz's

experiments step by step as they became known and to explain them with the aid of the difficult original presentation¹ in Maxwell's Treatise.

It was as though scales fell from my eyes when I read Hertz's great paper:² "Über die Grundgleichungen der Elektrodynamik für ruhende Körper." Here Maxwell's equations, purified by Heaviside and Hertz, were made the axioms and the starting point of the theory. The totality of electromagnetic phenomena is derived from them systematically by deduction. Coulomb's law, which formerly provided the basis, now appears as a necessary consequence of the all-inclusive theory. Electric currents are always closed. Current elements arise only as mathematical increments of line integrals. All effects are transmitted by the electromagnetic field, which may be represented by force-line models. *Action at a distance* gives way to field action,³ the "constructable representation" of a space-time propagation postulated already by Gauss.⁴

I have held to the order of Hertz's paper in all my lectures on Maxwell's theory. In this presentation, too, we shall not begin with electrostatics, as is done so commonly and also in Maxwell's Treatise, but treat it merely as an extreme simplification of the general field theory. We shall deviate from Hertz only insofar as we shall start not from Maxwell's equations in differential form, but in integral form. It goes without saying that we shall replace the rather extensive coordinate calculations of Hertz by vector algebra, which is perfectly suited to the electromagnetic field. We shall see that this algebra, extended to four dimensions, leads directly to the special theory of relativity. The latter will provide an approach to the electrodynamics of moving bodies, which Hertz unsuccessfully sought to master in the second paper cited. In agreement with Hertz we see in Maxwell's *equations* the essence of his theory. We need not discuss the *mechanical pictures*, which guided Maxwell in the setting up of his equations. We have discussed one such picture in Vol. II, §15 of these lectures.

¹ The great student of electrolysis, Wilhelm Hittorf, who had heard much of the new theory of electricity, in advanced years attempted to study the Treatise, but was unable to find his way through the unfamiliar mass of equations and concepts. He was thus led into a state of deep depression. His colleagues in Münster persuaded him to take a vacation trip to the Harz Mountains. However when just before his departure they checked his luggage they found in it—the two volumes of the Treatise on Electricity and Magnetism by James Clerk Maxwell. (As told by A. Heidweiller.)

² Göttinger Nachr. March 1890 and Ann. Physik, Vol. 40; continued in Ann. Physik, Vol. 41: "Über die Grundgleichungen der Elektrodynamik für bewegte Körper."

³ We avoid the alternative term "near action" which signifies merely action at a small distance, and by our notation direct attention to the medium transmitting the effect, namely the field.

⁴ In a letter to Wilhelm Weber, of 1845. See Collected Works, Vol. V, p. 627.

Biographical Notes

MICHAEL FARADAY, 1791-1867

He was born as son of a blacksmith in impecunious circumstances. The family belonged to the pious sect of the Sandemanians, to which Faraday remained faithful to his death. His high ethical concept of life and human kindness derived from the religious spirit of his family. He was first newspaper carrier, then bookbinder. In science and letters he was entirely self-taught. The lectures of Sir Humphry Davy at the Royal Institution were decisive for his career; he wrote them up carefully and found an opportunity to present them to the great chemist. He became his laboratory assistant in the Royal Institution. His first important work was "the rotation of a current about a magnet and the rotation of a magnet about a current," and also the liquefaction of chlorine. This work brought about his election as Fellow of the Royal Society and later the indirect succession to Davy at the Royal Institution. In 1832 he began the publication of the "Experimental Researches." His discoveries recorded in these extend to the most diverse fields of physics, electrochemistry, and the study of materials. We mention as most significant for us: The discoveries of the law of electromagnetic induction in 1831, the dielectric constant, para- and diamagnetic behavior, and the picture of electric and magnetic lines of force. His magneto-optical discoveries are discussed in Vol. IV. The failing of his memory forced many pauses in his work, as well as the repetition of experiments made at an earlier date. It is uncertain whether this is to be attributed to mental overexertion or, as is commonly assumed today, to mercury poisoning in the poorly ventilated basement rooms of the Royal Institution. Certainly his purely intuitive method of working, devoid of any mathematical aid, required tremendous mental concentration. In his last years a restful summer retreat in the royal palace, Hampton Court, was made available to him at the suggestion of the Prince Consort, Albert. At his death there were found ninety-five honorary diplomas of learned societies, bound with his own hand.

JAMES CLERK MAXWELL, 1831-1879

He came from a prominent Scottish family (the father's name was Clerk, the added name Maxwell being derived from his mother) and was given the best in education that his time offered, both in the field of letters and that of science and mathematics. Thus, at an early date, he could translate Faraday's pictures of lines of force into a mathematical form which could be generally understood. See his paper of 1855 "On Faraday's Lines of Force" (translated into German by Boltzmann in Ostwald's *Klassiker* Nr. 69). In the preface to his Treatise he states: "Faraday, in his mind's eye, saw lines of force traversing all space where the mathematicians

(from the preceding discussion it is apparent that he refers particularly to Gauss, Wilhelm Weber, Riemann, Franz and Carl Neumann) saw centres of force attracting at a distance: Faraday saw a medium where they saw nothing but distance: Faraday sought the seat of the phenomena in real actions going on in the medium, they were satisfied that they had found it in a power of action at a distance impressed on the electric fluids. When I had translated what I considered to be Faraday's ideas into a mathematical form, I found that in general the results of the two methods coincided, . . . but that . . . several of the most fertile methods of research discovered by the mathematicians could be expressed much better in terms of ideas derived from Faraday than in their original form."

The *Traité* appeared in 1873. Its greatest achievement is the unification of optics and electrodynamics. The simplified form of the Maxwell equations, later rediscovered by Heaviside and Hertz, is to be found already in Part III of his paper for the Royal Society of 1864. Almost as important as his electromagnetic papers are those on the kinetic theory of gases (Maxwellian velocity distribution) and on general statistics, to which belongs also his theory of the rings of Saturn. He is also the author of purely mathematical papers (on cycloidal surfaces, the theory of the top, and the determination of magnitudes in Helmholtz's color triangle) and of an important paper on lattice structures (see Vol. II of these Lectures, p. 310).

After a brief teaching engagement in Aberdeen he became the first director of the newly founded Cavendish Laboratory in Cambridge; he died there at an early age.

ANDRÉ MARIE AMPÈRE, 1775-1836

We shall add a biographical note on Ampère not on account of the fundamental law already mentioned, nor because of the classical experiments, which enabled him to derive it with the simplest possible means, but for his discovery of the general relationship between the magnetic field and electric currents.

Born in Lyon, as a precocious boy he occupied himself with philological and mathematical studies. His father was a victim of the Revolution. Because of his mathematical papers he was named professor at the *École Polytechnique* in Paris in 1804. Here he soon directed his attention to chemistry, where he was able to compete with Avogadro in the field of atomism. There follow five years in which he is concerned primarily with psychology and metaphysics, though accepted as a mathematician into the Academy of Sciences of Paris. His interest in physics is not awakened until 1820, when he hears of Oersted's discovery. In a few weeks he verifies his belief that electricity in motion, and not electricity at rest, has a mag-

netic effect. The years 1820–1826 he spent elaborating his concept of the connection between the magnetic field and the electric current, which is equivalent to half of Maxwell's equations provided that the concept of the electric current is extended by the addition of Maxwell's displacement current. We shall hence denote this portion of the Maxwell equations (in integral form) in §3 directly as Ampère's law. From this point of departure Ampère recognized the equivalence of a solenoid traversed by current to a permanent magnet. The strengthening of the magnetic field by a soft-iron core placed in the solenoid is also to be attributed to him. Ampère may thus be regarded as the father of the "electromagnet." We may mention in addition Ampère's molecular currents and the elegant method of the magnetic sheet.

When, in 1826, however, Ampère obtained a professorship in physics at the Collège de France his interests changed once more: he returned to philosophy and logic and devoted himself finally to biology and comparative anatomy. Altogether a scientific career of extraordinary breadth and depth, of intensity and versatility! (This material has been taken from an essay by Louis de Broglie in his book *Continu et Discontinu*, Paris, 1941.)

HEINRICH HERTZ, 1857–1894

He was born in Hamburg the son of a respected merchant family; his father was in later years Senator of the Free City. Initially his great modesty prevented Heinrich Hertz from entering upon the career of a scholar; instead, he turned to engineering at the Technische Hochschule in Munich. Soon, however, he begged his father to permit him to transfer to pure physics. He studied first in Munich, then in Berlin, and became the favorite student and assistant of Helmholtz. The relationship between teacher and student was the closest imaginable and finds touching expression in the memorial addressed to him by Helmholtz (reprinted in Vol. I of Hertz's *Collected Works*). A prize problem set up by Helmholtz directed him to the testing of Maxwell's theory. After a short term as Privatdozent in Kiel he was called to the Technische Hochschule in Karlsruhe.

Even the earliest papers of Hertz show his mastery in relating theory and experiment. Several of them received the warm recognition of his colleagues, as his quantitative determination of hardness among engineers, and his description of the condensation processes in rising air currents among meteorologists. His years in Karlsruhe, from 1885 to 1889, represent the high point in his creative activity. We mention in particular his paper of 1888: "Forces of electrical oscillations treated by Maxwell's theory." It provides the characteristic solution now generally designated as the Hertzian vector and shows the familiar force-line pictures of the

Hertzian dipole. It is amazing how much of the later development of radio telegraphy has been anticipated in this paper. We should also point out the great paper on "Rays of electric force." The theoretical papers (basic equations of electrodynamics) have already been discussed.

The discovery of the photoelectric effect also falls into this period. With his last experimental paper of 1891 "On the passage of cathode rays through thin metal films" he reached beyond the problems set by Maxwell's theory and without knowing it, blazed the path to the electron theory. The very thin metal films later designated as "Lenard windows" are described already in this paper.

In 1889 he was called to Bonn. Here he prepared his last work, "Principles of Mechanics," which we have discussed in Vol. I, §39. The introduction of non-holonomic auxiliary conditions, the polydimensional treatment of mechanical systems of many degrees of freedom, the principle of the straightest path attest the keen logic and the geometric intuition of their author. Increasing illness prevented experimental work. He died on January 1, 1894, 37 years of age.

§2. *Introduction to the Basic Concepts of the Electromagnetic Field*

We regard the existence of electric charges as an established fact, whether we produce them by rubbing a piece of amber, the godparent of electricity, or recognize them from the spark when connecting the poles of a battery. We interpret the observed attraction, repulsion, and heat generation as the result of charges which have been produced. We take care not to define the charge verbally or to ascribe a derived dimension to it by some arbitrary procedure. Instead we regard it as having its own dimension, as an entity beyond the range of mechanics. We call this quantity Q . We could choose as unit of charge, whether negative or positive, the familiar universal charge of the electron. We prefer however to let Q stand for the coulomb, the accepted unit in the practical system, in terms of which the electron charge is expressed by $e = 1.60 \cdot 10^{-19}$ coulomb. We assume that electrometer apparatus is available with which we can compare different charges with each other and with the coulomb as unit of charge. The atomistic nature of charge is disregarded in the Maxwell theory proper. The charge of the atoms and elementary particles is to a much higher degree an absolute constant than the mass (see §27J).

In addition to the electric unit Q we normally employ as mechanical units of length, mass, and time the Giorgi units M (meter), K (kilogram mass), and S (second), which have been established internationally by the decision of the appropriate commissions. As already pointed out in Vol. I, p. 8, there is the advantage that in this system the units of energy and power correspond exactly (without multiplying powers of ten) to the joule and watt introduced previously in the cgs system. We designate them as

$$1 \text{ joule} = 1 \text{ M}^2\text{KS}^{-2} = 10^7 \text{ cm}^2 \cdot \text{g} \cdot \text{sec}^{-2} = 10^7 \text{ erg}$$

$$1 \text{ joule/S} = 1 \text{ M}^2\text{KS}^{-2} = 10^7 \text{ cm}^2 \cdot \text{g} \cdot \text{sec}^{-3} = 10^7 \text{ erg/sec} = 1 \text{ watt}$$

and define correspondingly

$$1 \text{ newton} = 1 \text{ MKS}^{-2} = 10^5 \text{ cm} \cdot \text{g} \cdot \text{sec}^{-2} = 10^5 \text{ dynes}$$

This unit of force "newton" is seen to be conveniently comparable in size with the practical unit of force, the "kilogram" = $9.81 \cdot 10^5$ dynes.

We will show presently that the annoying powers of ten vanish also for the practical units of the volt and ohm when the MKSQ system is employed.

We now proceed to examine in sequence the basic electromagnetic concepts. In most cases we shall be concerned with a dimensional description rather than with a complete definition; the latter will be derived from their interrelation through the basic equations of the theory, which can be tested by experiment. In the succeeding section we will follow directly the present day enumeration of the basic concepts.

We begin with the *electric fieldstrength*, for which a true definition is possible and is generally conventional. Let this quantity be denoted by E .¹ We define it as the mechanical force exerted in an electric field on an (infinitesimally small) test body, divided by the charge of the test body. E is therefore a vector with the dimension²

$$E = \frac{\text{Force}}{\text{Charge}} = \frac{\text{newton}}{Q}; \quad (1)$$

within the field it varies from point to point in direction and magnitude. In following everywhere the direction of E we describe an electric line of force.

We now consider the *line integral*

$$\int_A^B E_s ds = \int_A^B \mathbf{E} \cdot d\mathbf{s} \quad (2)$$

between two points A and B . E_s is the perpendicular projection of E on the direction of the line element ds and ds is the line element regarded as vector; $\mathbf{E} \cdot d\mathbf{s}$ denotes, as usual, the scalar product. We call this line in-

¹ Maxwell employed gothic letters (rather than bold-face letters) for the vectors of the electromagnetic field (see Vol. II of the Treatise, art. 618). Except for this distinction we use the symbols here given. J will denote the electric current density, I the total current in a wire.

² Here, and at many other points, we use the equality sign to indicate equality of dimension. Where, as in Eq. 2a, we wish to distinguish between actual numerical equality and mere dimensional equality, we write $= \dots$, i.e., "equal except for a numerical factor."

tegral the "voltage" V :

$$\begin{aligned} V &= \int_A^B \mathbf{E} \cdot d\mathbf{s} = \dots \frac{\text{newton} \cdot \text{M}}{Q} = \dots 10^7 \frac{\text{dyne} \cdot \text{cm}}{Q} \\ &= \dots 10^7 \frac{\text{erg}}{Q}. \end{aligned} \quad (2a)$$

The conversion of the dimension from the MKSQ- to the cgs-system shows that our unit of voltage is identical with

$$1 \text{ volt} = 10^8 \text{ cgs units} \quad (2b)$$

if, as decided above, we fix Q at

$$1 \text{ coulomb} = \frac{1}{10} \text{ cgs unit}. \quad (2c)$$

For the definition of the voltage it is necessary that in addition to the *terminal points* A, B , the path between them be prescribed. Only in lamellar fields (see Vol. I, Eq. 6.16, and Vol. II, p. 137) is the independence of the line integral with respect to the path guaranteed by Stokes' law (see Vol. II, Eq. 3.6). In place of voltage we may then speak of difference of potential between the two points A and B , designated by V_{AB} .

We introduce as companion to the fieldstrength \mathbf{E} a second electric vector \mathbf{D} . We shall call this preferably *electric "excitation,"* but shall also frequently employ, particularly in the first part of these Lectures, the customary term "*dielectric displacement*" (Maxwell's designation).

We make the introduction of \mathbf{D} comprehensible by the following consideration: Charge, in its historical origin, is a concept based on the notion of action at a distance. To adapt it to the viewpoint of action by a field it is necessary to imagine an excitation of the surrounding medium proceeding from the charge centers, which excitation will be described by the vector \mathbf{D} . For a single point charge e we imagine " \mathbf{D} lines" leaving e uniformly in all directions, with such density that the " \mathbf{D} -flux" becomes

$$\oint D_n d\sigma = e. \quad (3)$$

$d\sigma$ is an element of an arbitrary surface surrounding e . If, in particular, we choose a spherical surface of radius r , we find

$$4\pi r^2 D = e. \quad (3a)$$

For arbitrarily, including continuously, distributed charges, Eq. (3) is replaced by

$$\oint D_n d\sigma = \bar{e}, \quad \bar{e} = \sum e \quad (3b)$$

where $\bar{\epsilon}$ indicates the total charge within σ , the algebraic sum of positive and negative charges. We will see in §4 that this description of \mathbf{D} , for an arbitrary choice of σ , is selfconsistent, but does not suffice for a unique definition of \mathbf{D} . We will also see there that in the simplest case (isotropic medium, linear relation between \mathbf{D} and \mathbf{E}) the "D-lines" are identical with the lines of force defined by the \mathbf{E} vector.

From the preceding equations the dimension of \mathbf{D} is seen to be

$$\mathbf{D} = \frac{\text{charge}}{\text{area}} = \frac{Q}{M^2} \quad (4)$$

This dimension is entirely different from the dimension of the fieldstrength \mathbf{E} , given by Eq. (1). With regard to Maxwell's designation "dielectric displacement," we note that it fits strictly not the vector \mathbf{D} itself, but only that fraction of \mathbf{D} which arises from the presence of ponderable matter and which will later (see §11C) be designated as the *polarization* \mathbf{P} . Thus this portion \mathbf{P} vanishes for vacuum, the medium which is of greatest importance to us. Nevertheless the "displacement" \mathbf{D} retains its individual meaning, distinct from \mathbf{E} , in this case also.

We compare Eq. (4) with the dimension of the *electric current density* \mathbf{J} . One knows that this is to be defined as the quantity of electricity traversing unit area in unit time in a conductor. Its dimension is therefore

$$\mathbf{J} = \frac{\text{charge}}{\text{area} \cdot \text{time}} = \frac{Q}{M^2S} \quad (4a)$$

Depending on whether the unit area is placed perpendicular to the direction of the current or at an angle thereto, the absolute magnitude of \mathbf{J} or a component of it is obtained. \mathbf{J} is thus a vector similar in character to \mathbf{D} . Dimensionally, however, not \mathbf{D} , but the time rate of change of \mathbf{D} , the so-called *displacement current* $\dot{\mathbf{D}}$, corresponds to \mathbf{J} .

We have here assumed a sharp distinction between conductor and non-conductor (dielectric medium). Actually, no perfect insulator exists since even the best nonconductor conducts to some extent, e.g. under the influence of cosmic radiation. Maxwell therefore supplements the displacement current to form the total current

$$\mathbf{C} = \dot{\mathbf{D}} + \mathbf{J}; \quad (5)$$

the designation \mathbf{C} (current) was introduced by Maxwell. This notion of the equivalence of $\dot{\mathbf{D}}$ and \mathbf{J} is a basically new idea of Maxwell, which is a prerequisite for the unified representation of electromagnetic phenomena. Similarly, he supplements in the metallic conductor the conduction current \mathbf{J} by the addition of a hypothetical displacement current $\dot{\mathbf{D}}$, although here the first term completely outweighs the second.

We now pass to the *magnetic field*. This quantity exerts a mechanical

force on a magnetic pole P , which, to begin with, may be thought of as isolated. With the same letter P we designate also the strength of the magnetic pole and with P the as yet undetermined dimension "pole strength." The mechanical force divided by P we should most properly call the *magnetic field strength*. We will however, at least in the beginning, adhere to custom and call this quantity the *magnetic induction* B :

$$B \equiv \frac{\text{force}}{\text{pole strength}} = \frac{\text{newton}}{P}. \quad (6)$$

We shall even go a step further in our adherence to customary notions and utilize the relation between current and magnetism elaborated by Ampère, whose systematic description must however be postponed until §17. Thus, for example, the magnetic field of a plane circulating current I about the area F is, at a great distance from I , equal to the field of a bar magnet placed normal to F at I , with the moment

$$m = IF. \quad (6a)$$

This relation, which in the conventional cgs system serves to measure the current I "magnetically," we shall here employ to define the pole strength P in terms of our electric unit of charge Q . We set

$$m = \text{pole strength} \cdot \text{pole separation} = Pl \quad (6b)$$

and obtain from Eq. (6a)

$$P = I \cdot \frac{F}{l} = \frac{Q}{S} \cdot \frac{M^2}{M} = Q \frac{M}{S}. \quad (7)$$

Our dimensional equation (6) thus becomes

$$B = \frac{\text{newton}}{Q} \frac{S}{M}. \quad (8)$$

A complete description of the magnetic field also requires in addition to B a second vector which we shall designate with H . We cannot however adhere to the customary notation "magnetic field strength," which, as we have seen, rightfully belongs to the vector B , but will call H the *magnetic excitation*. We follow here the carefully thought-out representation of electrodynamics of Mie.¹ With the name magnetic excitation we place H in parallel with the "electric excitation" D . Corresponding to Eq. (4) we therefore define H dimensionally by

$$H = \frac{\text{pole strength}}{\text{area}} = \frac{P}{M^2}, \quad (9)$$

¹ Gustav Mie, *Lehrbuch der Elektrizität und des Magnetismus*, 2nd Ed., Enke, Stuttgart, 1941, and *Handbuch der Experimentalphysik* Vol. XI, Part 1, *Elektrodynamik*.

which, in view of Eq. (7), we may write

$$H = \frac{Q}{MS}. \quad (9a)$$

This representation also justifies a designation which is commonly employed in engineering and which, though rather awkward, is more appropriate than the unfortunate name "magnetic field strength," namely, the designation "ampere turns per unit length." For further details see the end of §4.

The direction of the field vector \mathbf{B} , varying from point to point, is represented by the form of the *magnetic lines of force*. As is well known, these are made evident by the automatic alignment of iron filings which are brought into the neighborhood of the magnet and were known long before the corresponding *electric* lines of force. Their expressive appearance still contributes greatly to the understanding of the field concept. Because of the equality of direction of \mathbf{H} and \mathbf{B} in air or any other isotropic medium the line patterns corresponding to the \mathbf{H} vector are identical with the lines of force of the \mathbf{B} vector.

We may indicate finally a subdivision of physical entities into entities of intensity and entities of quantity. \mathbf{E} and \mathbf{B} belong to the first class, \mathbf{D} and \mathbf{H} , to the second. The entities of the first class are answers to the question "how strong," those of the second class, to the question "how much." In the theory of elasticity, for example, the stress is an entity of intensity, the corresponding strain, one of quantity; in the theory of gases pressure and volume form a corresponding pair of entities. In \mathbf{D} the quantity character is clearly evident as the quantity of electricity that has passed through; in \mathbf{H} the situation is slightly obscured by the fact that there are no isolated magnetic poles (see §3). We are in general inclined to regard the entities of intensity as cause, the corresponding entities of quantity as their effect.

§3. Maxwell's Equations in Integral Form

After this very incomplete preparation we pass to the *axiomatic foundation of Maxwell's theory*. The axioms of electrodynamics, just as the Newtonian axioms of mechanics, rest on experience—more exactly on the ordering of the totality of experience into a simplified and idealized form. Thus the law of inertia of mechanics appears very different from what is observed in a particular case for terrestrial bodies. Similarly, our electromagnetic axioms are much more abstract and mathematically generalized than what is measured with coils, wires, and pointer instruments. Nevertheless like the mechanical axioms, they are simply a summary of diverse observations.

To begin with we set up two principal axioms which we shall then supple-

ment by secondary axioms. One of these we shall call *Faraday's law of induction*. We shall state it, as far as practicable, in Faraday's own line-of-force language. The other axiom we shall name after Ampère, since he was the first to formulate the relationship between current and magnetic fields. The fact that *Ampère's law* also rests on experience has been emphasized by its author.¹ We shall, however, state both axioms in the universal form whose possibility was first realized by Maxwell.

For this purpose we consider an arbitrary surface σ with the boundary curve s . We provide the latter with a pointer indicating sense of travel and shall define that direction of the normal to the surface as positive which forms a *right-handed screw* with the s -pointer. We compute the surface integrals

$$\int B_n d\sigma \quad \text{and} \quad \int C_n d\sigma \quad (1)$$

extended over σ and shall call them *magnetic flux* and *electric current flux*. *Number of lines of force* and *number of lines of current* is another common designation. This notation is of course audacious since these bundles of lines are not countable. It is first necessary to group them in "tubes," just as in Vol. II (p. 136) the lines of turbulence were grouped in tubes of turbulence. The tubes must be constructed so that their cross section becomes inversely proportional to the magnitude of B and C , respectively, at the point in question. The counting of the tubes of force or current traversing our surface then amounts to the same as the evaluation of the integrals (1).

Next we compute the following line integrals extended over the boundary curve s :

$$\oint \mathbf{E} \cdot d\mathbf{s} \quad \text{and} \quad \oint \mathbf{H} \cdot d\mathbf{s}. \quad (2)$$

We call these the *electric* and *magnetic loop tension*. The first has also for a long time been called E.M.F. or electromotive force; included in this designation, it is true, are also other "electromotive" causes, such as differences in temperature and chemical effects. The word "force" is here used in its antiquated meaning of energy.

The remarkable thing in Maxwell's point of view is that the E.M.F., which to the experimenter had had meaning only for closed metallic circuits, is here defined for arbitrary loops, whether they pass through conductors, nonconductors, or through parts of both. The same geometric freedom then exists also for the magnetic loop tension or magnetomotive force. We now write down the two principal axioms which relate the

¹ In the title of his comprehensive paper: *La théorie analytique des phénomènes électrodynamiques, uniquement déduite de l'expérience.*

quantities defined in Eqs. (1) and (2) in this completely general sense. They are:

$$\frac{d}{dt} \int B_n d\sigma = - \oint \mathbf{E} \cdot d\mathbf{s}, \quad (3)$$

$$\int C_n d\sigma = \oint \mathbf{H} \cdot d\mathbf{s} \quad (4)$$

In words: *Every change in the number of magnetic lines of force which traverse a given surface σ produces in its boundary s an electric loop tension which is numerically equal to the rate of change, but opposite in sign (Faraday's law of induction) and*

The number of electric current lines, which traverse an arbitrary surface σ is accompanied by a magnetic loop tension in the bounding curve s of σ which is equal to it in both magnitude and direction (Ampère's law relating magnetic field and electric current).

Let us convince ourselves first that this equating of electric and magnetic quantities is dimensionally proper. The two surface integrals defined in (1) (in spite of their dimensionally incorrect designation as *numbers* of force lines or current lines) have, according to (2.8) and 2.4a), the dimensions

$$\frac{\text{newton MS}}{Q} = \frac{\text{joule S}}{Q} \quad \text{and} \quad \frac{Q}{S}, \text{ respectively.}$$

According to (2.9a) the latter dimension agrees with the dimension of the line integral in (4). The time rate of change of the first expression yields joule/ Q , i.e. the dimension of an electric tension (expressible in volts), in agreement with the right side of Eq. (3). From this dimensional check our fundamentally different conception of \mathbf{B} and \mathbf{H} becomes apparent, and it is clear that our special introduction of the symbol Q for the dimension of charge is unavoidable.

Next we concern ourselves with the signs in Eqs. (3) and (4). They correspond to the rules of Lenz and Ampère. Ampère's rule is simply the right-handed screw rule, by which we correlated the positive normal of the surface σ with the sense of travel along the boundary s . The various rules of thumb commonly given in textbooks are merely specializations of our righthanded screw convention. To check Lenz's rule we imagine in Eq. (3) the boundary curve s to be realized by a wire loop, and the magnetic flux traversing the surface σ in the direction n as lines of force proceeding from the positive pole P of a bar magnet, the negative pole being assumed to be sufficiently far away. We bring (see Fig. 1) the bar magnet near to the wire loop and thus increase the magnetic flux, so that the left side of (3) becomes *positive*. Then, as shown by the equation, the line integral on the right side must become *negative*. The E.M.F. and the corresponding cur-

rent induced in the wire loop then form a left-handed screw with the direction of motion of the bar magnet. The magnetic field corresponding to the induced current is, on the other hand, represented, according to our right-hand screw rule, by the arrow P' in Fig. 1. The positive pole of this magnetic field thus points in the direction from which the positive pole P of the magnet approaches the loop: The two poles repel each other or the induced current *inhibits* the motion of the inducing magnet. This is the meaning of Lenz's rule: The appearance of the induced current opposes the disturbance of equilibrium produced by the motion of the bar magnet.

We emphasized above that the bounding curve s may be fixed quite arbitrarily; the same remark applies also for fixed boundary to the surface σ . If two different surfaces σ_1 and σ_2 are passed through the same curve s , the left sides of Eqs. (3) and (4) computed for σ_1 and σ_2 , must turn out to

FIG. 1. Lenz's rule.

be equal. This is equivalent to stating that they must vanish for the closed surface formed by σ_1 and σ_2 if the positive normal (n always pointing outward) is defined in a uniform manner. We realize this fact also from the following: We consider a closed surface σ with a boundary curve which has contracted to a point. This does not contribute to the line integrals in Eqs. (3) and (4). If we indicate the integration over the now unbounded surface with \oint , we thus obtain

$$\frac{d}{dt} \oint B_n d\sigma = 0 \quad \text{and} \quad \oint C_n d\sigma = 0; \quad (5)$$

by Eq. (2.5) the second equation may also be written

$$\oint J_n d\sigma + \frac{d}{dt} \oint D_n d\sigma = 0. \quad (5a)$$

More particularly, if the surface σ lies entirely in nonconducting material and is hence traversed by no conduction currents,

$$\frac{d}{dt} \oint D_n d\sigma = 0. \quad (5b)$$

The first equation (5) and Eq. (5b) state, in integrated form,

$$\oint B_n d\sigma = \text{const.}, \quad \oint D_n d\sigma = \text{const.}, \quad (6)$$

while the second Eq. (5) and Eq. (5a) show that the total electric current is always *closed* in Maxwell's theory: the quantities entering and leaving just compensate each other; the current lines traversing our surface σ form closed loops somewhere outside of it. Furthermore, the *magnetic* lines of force also are always closed. If a magnet (or electromagnet) is subdivided, north poles and south poles, which compensate each other as far as the total magnetic flux is concerned, are formed anew on every part. It follows that the constant in the first Eq. (6) *must be zero*, while in the second equation this constant is the algebraic sum \bar{e} of the charges e enveloped by the surface σ . According to the above this must be a *constant in time for a nonconductor*:

$$\oint B_n d\sigma = 0, \quad \oint D_n d\sigma = \bar{e}, \quad \bar{e} = \sum e = \text{const.} \quad (6a)$$

The first Eq. (6a) is a *supplementary axiom*, an addition to our principal axioms required by experience. The second Eq. (6a) agrees with our earlier Eq. (2.3b) and states the constancy in time of the charge in nonconductors. The D-lines and the E-lines coinciding with them geometrically originate at points of positive charge and end at points of negative charge. Eq. (5a) generalizing the second Eq. (6a), may be designated in hydrodynamic terminology as the *continuity equation of electricity*. If the definition of \bar{e} in Eq. (6a) is employed it takes on the form

$$\frac{d\bar{e}}{dt} + \oint J_n d\sigma = 0. \quad (6b)$$

This expresses the fact that the electricity within a surface σ may decrease as the result of flowing off through metallic portions of σ .

The first Eq. (6a) may be expressed, with Heriz, in the form: *There is no true magnetism*. In this statement one proceeds from the assumption, formerly regarded as obvious, that \mathbf{B} is the magnetic analogue of \mathbf{D} . From our standpoint, however, this analogue is \mathbf{H} , and not \mathbf{B} . We shall hence have to relate the definition of "magnetism," in particular of the pole strength P (see §7), not to \mathbf{B} but to \mathbf{H} .

We now apply the first Eq. (6a) to the neighborhood of the *boundary surface between two bodies of different magnetic properties* such as iron and air. Let the closed surface σ be the surface of a very flat prism (Fig. 2), whose height Δh is very small compared to the base Δf , and let this base lie for example in iron, while the parallel top side is in air. Eq. (6a) then

demands, with arbitrary accuracy in view of the arbitrary smallness of Δh ,

$$(B'_{n'} + B_n) \Delta f = 0. \quad (7)$$

Let B' refer, for example, to iron, B , to air. The normal (n' in iron, n in air) points outward on both surfaces Δf . Then, in view of Eq. (7),

$$B'_{n'} = -B_n \quad \text{and hence also} \quad B'_{n'} = B_n,$$

provided that now n denotes the same direction in both media. We have thus obtained a first *boundary condition* for the magnetic field: At the transition between two magnetically different media the *normal component of the induction is continuous*.

FIG. 2. Derivation of the continuity of B_n at the boundary between two media from the relation $\oint B_n d\sigma = 0$.

We will show that the same applies to the *tangential component of the excitation H*. For this purpose we consider a very small rectangular loop s (Fig. 3), with the height Δh normal to the boundary surface and the side length Δs parallel to it. Here we assume that $\Delta h \ll \Delta s$ so that in the limit $\Delta h \rightarrow 0$ the area $\Delta\sigma = \Delta h \Delta s$ vanishes. With the assumption that the current density parallel to the boundary surface, referred to in Eq. (4), does not become infinitely large¹ we obtain from Eq. (4):

$$0 = (H'_{s'} + H_s) \Delta s \quad (8)$$

so that

$$H'_{s'} = -H_s \quad \text{and hence also} \quad H_s = H'_{s'} \quad (8a)$$

where again s denotes the same direction in the two media.

From exactly the same figure and the same consideration for two electrically different media we are led from Faraday's law of induction to the conclusion that the *tangential components of the electric field strength E* are continuous along the boundary of the two media:

$$E'_{s'} = E_s. \quad (9)$$

¹ This limiting case is the normal one for good conductors at high frequencies. - Then H_s becomes discontinuous and B_n vanishingly small.

Nothing has been said regarding the *normal component* of \mathbf{E} . Furthermore, the continuity of the normal component of \mathbf{D} (unlike that of \mathbf{B}) is not required by Eq. (6a). For, if D_n has a discontinuity at the boundary of two electrically different media (e.g. glass and air) or at any other surface, we say that a surface charge is present on the surface. If we call this surface charge ω (dimension Q/M^2), the charge present in the prism in Fig. 2 for the transition to the limit $\Delta h \rightarrow 0$ is,

$$\bar{e} = \omega \Delta f. \quad (10)$$

thus by the consideration leading to Eqs. (7) and (7a), the second Eq. (6a) demands

$$(D'_n + D_n) \Delta f = \omega \Delta f, \quad (10a)$$

or, employing the same direction of the normal n :

$$D_n - D'_n = \omega. \quad (11)$$

Discontinuous behavior of the normal component of \mathbf{D} signifies that the boundary surface considered carries a surface charge; the magnitude of the discontinuity indicates the surface charge directly.

FIG. 3. Derivation of the continuity of H_s at the boundary between two media from the relation $\oint \mathbf{H} \cdot d\mathbf{s} = 0$.

Finally, we obtain from Eq. (6b) for the boundary surface between a conductor and a nonconductor by utilizing Fig. 2 and Eq. (10),

$$\frac{d\omega}{dt} + J_n = 0, \quad (12)$$

that is, a loss of surface charge if electric current is possible in the conductor. In electrostatics, where the interior of conductors is fieldfree ($\mathbf{D} = 0$, $\mathbf{J} = 0$), Eq. (12) is fulfilled identically and Eq. (11) takes on the special form

$$\omega = D_n. \quad (12a)$$

In the static field conductors bear a surface charge varying from point to point and given by the normal component of \mathbf{D} .

§4. The Maxwell Equations in Differential Form and the Material Constants of the Theory

We pass from the integral to the differential form by allowing the loops s in the integral form, and hence also the surfaces σ passed through them, to become arbitrarily small. If we call the latter $\Delta\sigma$ we can write in the limit:

$$\int B_n d\sigma = \Delta\sigma B_n, \quad \int C_n d\sigma = \Delta\sigma C_n. \quad (1)$$

Furthermore we recall the definition of the vector operation "curl" by the transition to the limit of a loop integral (Vol. II, Eq. 2.21). For our infinitesimal loops this leads to

$$\oint E_s ds = \Delta\sigma \text{curl}_n E, \quad \oint H_s ds = \Delta\sigma \text{curl}_n H. \quad (2)$$

We must form the time derivative of the first Eq. (1). We will here imagine the surface $\Delta\sigma$ to remain fixed, which obviously applies to media *at rest*, to which we shall confine ourselves initially. We then obtain

$$\frac{d}{dt} \int B_n d\sigma = \Delta\sigma \dot{B}_n, \quad \dot{B} = \frac{\partial B}{\partial t}. \quad (3a)$$

At the same time, using Eq. (2.5), we write Eq. (1) in the form

$$\int C_n d\sigma = \Delta\sigma (J_n + \dot{D}_n), \quad \dot{D} = \frac{\partial D}{\partial t}. \quad (3b)$$

With Eqs. (2) and (3a, b), cancelling the factor $\Delta\sigma$ which is common to all terms, as well as omitting the common index n , the principal axioms (3.3) and (3.4) lead to the two *vectorial differential equations*:¹

$$\dot{B} = - \text{curl } E \quad (4)$$

$$\dot{D} + J = \text{curl } H.$$

The universal importance and impressive beauty of these equations led Boltzmann² to quote: "Was it a god who wrote these lines . . ."

¹ Our second equation (4) is usually called the first set of Maxwell's equations, our first Eq. (4), the second set. We prefer the sequence of the text since in our presentation the intensity entities E and B were introduced first as being more readily interpreted. We can also point to §7, where electrostatics will result from the specialization of the first, magnetostatics, from the specialization of the second Eq. (4), in support of our order. Since it would be improper to treat magnetostatics ahead of the simpler electrostatics the numbering of the Maxwell equations which differs from ours appears unsuitable.

² Motto of the second volume of his "Vorlesungen über Maxwells Theorie der Elektrizität und des Lichtes," München 1893. Our formulation, which deviates slightly from Boltzmann's (vector in place of coordinate notation), clearly only serves to enhance the beauty and simplicity of the equations.

We complete them by the supplementary axiom (3.6a) for \mathbf{B} , and the relation between \mathbf{D} and the charge, contained in the same equation. We shall now regard the latter as continuously distributed in accord with our differential point of view. Thus, we shall not speak of point charges e , but of finite densities in space ρ , so that the infinitesimal charge

$$\Delta e = \rho \Delta \tau$$

is contained in an element of volume $\Delta \tau$ which approaches zero in magnitude. At the same time we recall the vector operation "divergence" and its representation (in Vol. II, Eq. 2.20) by the limit of a volume integral.¹ For our present purposes we write this representation

$$\lim \frac{1}{\Delta \tau} \oint B_n d\sigma = \text{div } \mathbf{B}, \quad \lim \frac{1}{\Delta \tau} \oint D_n d\sigma = \text{div } \mathbf{D}$$

and obtain for Eqs. (3.6a, b), omitting the factor $\Delta \tau$, their differential form:

$$\text{div } \mathbf{B} = 0, \quad (4a)$$

$$\text{div } \mathbf{D} = \rho, \quad (4b)$$

$$\frac{\partial \rho}{\partial t} + \text{div } \mathbf{J} = 0. \quad (4c)$$

Our Eqs. (4) and (4a, b, c) set up the framework into which the phenomena of electrodynamics must be fitted. But this framework is still *too wide*. Five vectors \mathbf{E} , \mathbf{D} , \mathbf{J} , \mathbf{B} , and \mathbf{H} occur in our equations, or altogether 15 unknown functions of time and space. (The scalar ρ is referred back to the vectors \mathbf{D} and \mathbf{J} by the Eqs. (4b) and (4c) respectively.) For their determination we have two vector equations (4), i.e., altogether only six differential equations. We must narrow down the framework to be able to fill it out with a unified electrodynamic model. The electromagnetic

¹ We contrast the volume divergence here introduced with the term *surface divergence*. Referring to Fig. 2 and the integration there carried out over a prism with a base Δf and vanishing height, we understand by this the result of the integration divided by Δf . According to Eq. 3.7 and with the meaning of the normals \mathbf{n} and \mathbf{n}' there given, the surface divergence of an arbitrary vector \mathbf{A} is:

$$A_{n'} + A_n; \quad (4d)$$

Eqs. 3.7a and 3.10a then state simply: *The surface divergence of \mathbf{B} vanishes, that of \mathbf{D} equals the surface charge.*

Similarly, we can contrast the volume curl with the *surface curl*. Referring to Fig. 3 and the integration over a rectangle of base Δs and vanishing height carried out in Eq. 3.8, we understand by the surface curl the result of the integration divided by Δs . The surface curl of an arbitrary vector \mathbf{A} is hence, according to Eq. 3.8,

$$A_{s'} + A_s; \quad (4e)$$

it represents the discontinuity of \mathbf{A} at the surface in question.

material constants serve this purpose. We shall discuss them in the sequence conductivity, dielectric constant, permeability.

1. Conductivity and Ohm's Law

The electric current density \mathbf{J} depends on the electric field strength \mathbf{E} within the conductor. We assume a linear dependence

$$\mathbf{J} = \sigma \mathbf{E} \quad (5)$$

and call the real positive constant σ the *electric conductivity*. Eq. (5) expresses *Ohm's law* for unit length of a wire carrying a stationary current. To recognize this, we replace \mathbf{J} by the total current $I = qJ$ (q = cross section of the wire) and multiply Eq. (5) with the length of the wire. We obtain

$$RI = V \cdot \begin{cases} R = \frac{1}{q\sigma} \\ V = lE = \int_0^l E ds = \text{voltage} \end{cases} \quad (5a)$$

The concept of voltage had been created already by Volta, while the concept of resistance was first introduced by Georg Simon Ohm in 1827. For us Ohm's law signifies the introduction of the material constant σ . According to Eq. (5) its dimension is:

$$\sigma = \frac{Q^2}{M^2 S \text{ newton}} = \frac{Q^2}{MS \text{ joule}} \quad (5b)$$

According to Eq. (5a) σ may also be designated as the reciprocal of the *specific electric resistance*, i.e. the resistance of a prism of the length $l = 1 M$ and of the cross section $q = 1 M^2$. The dimension of the resistance is by Eqs. (5a, b):

$$R = \frac{\text{joule S}}{Q^2} \quad (5c)$$

The unit of resistance in the practical system of units is the Ω (pronounced "ohm") = 10^9 cgs units. It is identical with the unit in our MKSQ system provided that we choose, according to our convention, Q equal to 1 coulomb = $\frac{1}{10}$ cgs unit. We then obtain

$$1 \frac{\text{joule S}}{Q^2} = 10^7 \frac{\text{erg sec}}{Q^2} = 10^9 \text{ cgs units} = 1\Omega. \quad (5d)$$

Ohm's law applies only to macrophysical events, not to Ampère's molecular currents, electron paths in atoms, Larmor precessions; cathode rays in vacuum tubes are also resistance-free electric currents.

2. Dielectric Constant

The displacement \mathbf{D} depends on the electric field strength \mathbf{E} at the point in question. We assume the dependence to be linear:

$$\mathbf{D} = \epsilon \mathbf{E} \quad (6)$$

and call the real positive constant ϵ the dielectric constant. Its dimension is, by Eqs. (2.4) and (2.1),

$$\epsilon = \frac{Q^2}{M \text{ joule}} \quad (6a)$$

We denote the dielectric constant of vacuum by ϵ_0 . It also is a definite quantity of the dimension (6a). The relation

$$\mathbf{D} = \epsilon_0 \mathbf{E}, \quad (6b)$$

valid for vacuum, was pointed out already in §2. Invariably $\epsilon > \epsilon_0$.

3. Permeability

A relation also exists between the two magnetic vectors \mathbf{H} and \mathbf{B} , which, as a first approximation, we shall also assume to be linear. We would like to write it in the form

$$\mathbf{H} = \mu' \mathbf{B},$$

since we regard \mathbf{H} as analogue of \mathbf{D} and \mathbf{B} as analogue of \mathbf{E} . However, we are unfortunately obliged to follow general usage and choose the form

$$\mathbf{B} = \mu \mathbf{H}. \quad (7)$$

The material constant μ is called *permeability* and has, according to Eqs. (2.8) and (2.9a), the dimension

$$\mu = \frac{\text{joule S}^2}{Q^2 M}. \quad (7a)$$

This introduction of μ , which is illogical in view of Eq. (6), leads to the obvious consequence that in later formulas, such as Coulomb's law, not μ , but its reciprocal μ' will take the place of ϵ . For vacuum we write

$$\mathbf{B} = \mu_0 \mathbf{H}; \quad (7b)$$

μ_0 also obviously has the dimension given in Eq. (7a). For *paramagnetic* bodies $\mu > \mu_0$, for *diamagnetic* bodies, $\mu < \mu_0$. Our formulas (5), (6), and (7) do not have the same degree of certainty and general validity as Maxwell's equations (4). This has long been known for the *ferromagnetic materials*, where a general functional relationship

$$\mathbf{B} = \mathbf{B}(H, T), \quad T = \text{absolute temperature}$$

takes the place of the linear relation (7). Rochelle salts¹ show a dielectric behavior similar to that of the ferromagnetic materials, exhibiting, like the latter, both saturation and hysteresis phenomena.

For paramagnetic materials deviations from linearity occur only at extremely high field strengths or extremely low temperatures. Deviations from the linearity of Ohm's law have been expected at very high field strengths; the failure of this law for superconductors is obvious. Furthermore the simple proportionality between corresponding vectors expressed by Eqs. (5), (6), and (7) is true only for isotropic bodies. In *crystals* the dependence is expressed instead quite generally by a *linear vector function* (see Vol. II, Eq. 1.10). The varied and interesting phenomena of crystal optics, which we shall treat in Vol. IV, rest on this fact.

On the other hand, the general field equations (4) apply also for anisotropic bodies. Beyond this, they appear to hold true even in the face of all new proposals of a *generalized* electrodynamics, proposals which are concerned with extremely strong fields (such as must occur, for example, close to an electron), but intrinsically amount merely to a replacement of the linear relation (6) by a generalized variation of \mathbf{D} with \mathbf{E} (see the final section of this volume). The deeper reason for the remarkable vitality of the form of equation discovered by Maxwell will be found to rest in its invariance properties, which will not, however, be taken up until Part III.

We can now undertake the required contraction of our electrodynamic framework. If, in particular, we employ for this purpose our simple linear relations and treat σ , ϵ , and μ as quantities independent of t (restriction to media *at rest*), we obtain by substituting Eqs. (5), (6), and (7) in Eq. (4):

$$\begin{aligned}\mu \frac{\partial \mathbf{H}}{\partial t} &= - \text{curl } \mathbf{E}, \\ \left(\epsilon \frac{\partial}{\partial t} + \sigma \right) \mathbf{E} &= \text{curl } \mathbf{H},\end{aligned}\tag{8}$$

i.e., six simultaneous differential equations of the first order for six unknowns, the 2 · 3 components of \mathbf{E} and \mathbf{H} . Thus we find ourselves presented with a well-defined mathematical problem.²

¹ Also known as Seignette salts. Seignette was the name of a pharmacist in the French fortress La Rochelle. We are here concerned with hydrated sodium potassium tartrate:

² We could of course also have written Eqs. (8) as relations between \mathbf{E} and \mathbf{B} , or also between \mathbf{D} and \mathbf{H} . However, the form in the text is the customary one and, in general, also the most convenient one.

At the same time the conditions (4a, b, c) take on the form

$$\operatorname{div}(\mu \mathbf{H}) = 0, \quad \operatorname{div}(\epsilon \mathbf{E}) = \rho, \quad (8a, b)$$

$$\operatorname{div} \left\{ \left(\epsilon \frac{\partial}{\partial t} + \sigma \right) \mathbf{E} \right\} = 0. \quad (8c)$$

Eq. (8a) is to be regarded as a restrictive supplementary condition on Maxwell's equations, Eq. (8b), as defining equation for ρ . Eq. (8c) is obtained by forming the divergence of the second equation (8). Its simplest solution results from setting the parenthesis $\{\}$ equal to zero; it is represented by the exponential function

$$\mathbf{E} = \mathbf{E}_0 \exp \left(-\frac{\sigma}{\epsilon} t \right), \quad \mathbf{E}_0 = \text{arbitrary function of space.} \quad (9)$$

We set

$$\frac{\epsilon}{\sigma} = T, \quad (9a)$$

and call T the *relaxation time of the conductor*. Its dimension is the second by Eq. (5a) and (6a), as must be the case, its magnitude for good conductors a very small fraction of a second. The field decays within the conductor everywhere in accord with this relaxation time and is known, provided that \mathbf{E}_0 is given.

We might continue with the already discussed conditions at the boundary between two electromagnetically different media. To use the differential form of the Maxwell equations, however, it would be necessary to regard the transition between the two media as continuous, i.e., to speak of a "boundary layer" rather than a "boundary surface." We will carry out this procedure in problem I.1, where we shall find that the derivation becomes less straightforward than in the Eqs. 3.7 to 3.12, which followed from the integral form of Maxwell's equations.

The same conclusion is reached in other problems distinguished by a particular symmetry: *The general development of Maxwell's theory must proceed from its differential form; for special problems the integral form may, however, be more advantageous.*

The following two fundamental problems, which will be treated also by the differential method in problem I.2 and I.3, are examples of this:

1. An infinitely long wire in the form of a circular cylinder is traversed by current distributed uniformly over its cross section. The return of the current may take place through a similarly traversed hollow cylinder which is coaxial with the wire. The magnetic excitation is to be determined within the wire, within the hollow cylinder, and in the region between them.

2. An infinitely long, tightly wound coil is traversed similarly by stationary current. The magnetic excitation is to be determined at any point within the coil.

Regarding 1: Let a be the radius of the wire, b and c , the inner and outer radius of the cylindrical return conductor. We introduce a right-handed coordinate system about the center line of the wire as z -axis. Let the current density have the direction of the positive z -axis in the wire, that of the negative z -axis in the return conductor. Let the total current be I and $-I$ respectively:

$$I = \pi a^2 J_z, \quad -I = \pi(c^2 - b^2) J_{-z}.$$

The symmetry of the problem indicates that \mathbf{H} is independent of φ and has the direction of increasing φ . We write $H_\varphi = H$ and carry out the line

FIG. 4. A straight wire carrying a stationary current and a hollow cylinder surrounding it as return conductor. The magnetic excitation $H_\varphi = H$ within the wire, in the air space between the two conductors, and in the return conductor.

integral of \mathbf{H} about any circle $r = \text{const}$ in any cross-section plane of the wire. Since the displacement current vanishes everywhere in view of the assumed stationary condition, we obtain

$$0 < r < a: \quad 2\pi r H = \pi r^2 J_z = \frac{r^2}{a^2} I, \quad H = \frac{r}{a} \frac{I}{2\pi a}, \quad (10)$$

$$a < r < b: \quad 2\pi r H = I, \quad H = \frac{I}{2\pi r} \quad (11)$$

$$b < r < c: \quad 2\pi r H = I + \pi(r^2 - b^2) J_{-z} = I \left(1 - \frac{r^2 - b^2}{c^2 - b^2} \right), \quad (12)$$

$$H = \frac{I}{2\pi r} \frac{c^2 - r^2}{c^2 - b^2}$$

$$c < r: \quad 2\pi r H = I - I, \quad H = 0. \quad (13)$$

The boundary conditions for \mathbf{H} at the surface of the wire $r = a$ and at the cylinder surfaces $r = b, c$ are satisfied automatically by Eqs. 10 to 13. The variation of H is plotted in Fig. 4.

Regarding 2: We use a right-handed system r, φ, z which has the center line of the coil as z -axis. For sufficient length of the coil and sufficiently close winding no magnetic lines of force penetrate to the exterior of the coil; the current I has the direction of increasing φ , the excitation \mathbf{H} that of increasing z . We shall show that $H_z = H$ is constant within the coil.

For this purpose we consider the rectangular loop, of length l in the z -direction, shown in Fig. 5. Its plane intersects the coil in $N_1 l$ points, where N_1 is the number of turns per unit length of the coil. Since $H_r = 0$ both

FIG. 5. The magnetic excitation \mathbf{H} within an infinitely long coil.

within and outside of the coil and $H_r = 0$ outside of the coil, only one side of the loop contributes to the line integral. We find

$$Hl = N_1 l I, \quad H = N_1 I. \quad (14)$$

The magnetic excitation within the coil is given by the "number of ampere turns per unit length" $N_1 I$. This explains the designation of H customary in engineering practice which was introduced on p. 12. The value of H given by Eq. 14 is independent of r , i.e. the same throughout the interior of the coil.

§5. Law of Conservation of Energy and Poynting Vector

Starting from Eqs. (4.4) we carry out a scalar multiplication of the first with \mathbf{H} , a scalar multiplication of the second with \mathbf{E} . We obtain as the sum of the two:

$$\mathbf{H} \cdot \dot{\mathbf{B}} + \mathbf{E} \cdot \dot{\mathbf{D}} + \mathbf{E} \cdot \mathbf{J} = \mathbf{E} \cdot \text{curl } \mathbf{H} - \mathbf{H} \cdot \text{curl } \mathbf{E}. \quad (1)$$

On the right-hand side we apply the transformation, valid for arbitrary vectors \mathbf{U}, \mathbf{V} :

$$\mathbf{V} \cdot \text{curl } \mathbf{U} - \mathbf{U} \cdot \text{curl } \mathbf{V} = \text{div}(\mathbf{U} \times \mathbf{V}).$$

We prove this relation most readily by utilizing the symbol "nabla operator"

$$\nabla = \frac{\partial}{\partial x}, \frac{\partial}{\partial y}, \frac{\partial}{\partial z}$$

(see Vol. II, footnote 1 on p. 23) and interpreting the divergence as scalar multiplication, the curl as vector multiplication with this vector:

$$\text{div}(\mathbf{U} \times \mathbf{V}) = \nabla \cdot (\mathbf{U} \times \mathbf{V}) = \nabla_U \cdot (\mathbf{U} \times \mathbf{V}) + \nabla_V \cdot (\mathbf{U} \times \mathbf{V}), \quad (2a)$$

$$\text{curl } \mathbf{U} = \nabla \times \mathbf{U}, \quad \text{curl } \mathbf{V} = \nabla \times \mathbf{V}. \quad (2b)$$

In Eq. (2a) the subscripts U, V indicate that the ∇ -differentiations are to be carried out only on the vectors \mathbf{U} and \mathbf{V} , respectively. Since the sequence of the vectors may be cyclically interchanged in the double products, Eq. (2a) may also be written

$$\begin{aligned} \text{div}(\mathbf{U} \times \mathbf{V}) &= \mathbf{V} \cdot (\nabla \times \mathbf{U}) + \mathbf{U} \cdot (\nabla \times \mathbf{V}) \\ &= \mathbf{V} \cdot (\nabla \times \mathbf{U}) - \mathbf{U} \cdot (\nabla \times \mathbf{V}). \end{aligned} \quad (2c)$$

Here the right side, in view of Eq. (2b), is the same as the left side of Eq. (2), so that Eqs. (2c) and (2) become identical. This proof of Eq. (2) is only an abbreviated form for the direct, but much more involved, calculation with rectangular coordinates x, y, z .

Let us now set $\mathbf{V} = \mathbf{E}$ and $\mathbf{U} = \mathbf{H}$ in Eq. (2) and introduce the abbreviation

$$\mathbf{S} = \mathbf{E} \times \mathbf{H}, \quad (3)$$

Then Eq. (1) becomes

$$\mathbf{H} \cdot \dot{\mathbf{B}} + \mathbf{E} \cdot \dot{\mathbf{D}} + \mathbf{E} \cdot \mathbf{J} + \text{div } \mathbf{S} = 0. \quad (4)$$

Eq. (4) is *Poynting's theorem*, \mathbf{S} , the *Poynting vector*. We shall show that \mathbf{S} is the *energy flux vector*.

We consider first the dimension of the individual terms of Eq. (4). The first two terms have, according to Eqs. (2.9a) and (2.8), and (2.1) and (2.4), respectively, the dimension

$$\frac{\text{newton}}{\text{M}^3\text{S}} = \frac{\text{joule}}{\text{M}^3\text{S}} = \text{energy per unit volume and unit time}. \quad (4a)$$

The third term has, as must be the case, the same dimension (see Eqs. (2.1) and (2.4a)). The dimension of Eq. (3) is, by Eqs. (2.1) and (2.9a),

$$\frac{\text{joule}}{\text{M}^2\text{S}} = \text{energy per unit area and unit time}. \quad (4b)$$

The operation div , which indicates a differentiation with respect to the space coordinates, yields for the dimension of the fourth term in Eq. (4) the same result.

We see that our *electrical unit* Q does not occur in (4a, b). It has *discreetly withdrawn from the company of the mechanical units MKS*. The same will be noted in many later dimensional considerations in which

we are dealing with purely mechanical quantities, which are independent of the choice of the electrical unit.

We pass to the physical interpretation of the individual terms in Eq. (4). It is simplest for the third term: this signifies the work done by the electric field on moving electric charge per unit volume and per unit time. It is generally converted into heat and is known as *Joule heat*. We designate it W_J , transferring the symbol W (work), which Maxwell generally employs for total energy, to *energy density*. Thus we obtain

$$W_J = \mathbf{E} \cdot \mathbf{J}. \quad (5)$$

We shall see right away that the two first terms of (4) are the time rate of change of the *magnetic* and *electric energy densities*; the latter are defined, in accord with Maxwell, by

$$W_m = \frac{1}{2} \mathbf{H} \cdot \mathbf{B}, \quad W_e = \frac{1}{2} \mathbf{E} \cdot \mathbf{D}. \quad (6)$$

By this definition the energy is *localized* in the field; a definite electric and magnetic energy content $W_e d\tau$ and $W_m d\tau$ is ascribed to every element of volume $d\tau$. This constitutes a first step in the adaptation of the energy concept to the ideas of field theory.

The factor 1/2 in the two defining equation (6) evidently points to a continuous generation of energy, comparable with the stretching of a spring. In accord with the pattern force \times increase in path length = intensity entity \times change in quantity entity, we obtain

$$W_e = \int \mathbf{E} \cdot d\mathbf{D},$$

which, for a linear relationship between \mathbf{E} and \mathbf{D} , reverts, in fact, to (6). The situation is slightly different for the magnetic energy. Here Poynting's theorem (4) directs us to start from

$$W_m = \int \mathbf{H} \cdot \dot{\mathbf{B}} dt = \int \mathbf{H} \cdot d\mathbf{B}. \quad (6a)$$

From the point of view of our general system (\mathbf{B} = intensity entity, \mathbf{H} = quantity entity) it would have seemed more reasonable to represent the energy density not by (6a), but by

$$W_m = \int \mathbf{B} \cdot d\mathbf{H}. \quad (6b)$$

For a linear relationship between \mathbf{H} and \mathbf{B} this of course leads again to Eq. (6); for a nonlinear variation, on the other hand, it leads to a result which differs from $\int \mathbf{H} \cdot d\mathbf{B}$, and is therefore *incorrect* by Poynting's theorem. From this we learn that work need not be expressible in the form intensity entity \times change in quantity entity.

G. Mie, who takes the same standpoint throughout in respect to the meaning of \mathbf{B} and \mathbf{H} as we do, on p. 467 of his excellent textbook cited in §2, points to the following mechanical analogue: a moving body carries with it, in unit volume, the momentum (intensity entity) \mathbf{p} . For its acceleration the force per unit volume $d\mathbf{p}/dt$ is required, and hence the work

$$\frac{d\mathbf{p}}{dt} \cdot d\mathbf{s} = d\mathbf{p} \cdot \mathbf{v} = \mathbf{v} \cdot d\mathbf{p};$$

This is a product of the type $\mathbf{H} \cdot d\mathbf{B}$, i.e. quantity entity \times change in an intensity entity.¹

In this representation the magnetic energy parallels the *kinetic* energy of mechanics. We shall meet the same correspondence in electron theory. Also in Helmholtz's analogy between vortices in fluids and electric currents the magnetic energy corresponds to the kinetic energy of the fluid. The same applies for our semielastic ether model in Vol. II, §15.

If we should refer to Maxwell in connection with Eqs. (6), we would find that in Maxwell's work the factor $1/2$ is replaced by $1/(8\pi)$, which from Maxwell has passed over into the major portion of the literature. It evidently lacks the simple logical basis of the factor $1/2$ and has only historical justification.

We must now belatedly give the proof that the quantities $\mathbf{H} \cdot \dot{\mathbf{B}}$ and $\mathbf{E} \cdot \dot{\mathbf{D}}$ occurring in (4) are identical with the time rates of change of the energy densities given by (6). For this purpose we deduce from (6)

$$\dot{W}_e = \frac{1}{2} \mathbf{E} \cdot \dot{\mathbf{D}} + \frac{1}{2} \dot{\mathbf{E}} \cdot \mathbf{D}. \quad (6c)$$

The two terms on the right are equal, to begin with, in an *isotropic* medium, where $\mathbf{D} = \epsilon \mathbf{E}$. They are also equal in an *anisotropic crystal*, where a "linear vector function" replaces the simple proportionality (see p. 22):

$$D_i = \sum_k \epsilon_{ik} E_k.$$

From this we calculate for the two expressions on the right side of (6)

$$\begin{aligned} \sum_i E_i \dot{D}_i &= \sum_i E_i \sum_k \epsilon_{ik} \dot{E}_k, & \sum_k \dot{E}_k D_k &= \sum_k \dot{E}_k \sum_i \epsilon_{ki} E_i \\ & & &= \sum_i E_i \sum_k \epsilon_{ki} \dot{E}_k \end{aligned}$$

¹ For the elementary relationship between \mathbf{p} and \mathbf{v} , i.e. $\mathbf{p} = M\mathbf{v}$, and for constant mass we have again $d\mathbf{p} \cdot \mathbf{v} = \mathbf{p} \cdot d\mathbf{v}$. However, for a mass varying with time, in particular, the velocity-dependent mass of relativity theory, this is not the case. Then the form $d\mathbf{p} \cdot \mathbf{v}$ of the text expresses the energy change uniquely.

The two expressions are equal to each other since, irrespective of the crystal symmetry¹

$$\epsilon_{ik} = \epsilon_{ki} \quad (6d)$$

It follows from (6c) that for the anisotropic case, as for the isotropic case,

$$\dot{W}_e = \mathbf{E} \cdot \dot{\mathbf{D}}. \quad (6e)$$

The same applies for the magnetic energy density both for the isotropic medium (proportionality between \mathbf{H} and \mathbf{B}) and for the magnetic crystal (linear vector function with $\mu_{ik} = \mu_{ki}$). Here also

$$\dot{W}_m = \frac{1}{2} \mathbf{H} \cdot \dot{\mathbf{B}} + \frac{1}{2} \dot{\mathbf{H}} \cdot \mathbf{B} = \mathbf{H} \cdot \dot{\mathbf{B}}. \quad (6f)$$

In view of (5) and (6e, f), (4) yields

$$\dot{W} + \text{div } \mathbf{S} = -W_J, \quad W = W_e + W_m. \quad (7)$$

In this form Poynting's theorem expresses the *energy balance* in the electromagnetic field. The Joule heat is recorded as a loss on the right side of the equation. The left side corresponds to the energy exchange between the volume element $d\tau$ in question and neighboring elements. This becomes even clearer if Eq. (7) is integrated over a given volume; then the application of Gauss's theorem leads to

$$\frac{\partial}{\partial t} \int W d\tau + \int S_n d\sigma = - \int W_J d\tau. \quad (7a)$$

The significance of \mathbf{S} as energy flux through the surface of the volume considered is now evident.

With the introduction of this concept Poynting passes beyond Maxwell's localization of the energy. We now learn not merely how much energy exists at any place, but also where it will go or (for the opposite sign of \mathbf{S}) from where it has come.

¹ This restriction on the otherwise arbitrary coefficients ϵ_{ik} is necessary in order that the work done on an element of volume, $\mathbf{E} \cdot d\mathbf{D}$, may be a complete differential. Otherwise the electric energy density would not be a characteristic function of the state, as we postulate for ideal solid bodies. (It is true that for certain known crystals hysteresis phenomena occur which make the notion of a quantity characteristic of this state illusory). Compare the quite analogous situation in the case of the elastic body, Vol. II, p. 72 and p. 288.

In the crystal W_e is a general positive form of the second order in the E_i , not a simple sum of squares as for the isotropic case. The notation in the text as scalar product is in any case conceptually preferable, particularly since it becomes necessary for \dot{W}_e , where \mathbf{E} and $\dot{\mathbf{D}}$ need not have the same direction even in the isotropic case.

In contrast with W_e and W_m , W_J is not a state function. The condition $\sigma_{ik} = \sigma_{ki}$ should hence apply, in the crystalline conductor, only for a particular crystal symmetry.

In the ideal nonconductor the right side of (7) vanishes, so that (7) takes on the form of the *hydrodynamic equation of continuity* (see Vol. II, Eq. (5.4)): W replaces the hydrodynamic density ρ , S replaces ρv . Continuing with this hydrodynamic analogy, we may say that even in the insulator the energy flows not like an incompressible but like a compressible fluid. In a conductor it is absorbed furthermore, in the measure in which heat is generated in any element of volume.

In optics S plays a dominant role as *ray vector*; the emission and irradiation of a given surface element $d\sigma$ is distinguished by the positive and the negative sign of S .

We know from mechanics that the law of conservation of energy is not only of fundamental importance physically, but is also highly useful mathematically as a first integral of the equations of motion. Something similar applies for our electrodynamic law of conservation of energy: From it may be derived the *uniqueness* of the integration of the Maxwell equations for given *initial condition* and suitably prescribed *boundary conditions* on the boundaries of the region considered.

As usual, the proof is indirect: We assume the existence of two solutions, form their difference, and deduce therefrom a contradiction.

Let the two solutions be E_1, H_1 and E_2, H_2 (by §4 the corresponding vectors D, B are then also known).

We put

$$E = E_1 - E_2, \quad H = H_1 - H_2. \quad (8)$$

In view of the *linearity* of Maxwell's Eqs. (4.8), E and H are solutions as well as E_1, H_1 and E_2, H_2 . Hence Poynting's theorem, e.g. in the form (7a), applies formally also for them. However, the quantities W, S, W_s , because of their *quadratic* character, are composed not merely of the corresponding quantities of the individual fields 1 and 2, but also of *mixed* terms involving 1 and 2. We show this for the quantity W , as example, assuming isotropy for the sake of brevity.

$$W_s = \frac{1}{2} E \cdot D = \frac{\epsilon}{2} E^2 = \frac{\epsilon}{2} (E_1 - E_2)^2, \quad (9)$$

or expanded

$$W_s = \frac{\epsilon}{2} E_1^2 + \frac{\epsilon}{2} E_2^2 - \epsilon E_1 \cdot E_2. \quad (9a)$$

The last expression on the right is the mixed term mentioned above, while the first two terms denote the electric energy of the individual fields 1 and 2. However, we shall not need this expanded form and shall refer below to the representation in (9). Now, including the quantity W_m and the case of anisotropic media in our consideration, we can say: The quan-

tity W in (7a) represents a *definitely positive* quadratic form, formed with the components of the difference field \mathbf{E} , \mathbf{H} . The same applies for the quantity W_j . Finally the quantity \mathbf{S} is (irrespective of the difference terms arising in its calculation) the vector product $\mathbf{E} \times \mathbf{H}$ formed by the difference fields.

Let the domain over which (7a) is integrated be composed of partial domains $a, b, \dots j, \dots$ with, in general, different material constants ϵ, μ, σ . We indicate this by replacing W and W_j by $\sum_j W$ and $\sum_j W_j$, which, according to the preceding, can, just like the individual W , *never become negative*. Consider now the term

$$\sum_j \int S_n d\sigma_j \quad (10)$$

which arises from (7a) in the same manner. Pairs of terms which refer to the same *inner* boundary surface cancel here because for them the S_n are equal and opposite—*opposite* because of the opposite direction of the normal n , *equal* because of the boundary conditions for the tangential components of the fields $\mathbf{E}_1, \mathbf{E}_2$ and $\mathbf{H}_1, \mathbf{H}_2$, from which follows the equality of the tangential components of the difference fields \mathbf{E}, \mathbf{H} and of the component of \mathbf{S} normal to the boundary surface. The sum (10) becomes, therefore, simply equal to the surface integral over the outer boundary of the region of integration

$$\int S_n d\sigma. \quad (10a)$$

Let the boundary condition to be prescribed for this outer boundary simply consist in the tangential component of either the electric or the magnetic field being given everywhere on it. For the difference field (8) this signifies that the tangential components of either \mathbf{E} or of \mathbf{H} vanish. In either case the vector product \mathbf{S} formed with them and, hence, the integral (10a) vanish also.

Now (7a) applied to our case takes on the form

$$\frac{\partial}{\partial t} \sum_j \int W d\tau_j = - \sum_j \int W_j d\tau_j, \quad (11)$$

or, integrated with respect to t :

$$\sum_j \int W d\tau_j \Big|_0^t = - \int_0^t dt \sum_j \int W_j d\tau_j. \quad (11a)$$

Here the right side is less than or at most equal to zero. The left side vanishes at the lower limit $t = 0$, since for prescribed initial values of the fields 1 and 2 $\mathbf{E} = 0$ and $\mathbf{H} = 0$ in every one of the domains j , so that $W = 0$ also. At the upper limit t , on the other hand, the left side of (11a) is, in

view of the meaning of W , certainly not negative; its least value is zero. Only then the inconsistency with the right side is resolved. For this value we must have for all $t > 0$

$$\mathbf{E} = 0, \quad \mathbf{H} = 0,$$

so that, by (8),

$$\mathbf{E}_1 = \mathbf{E}_2, \quad \mathbf{H}_1 = \mathbf{H}_2.$$

This proof of uniqueness satisfies any demand for rigor. An unrigorous proof may be deduced directly from the form of Eqs. (4.8). For these equations permit the determination of the change with *time* of \mathbf{E} and \mathbf{H} if their distribution in *space* is known at any one moment. This means in a sense: the values of \mathbf{E} and \mathbf{H} at the time $t + dt$ can be calculated from their values at the time t . This calculation is *unique* since the Maxwell equations are linear in \mathbf{E} and \mathbf{H} .

In the preceding we have confined ourselves to a finite closed domain. Physically the unlimited domain is of course of greater interest. The uniqueness of the integration problem can be proved here for the static case as in §10D. We will consider the significance of the Poynting vector for the unique formulation of the problem of waves along wires in §22.

§6. The Role of the Velocity of Light in Electrodynamics

It appears reasonable to eliminate \mathbf{H} from Eqs. (4.8) and to obtain in this manner a single vector equation for \mathbf{E} . For this purpose the operation curl is applied to the first Eq. (4.8), the operation $\mu\partial/\partial t$, to the second. Adding the two equations yields

$$\epsilon\mu \frac{\partial^2 \mathbf{E}}{\partial t^2} + \sigma\mu \frac{\partial \mathbf{E}}{\partial t} = - \text{curl curl } \mathbf{E}, \quad (1)$$

i.e., a linear differential equation of the second order in four coordinates of space and time.

We will convert this expression to a form which is more familiar to the mathematician. For this we utilize the general transformation (3.10) of Vol. II:

$$\text{curl curl } \mathbf{E} = \text{grad div } \mathbf{E} - \Delta \mathbf{E}. \quad (2)$$

As indicated there, this equation is to be applied with caution, since the Laplace operator Δ can, by its definition as div grad , only be applied to scalar quantities. Incidentally, (2) may also be derived from the well-known vector formula

$$\mathbf{A} \times (\mathbf{B} \times \mathbf{C}) = \mathbf{B}(\mathbf{A} \cdot \mathbf{C}) - \mathbf{C}(\mathbf{A} \cdot \mathbf{B}) \quad (2a)$$

by symbolic calculation with the nabla operator (see the beginning of §5), where it takes the form

$$\nabla \times (\nabla \times \mathbf{E}) = \nabla(\nabla \cdot \mathbf{E}) - (\nabla \cdot \nabla)\mathbf{E}. \quad (2b)$$

This is identical with Eq. (2), term for term. We consider similar vector formulas in Problem I.4.

Equation (1) is valid in any coordinates, curvilinear as well as Cartesian. On the other hand, Eq. (2), according to the above, is restricted to the Cartesian coordinates x, y, z and the components E_x, E_y, E_z , since only these may be treated as scalar quantities. With this restriction we find from (1) and (2)

$$\varepsilon_\mu \frac{\partial^2 \mathbf{E}}{\partial t^2} + \sigma_\mu \frac{\partial \mathbf{E}}{\partial t} = \Delta \mathbf{E} - \text{grad div } \mathbf{E}. \quad (3)$$

This can be further simplified if we specify that \mathbf{E} represents a solution for a medium of uniform dielectric constant and *free of charge*. Then Eq. (4.4b), with $\varepsilon = \text{const}$ and $\rho = 0$, becomes $\text{div } \mathbf{D} = \varepsilon \text{ div } \mathbf{E} = 0$. Thus the last term on the righthand side of Eq. (3) vanishes and Eq. (3) assumes the form of the wave equation:

$$\varepsilon_\mu \frac{\partial^2 \mathbf{E}}{\partial t^2} + \sigma_\mu \frac{\partial \mathbf{E}}{\partial t} = \Delta \mathbf{E}. \quad (4)$$

The same equation evidently applies, under similar restricting conditions, also for \mathbf{H} (as well as for \mathbf{D} and \mathbf{B}).

The first coefficient in (4) is, as can be read directly out of Eq. (4), the reciprocal square of a velocity. Correspondingly, we find from Eqs. (4.6a) and (4.7a):

$$\varepsilon_\mu = \frac{Q^2}{M \text{ joule}} \cdot \frac{\text{joule S}^2}{Q^2 M} = \left(\frac{M}{S} \right)^{-2}. \quad (5)$$

What is the meaning of this velocity? Maxwell's answer is: *It is the velocity of propagation of electromagnetic waves, which in vacuum is identical with that of light:*

$$(\varepsilon_0 \mu_0)^{-1} = c = (2.9978 \pm 0.0002) 10^8 \frac{M}{S} \sim 3 \cdot 10^8 \frac{M}{S}. \quad (6)$$

Even at an early date the velocity of light c , then denoted as "critical velocity," maintained an elusive existence in electrodynamics, as in the theorem of Wilhelm Weber and the numerous measurements of the ratio of an "electromagnetically" and "electrostatically" determined charge on a condenser (§16D). However the role of c in electrodynamics was first clarified by Maxwell's theory of light and Hertz's experiments.

If we pass from vacuum to an arbitrary electromagnetic medium, the velocity $(\epsilon\mu)^{-1/2}$ appearing in (5) signifies, according to Maxwell, the velocity of light (more precisely, the "phase velocity of the light") in a ponderable body characterized by ϵ and μ

$$(\epsilon\mu)^{-1/2} = v, \quad \frac{c}{v} = n = \text{refractive index.} \quad (7)$$

It is true that the statement (7) has by no means the same certainty as statement (6). For it does not account for dispersion phenomena and hence cannot even explain the prismatic colors. We will learn in Vol. IV how these are to be fitted into electromagnetic optics.

Eq. (6) is evidently a supplementation of Maxwell's theory derived from experiment, which establishes a relationship between the two material constants ϵ_0, μ_0 of vacuum. In the following section we will discuss how the constants are to be determined individually.

We now turn to the integration of Eq. (4) specialized for vacuum

$$\frac{1}{c^2} \frac{\partial^2 \mathbf{E}}{\partial t^2} = \Delta \mathbf{E} \quad (8)$$

with the auxiliary condition already made use of

$$\text{div } \mathbf{E} = 0. \quad (8a)$$

We seek, in particular, solutions of (8) which are independent of y and z . For purely periodic time dependence these represent monochromatic plane waves which advance along the x -axis. We shall show that they are necessarily transverse. In view of the assumed independence of y and z of the function Eq. (8a) reduces to

$$\frac{\partial E_x}{\partial x} = 0.$$

Equation (8) yields accordingly:

$$\frac{\partial^2 E_x}{\partial t^2} = 0. \quad (8b)$$

E_x would thus be a linear function of t , which is inconsistent with the periodic dependence on t . Hence $E_x = 0$. Thus we already note a decided advantage of electromagnetic optics over the old elastic optics. As we saw in Vol. II, §45, the latter could never get rid of the longitudinal component of the plane wave: Even if it was originally absent, a reflection or refraction would cause its appearance along with the transverse component. In contrast to this we have proved that the plane wave of the electromagnetic theory of light is necessarily transverse. We can designate Eq. (8a) as the condition of transversality.

If the wave has a single electrical component or, in the usual terminology, is plane polarized, we can take its direction of vibration¹ as the y -axis, so that, in addition to $E_z = 0$, also $E_x = 0$. Eq. (8) then becomes

$$\frac{1}{c^2} \frac{\partial^2 E_y}{\partial t^2} = \frac{\partial^2 E_y}{\partial x^2}. \quad (9)$$

The solution which is purely periodic in time is

$$E_y = a \cos(kx - \omega t + \alpha). \quad (10)$$

According to (9) the wave number k introduced here and the angular frequency ω are related by

$$\frac{\omega}{k} = c; \quad (10a)$$

in terms of the wave length λ and the period τ we have

$$k = \frac{2\pi}{\lambda}, \quad \omega = \frac{2\pi}{\tau}. \quad (10b)$$

Omitting the sign Re , denoting "real part of," we shall write (10) in a form which will prove more convenient for what follows:

$$E_y = A e^{ikx - i\omega t}, \quad A = ae^{i\alpha}. \quad (11)$$

This is permissible as long as we are dealing with linear relations, such as the Maxwell differential equations; in dealing with energetic quantities which are quadratic in the field components we must obviously return to real expressions such as (10).

We next investigate the magnetic component of the plane wave. It may be derived from the first vector equation (4.8), specialized for vacuum:

$$\mu_0 \frac{\partial \mathbf{H}}{\partial t} = - \text{curl } \mathbf{E}.$$

Since $E_z = E_x = 0$ and $\frac{\partial}{\partial y} = \frac{\partial}{\partial z} = 0$, this leads to

$$H_z = H_y = 0$$

and furnishes the following equation for H_x :

$$\mu_0 \frac{\partial H_x}{\partial t} = - \frac{\partial E_y}{\partial x} = - ikA e^{ikx - i\omega t}. \quad (12)$$

¹ It should be noted that we are here dealing with the direction of vibration of the electric field, not with the direction of any material displacement.

For purely periodic time dependence its integration with respect to t is carried out simply by dividing the right side by $-i\omega$. Accordingly,

$$\mu_0 H_z = \frac{k}{\omega} A e^{ikx - i\omega t} = \frac{1}{c} A e^{ikx - i\omega t},$$

and, in view of (6),

$$H_z = \sqrt{\frac{\epsilon_0}{\mu_0}} A e^{ikx - i\omega t}. \quad (13)$$

The dimension of the coefficient $(\epsilon_0/\mu_0)^{1/2}$ is that of a reciprocal resistance, i.e. Ω^{-1} . For, by (4.6a), (4.7a), and (4.5c),

$$\frac{\epsilon}{\mu} = \frac{Q^2}{\text{joule M}} / \frac{\text{joule S}^2}{Q^2 M} = \left(\frac{Q^2}{\text{joule S}} \right)^2 = \frac{1}{\Omega^2}. \quad (14)$$

$(\mu_0/\epsilon_0)^{1/2}$ is designated as "wave resistance of vacuum." We shall see in §18D that this quantity actually assumes the role of a resistance (voltage/current) in the telegraph equation.

FIG. 6. The relative orientation of \mathbf{E} , \mathbf{H} , and \mathbf{S} for a plane wave progressing in the x -direction.

Fig. 6 shows the orientation of \mathbf{E} and \mathbf{H} relative to each other and relative to the Poynting vector \mathbf{S} at a given instant. In this sequence they form a right-handed system. With increasing t the figure is displaced with the velocity of light in the direction of the positive x -axis. It may not be superfluous to point out that \mathbf{E} and \mathbf{H} become zero at the same point and attain their maxima at the same point. The situation differs from that of pendulum vibrations in mechanics, where the energy appears in turn in its kinetic and in its potential form.

For the experiments of Hertz and many optical experiments air and our vacuum are equivalent. A distinction between air and vacuum need only be made in high-precision wave-length determinations.

We have continually employed the term vacuum in preference to the term "ether" ("light ether"), which is frequently used elsewhere. This negative term appears to have more significance than the latter scholastic

word, which gives rise to false notions that cannot be reconciled with the theory of relativity.

We can indicate the material constants of ponderable bodies by their relative values referred to vacuum instead of by ϵ , μ , setting

$$\epsilon = \epsilon_{\text{rel}}\epsilon_0, \quad \mu = \mu_{\text{rel}}\mu_0. \quad (15)$$

ϵ_{rel} and μ_{rel} then are pure numbers, which in general do not differ greatly from 1. In a ponderable nonconductor Eq. (10a) must of course be replaced by

$$\frac{\omega}{k} = v = \frac{c}{n} \quad (16)$$

and Eq. (13) by

$$H_x = \sqrt{\frac{\epsilon}{\mu}} A e^{ikx - i\omega t} \quad (17)$$

Plane transverse waves are possible also in an absorbing medium ($\sigma \neq 0$). The general wave equation (4) is satisfied by the form (11), for given ω , by subjecting k to the condition generalizing Eq. (16):

$$k^2 = \epsilon\mu\omega^2 + i\sigma\mu\omega, \quad k = \sqrt{\epsilon'\mu}\omega, \quad \epsilon' = \epsilon + \frac{i\sigma}{\omega}. \quad (18)$$

ϵ' is the "complex dielectric constant" frequently employed in the optics of absorbing media. If the relaxation time introduced in (4.9a) is employed, we obtain

$$\frac{\epsilon'}{\epsilon} = 1 + \frac{i\sigma}{\epsilon\omega} = 1 + \frac{i}{2\pi} \frac{\tau}{T_r}. \quad (18a)$$

If $T_r \gg \tau$ the added imaginary term of k is merely a correction term; if $T_r \ll \tau$ the real and imaginary parts of k become equal (because $\sqrt{i} = (1+i)/\sqrt{2}$). In both cases the wave is damped exponentially as it progresses along the positive x -axis.

§7. The Coulomb Field and the Fundamental Constants of Vacuum. Rational and Conventional Units

On the basis of their time dependence we classify fields as *static*, *stationary*, *quasistationary*, and *rapidly varying fields*.

In *static fields* not only field and density variations, but also currents of electricity and energy are to be zero. Hence we demand

$$\dot{\mathbf{B}} = 0, \quad \dot{\mathbf{D}} = 0, \quad \dot{\rho} = 0, \quad \mathbf{J} = 0, \quad \mathbf{S} = 0.$$

According to Eqs. (4.4) and the succeeding equations these conditions are fulfilled if we set:

A. Electrostatics

$$\begin{aligned}\text{curl } \mathbf{E} &= 0, & \text{div } \mathbf{D} &= \rho \text{ in nonconductors,} \\ \mathbf{D} &= \mathbf{E} = 0 \text{ in conductors,} \\ \mathbf{H} &= 0 \text{ in all cases.}\end{aligned}\quad (1)$$

B. Magnetostatics

$$\begin{aligned}\text{curl } \mathbf{H} &= 0, & \text{div } \mathbf{B} &= 0 \text{ always,} & \text{but eventually } \text{div } \mathbf{H} &= \rho_m, \\ \mathbf{E} &= 0 \text{ in all cases.}\end{aligned}\quad (2)$$

An explanation of the "magnetic density" ρ_m here introduced will be given in connection with Eq. (9a) below

In *stationary fields* we retain the conditions $\dot{\mathbf{E}} = 0$, $\dot{\mathbf{D}} = 0$, $\dot{\rho} = 0$, but prescribe current fields \mathbf{J} in the conductors, which according to Eq. (4.4c) must be free of sources. The electric field must still satisfy, both within and outside the currents, $\text{curl } \mathbf{E} = 0$; on the other hand, $\text{curl } \mathbf{H} = 0$ only outside the currents.

In *quasistationary fields* we shall determine the fields as in the stationary case, but take account of their time dependence in the first approximation. The system of the Maxwell equations is fully utilized only for *rapidly varying fields*.

A. Electrostatics

We defer all problems requiring the use of the theory of functions. These are the *boundary-value problems* with conductors or nonconductors of different dielectric constant present in the field. We shall therefore deal first of all only with a *uniform dielectric*, so that we may set $\epsilon = \text{const.}$ In this case we are faced with a simple *summation problem* instead of a boundary-value problem.

Eqs. (1) then take the simpler form

$$\text{curl } \mathbf{E} = 0, \quad (3) \quad \text{div } \mathbf{E} = \frac{\rho}{\epsilon}. \quad (3a)$$

Eq. (3) states that \mathbf{E} may be treated as gradient of a *scalar potential*

$$\mathbf{E} = - \text{grad } \Psi, \quad (4)$$

which evidently brings about a substantial simplification of the problem of integration.

According to (3a) this potential must satisfy the *Poisson equation*

$$\Delta \Psi = - \frac{\rho}{\epsilon}. \quad (4a)$$

Lamellar field ($\text{curl } \mathbf{E} = 0$) and *potential field* ($\mathbf{E} = -\text{grad } \Psi$) have the same meaning; the surfaces $\Psi = \text{const.}$ divide the field into layers (lamellae), to which the lines of force are orthogonal. The line integral of the field strength

$$\int_A^B \mathbf{E} \cdot d\mathbf{s} = \Psi_A - \Psi_B \quad (4b)$$

is independent of the path; carried out over any closed path ($B = A$) it vanishes. The voltage V_{ab} is identical with the *potential difference*

$$\Psi_A - \Psi_B.$$

The summation problem mentioned above consists in the integration of Eq. (4a) and can be carried out directly with the aid of *Green's theorem*, for which we refer to Vol. II, §20, Nr. 1a. We obtain

$$4\pi\epsilon\Psi = \int \frac{\rho}{r} d\tau, \quad r = r_{PQ}. \quad (5)$$

P is the point at which Ψ is to be calculated, Q is the point of integration. The left side results from the integration over a small sphere surrounding the point $r = 0$, $Q = P$; the integral over the sphere bounding the region of integration externally vanishes provided that the total charge enclosed by this sphere is finite.

If the charge is not distributed in space, but concentrated on a surface or on a line, the mathematical method employed in (5) leads to

$$4\pi\epsilon\Psi = \int \frac{\omega}{r} d\sigma, \quad (5a)$$

$$4\pi\epsilon\Psi = \int \frac{\lambda}{r} ds; \quad (5b)$$

ω is the surface density, λ the line density (charge per unit length). A final step in this series leads us to the charge e concentrated in a point:

$$4\pi\epsilon\Psi = \frac{e}{r}, \quad (6) \quad \mathbf{E} = E_r = -\frac{\partial\Psi}{\partial r} = \frac{e}{4\pi\epsilon r^2}. \quad (6a)$$

This is the *Coulomb field*. We could also have read it off directly from Eq. (3a), which, using Gauss's theorem, we could integrate over a sphere of radius r described about the charge e . We obtain then directly

$$\oint \mathbf{E}_n d\sigma = \int \frac{\rho}{\epsilon} d\tau = \frac{e}{\epsilon}. \quad (6b)$$

In view of the spherical symmetry we must put $E_n = E_r = \text{const.}$ on the left, whereupon (6b) becomes in fact identical with (6a).

The Coulomb force F , with which two equal charges e at the distance r repel each other, follows from (6) according to our definition of field strength:

$$F = F_r = eE_r = \frac{e^2}{4\pi\epsilon r^2}. \quad (7)$$

It has been customary in the past to write instead, for vacuum conditions,

$$F = f \cdot \frac{e^2}{r^2} \quad \text{with} \quad f = 1. \quad (8)$$

Here F is supposed to be measured in dynes, r in centimeters. However, in this manner the whole structure of our system of dimensions is cast aside; we pass from our former system of dimensions to the so-called *electrostatic*¹ system of cgs units. The charge e would then, according to (8), take on the unnatural and ungainly dimensions

$$e = \sqrt{\text{dyn cm}^2} = \text{cm}^{3/2} \text{ g}^{1/2} \text{ sec}^{-1}. \quad (8a)$$

Furthermore the charge e would be 1 if two equal charges e at a distance of 1 cm would repel each other in air with a force of 1 dyne.

We must reject, on dimensional grounds, Hertz's distinction between "true charge density" expressed by $\text{div } \mathbf{D}$ and "free charge density" expressed by $\text{div } \mathbf{E}$. We shall designate the latter quantity correctly as "divergence of the lines of force"; in the preceding we have avoided it by writing ρ/e for it.

B. Magnetostatics

Although in most treatments the analogy between electrostatics and magnetostatics is emphasized, our approach compels us to point out clearly the differences as well.

As we saw in (2), it is not the *intensity* \mathbf{B} , but the *quantity* \mathbf{H} that is lamellar. We again denote the corresponding scalar potential by Ψ , distinguishing where necessary between Ψ_e and Ψ_m , and find

$$\mathbf{H} = - \text{grad } \Psi. \quad (9)$$

We shall call the quantity ρ_m defined above in Eq. (2) simply "magnetic density"; in view of the correspondence of \mathbf{H} and \mathbf{D} we can regard it as the direct analog of the electric density ρ .

How can we reconcile its existence, i.e. the Eq. $\text{div } \mathbf{H} \neq 0$ with the universally valid Eq. $\text{div } \mathbf{B} = 0$? This is only possible at points of local varia-

¹ The term *electrical system* seems to us to be preferable in principle to the customary term *electrostatic system*, since its application is not limited to equilibrium conditions, but may also be extended to electrodynamic processes. See §16D.

tion of permeability, as is shown by the following lines:

$$\begin{aligned}\operatorname{div} \mathbf{B} &= \mu \operatorname{div} \mathbf{H} + \mathbf{H} \cdot \operatorname{grad} \mu = 0 \\ \rho_m &= \operatorname{div} \mathbf{H} = \mathbf{H} \cdot \operatorname{grad} \log (\mu_0/\mu).\end{aligned}\tag{9a}$$

We will give a physical interpretation of this rather formal explanation of the concept of magnetic quantity and density by introducing the "magnetization" \mathbf{M} in §12. We have no reason for a distinction between "true" and "free" magnetism, such as was also given by Hertz. For, since we have already interpreted $\operatorname{div} \mathbf{H}$ as magnetic density, the differently dimensioned quantity $\operatorname{div} \mathbf{B}$ is not a magnetic density. Furthermore it is everywhere equal to zero.

We now return to (9) and form the divergence of the vectors on the left and the right. We then obtain the Poisson equation of magnetostatics, i.e.

$$\Delta \Psi = -\rho_m \tag{9b}$$

If ρ_m is given throughout this is integrated, in analogy to (5), by

$$4\pi\Psi = \int \frac{\rho_m}{r} d\tau, \tag{10}$$

or, in analogy to (5a), for given surface charge ω_m , by

$$4\pi\Psi = \int \frac{\omega_m}{r} d\sigma. \tag{10a}$$

If the density is concentrated on a point pole and if we call

$$p = \int \rho_m d\tau$$

the pole strength (an opposite pole is imagined to lie at infinity), (10) leads to

$$4\pi\Psi = \frac{p}{r}, \tag{10b}$$

$$\mathbf{H} = \mathbf{H}_r = -\frac{\partial \Psi}{\partial r} = \frac{p}{4\pi r^2}. \tag{10c}$$

This is the *Coulomb field* of the isolated magnetic pole. The Coulomb force, with which two poles of equal magnitude and the same sign repel each other, is, however, not $p\mathbf{H}$, but, according to our definition of the intensity \mathbf{B}

$$\mathbf{F} = \mathbf{F}_r = p\mathbf{B}_r = p\mu\mathbf{H}_r = \frac{p^2\mu}{4\pi r^2}. \tag{11}$$

The fact that μ appears here in the numerator, although ϵ , in (7) appears in the denominator, results evidently from the inconsistency, pointed out

in connection with Eq. (4.7); in the introduction of μ as compared with that of ϵ . (We would have liked to define the reciprocal of μ as the magnetic constant at that point.) In (11) μ evidently signifies the permeability of the surroundings of the magnetic pole p ; for air (vacuum) we put $\mu = \mu_0$.

Just as in connection with (8) we took cognizance of an electrostatic system of units and a unit of charge corresponding to this system, so we can introduce, on the basis of (11), a magnetic system of units and a corresponding unit of pole strength. To this end (11) is replaced, for vacuum in particular, (we follow the pattern of Eq. (7) and what follows literally) by:

$$F = f \frac{p^2}{r^2} \quad (12)$$

and f is put equal to 1; F is supposed to be measured in dynes, r in centimeters. Our former system of units is once more cast aside, and we pass over to the *Gaussian magnetic cgs system*.¹ In this system the pole strength p has, according to (12), the same unsatisfactory dimension as the charge e in the electrical system (8a). Unity pole strength would correspond to a repulsion with a force of 1 dyne of two poles of equal sign and magnitude separated by 1 cm (in air as surrounding medium).

C. Rational and Conventional Units

We must now deal with the factor 4π in Coulomb's law. It is true that this is much less fundamental than the question of dimensions and bears to the latter only a historical relationship. Historically the forms (8) and (12) of Coulomb's law result from an effort to approach as closely as possible the customary form of Newton's law. We shall denote the suppression of the numerical factor 4π in Coulomb's law as *conventional*, our retention of it as *rational*. It is in fact evident that in a problem with spherical symmetry, such as the Coulomb problem, the factor 4π is appropriate (this follows in particular from our argument in (6b)). If we wish to avoid this factor, we must rewrite Poisson's equation (4a) as well as the second of Eqs. (1) as follows:

$$\Delta\psi = -4\pi \frac{\rho}{\epsilon}, \quad \text{div } \mathbf{D} = 4\pi\rho. \quad (13)$$

The factor 4π would thus be improperly introduced into the fundamental equations of the Maxwell theory. Furthermore, the transparent expression (5.6) for the energy density would be distorted into

$$W_e = \frac{1}{8\pi} \mathbf{E} \cdot \mathbf{D}. \quad (14)$$

¹ The fact that Gauss employed mm instead of cm as unit of length is a superficial distinction.

Heaviside fought a life-long battle for the rational units. In this connection he pointed also to the expression for the capacity of a condenser (for details see §10, where the relationship with the expression for the energy density is also indicated): The *plate condenser* (area F , plate separation a) has, in rational and conventional units respectively, the capacity

$$K = \frac{F\epsilon}{a} \quad \text{and} \quad \frac{F\epsilon}{4\pi a}, \quad (15)$$

the *spherical condenser* (radius of sphere r , outer sphere imagined at infinity), the capacity

$$K = 4\pi\epsilon r \quad \text{and} \quad \epsilon r. \quad (15a)$$

We see that, with rational units, the factor 4π appears for the sphere, where it belongs; with conventional units it is missing for the sphere and appears for the plane condenser, where it does not belong.

Heaviside makes the following striking comparison: In passing from the measurement of distance to the measurement of area one might define as unit of area the area of a circle of radius 1. This would be logically possible. It would however lead to the strange result that a square with the side 1 would have the area $1/\pi$. Everyone would then say that π was at the wrong place. We said the same of the factor 4π in the formulas to the right in (15) and (15a).

D. Final Determination of the Fundamental Constants ϵ_0 , μ_0 in the MKSQ System

The viewpoint of the rational units together with the requirement of meaningful dimensions and adaptation to the legal units leads to a quite definite choice of the fundamental constant μ_0 of vacuum. For we can obtain agreement between Eq. (11), which is dimensionally correct in our sense, and Eq. (12) by requiring

$$\left[\frac{\mu_0}{4\pi} \right] \frac{\text{joule S}^2}{\text{Q}^2 \text{M}} = [f] \text{ cgs.} \quad (16)$$

$[f]$ is the numerical value of f in the cgs-system, which we wished to set equal to 1. The brackets on the left are the numerical value of the quantity $\mu_0/(4\pi)$ in our MKSQ-system; its dimension (see e.g. (4.7a)) is indicated. The conversion of these dimensions into the cgs-system follows from

$$\text{Q} = 1 \text{ Coulomb} = \frac{1}{300} \text{ cgs}, \quad \text{M} = 10^3 \text{ cm}, \quad \text{joule} = 10^7 \text{ erg.}$$

Accordingly

$$1 \frac{\text{joule S}^2}{\text{Q}^2 \text{M}} = 10^7 \text{ cgs.}$$

With $[f] = 1$ we thus obtain, after cancelling the dimensional factor cgs on both sides of (16)

$$\left[\frac{\mu_0}{4\pi} \right] = 10^{-7}.$$

We obtain hence, entering the dimensions:

$$\mu_0 = 4\pi 10^{-7} \frac{\text{joule S}^2}{\text{Q}^2 \text{M}} = 4\pi 10^{-7} \frac{\Omega \text{S}}{\text{M}}. \quad (16a)$$

Regarding the unit of resistance, $\Omega = \text{"ohm,"}$ here employed, see Eq. (4.5d).

We have thus determined one of the two fundamental constants of vacuum in such a manner that the demands stated above are satisfied. The numerical value of μ_0 so obtained, which is accurate to an arbitrary number of digits, shows clearly that our determination is not established by direct measurements, but by our choice of the unit of Q and is equivalent to the latter. The other fundamental constant ϵ_0 of vacuum follows then from the relation (6.6) which is supported by the sum total of the Hertzian experiments:

$$\epsilon_0 = \frac{1}{\mu_0 c^2} = \frac{10^7}{4\pi c^2} \frac{\text{M}}{\Omega \text{S}}. \quad (17)$$

If we substitute for c the approximate value $c = 3 \cdot 10^8 \text{ M/S}$ we find

$$\epsilon_0 \sim \frac{10^{-9}}{36\pi} \frac{\text{S}}{\Omega \text{M}}. \quad (18)$$

We can also write (17) in the form

$$4\pi c^2 \epsilon_0 = 10^7 \frac{\text{M}}{\Omega \text{S}}. \quad (18a)$$

Division of (16a) by (18) and taking the square root leads to the following value for the "wave resistance of vacuum," introduced with (6.14), in terms of the unit Ω :

$$\sqrt{\frac{\mu_0}{\epsilon_0}} \cong 120\pi\Omega \cong 377\Omega. \quad (19)$$

In the preceding we have disregarded the small differences between the velocity of light c and its approximate value $3 \cdot 10^8 \text{ M/S}$, as well as the difference between the "international" and the "absolute," i.e., the ideal, ohm. These differences, which concern only the higher decimals, are of course of great importance in precision measurements and have called forth, in the determination of the Ω in relation to the old Siemens unit,¹

¹ Resistance of a mercury thread 1 m long and 1 mm² in cross section at 0° C = 0.937 Ω .

the competitive efforts of the best experimenters (Kirchhoff, Lord Rayleigh, F. Kohlrausch etc.). They play no role, however, in the general theory.

In summary: Our form of the Maxwell equations is adapted to the rational choice of the units MKSQ, with the value (16a) for μ_0 taken over from the conventional Gaussian magnetic units. Below we shall use the numerical values (16a), (18), (19) only in specific numerical computations and not introduce them, as often happens in engineering literature, into the general theory. Instead we shall always take account of the dimensions of all quantities, also those of ϵ_0 , μ_0 , and thus make ourselves independent of the particular choice of $Q = 1$ Coulomb.

§8. Four, Five, or Three Fundamental Units?

A. Supplementary Note on Our System of Four Units

Our four units MKSQ are simply intended to translate Giorgi's idea (introduction of a separate electrical unit) into a form which is particularly convenient for the theory. It is basically indifferent whether the unit of charge Q is employed or a standard resistance R , as Giorgi has occasionally advocated, for reasons of convenience of measurement. In view of the relationship $Q = \text{ampere-second}$ we would of course also be content with the ampere as fourth unit. We take less kindly to the designation of Giorgi's system by the units MKSVA. In view of

$$VA = \text{watt} = \text{joule/sec}$$

these units are not independent of each other. We can well understand that the long-employed quantities V and A appear more convenient in use than our unit of charge Q . Nevertheless, of the two dimensions

$$E = \frac{\text{newton}}{Q} \quad \text{and} \quad E = \frac{\text{Volt}}{M}$$

the first appears to be the more natural one. Kalantaroff's system of the four units MSQO (magnetic flux) is selfconsistent, but seems, by the elimination of the unit of mass, somewhat too artificial for general use in physics.

It is to be welcomed, from our point of view, that, by international agreement, separate designations gauss and oersted have been introduced for the two magnetic vectors B and H . Historically, the name gauss also seems proper for B , since Gauss' methods of determining magnetic moment rest on measurements of force and hence refer to B and not to H . The unhappy term "magnetic field" for H should be avoided as far as possible. It seems to us that this term has led into error none less than Maxwell himself, who, in art. 625 of the Treatise puts the force exerted by the field on a magnetic pole m equal to mH .

We have repeatedly stressed as an advantage of our system that it avoids the annoying powers of ten of the cgs-system. This applies to the electrical as well as to the mechanical quantities. The converse is true, however, for the *magnetic* quantities. The unit gauss of the magnetic induction B in the cgs-system is, by definition, equal to the unit in the cgs-system. Hence, transferred to our system of units, it acquires a power of ten. We determine the latter as follows:

Let $[B]$ be the numerical magnitude of a given field in our system of units, so that

$$B = [B] \frac{\text{newton S}}{QM} = [B] \frac{\text{joule S}}{QM^2} \quad (1)$$

We substitute again

$$\text{joule} = 10^7 \text{ erg}, \quad M = 10^2 \text{ cm}, \quad Q = \frac{1}{10} \text{ cgs-units}.$$

If, in particular, we set $[B] = 1$, we find from (1) as corresponding value of this quantity B in cgs-units:

$$B = 1 \frac{10^7}{10^2} \text{ cgs-units} = 10^5 \text{ gauss}, \quad (2)$$

and conversely

$$1 \text{ gauss} = 10^{-5} \frac{\text{joule S}}{QM^2} = 10^{-5} \frac{VS}{M^2}. \quad (3)$$

It may be mentioned in favor of this choice of unit that the gauss is inconveniently small for practical purposes, so that not only in engineering, but even in pure physics (except for terrestrial magnetism) the kilogauss must generally be employed (e.g. in the Zeeman effect). Hence our 10,000 times greater unit is to be preferred in practice.

In order to express the oersted in our system of units as well, we proceed from the relationship between H and B :

$$H = \frac{B}{\mu_0}. \quad (4)$$

We now set $H = 1$ oersted, $B = 1$ gauss, so that by (3)

$$B = 10^{-5} \frac{\text{joule S}}{QM^2}$$

and by (7.16a)

$$\mu_0 = 4\pi \cdot 10^{-7} \frac{\text{joule S}^2}{Q^2 M}.$$

We then obtain from (4)

$$1 \text{ oersted} = 10^{-4} \frac{\text{joule S}}{\text{QM}^2} / 4\pi \cdot 10^{-7} \frac{\text{joule S}^2}{\text{Q}^2 \text{M}}; \quad (5)$$

so that

$$1 \text{ oersted} = \frac{1}{4\pi} 10^3 \frac{\text{Q}}{\text{SM}} = \frac{1}{4\pi} 10^3 \frac{\text{amp}}{\text{M}} \quad (5a)$$

$$H_{\text{amp/M}} = 4\pi \cdot 10^{-3} H_{\text{oersted}}. \quad (5b)$$

B. The Five Units MKSQP

It may be stated generally: A dimensional analysis will be more successful¹ in the degree in which more independent units are at its disposal. Our four units are hence more informative than the three units of the "absolute" system, in which the dimensional character of the fundamental electromagnetic vectors is obscured. The five independent units considered below are of even greater value from a general theoretical point of view.

We introduced the magnetic pole strength P as a dimension in §2, but expressed it immediately in (2.7) in terms of the charge Q , in accord with Ampère's hypothesis. Is this hypothesis binding even today, after the discovery of the neutron, a nuclear particle as basic and universal as the proton? The neutron has a magnetic moment which is not associated with any charge, unlike the electron and proton which, though endowed with *equal* charge of opposite sign, have magnetic moments of entirely *different* magnitude. Certainly an attempt to abandon Ampère's hypothesis and to introduce P as *independent fifth dimension* is justified and instructive. We shall, for the present, refrain from fixing the magnitude of P .

We write down the following sets of dimensional relations, which now show a complete correspondence:

$$\begin{array}{ll} E = \frac{\text{newton}}{Q} & B = \frac{\text{newton}}{P} \\ D = \frac{Q}{M^2} & H = \frac{P}{M^2} \\ \epsilon = \frac{D}{E} = \frac{Q^2}{\text{joule M}} & \frac{1}{\mu} = \frac{H}{B} = \frac{P^2}{\text{joule M}} \\ E \cdot D = \frac{\text{newton}}{M^2} = \frac{\text{joule}}{M^2} & B \cdot H = \frac{\text{newton}}{M^2} = \frac{\text{joule}}{M^2} \end{array} \quad (6)$$

¹ E. Fues, Z. Phys. 107, 662, 1937, indicates an upper limit to the useful number of dimensions.

The entries for E , D , B , and H are identical with the original formulas in (2.1) to (2.9.) In accord with the note accompanying Eq. (4.7) we have entered the reciprocal of μ as analog of ϵ in our table.

The last line, which is *independent* of Q and P , has the dimension of energy density. On the other hand the (scalar or vector) product of \mathbf{E} and \mathbf{H} has a dimension which *depends* on P and Q :

$$\mathbf{E}\mathbf{H} = \frac{P}{Q} \frac{\text{newton}}{M^2} = \frac{P}{Q} \frac{S}{M} \frac{\text{joule}}{M^2 S}. \quad (7)$$

The last factor of the last expression has the dimension of energy flux (radiation vector). Let the factor multiplying it be $1/\Gamma$. We thus put

$$\Gamma = \frac{Q}{P} \frac{M}{S} \quad (8)$$

and write (7) in the form

$$\Gamma \mathbf{E}\mathbf{H} = \frac{\text{joule}}{M^2 S}. \quad (8a)$$

This dimensional equation suggests that the energy flux \mathbf{S} is now to be defined as $\Gamma \mathbf{E} \times \mathbf{H}$. We furthermore compute the product $\epsilon\mu$ from (6) and find

$$\epsilon\mu = \frac{Q^2}{P^2} = \Gamma^2 \left(\frac{S}{M} \right)^2. \quad (9)$$

We suspect from this that the velocity of light c is no longer given by $(\epsilon_0\mu_0)^{-1/2}$, but by $\Gamma(\epsilon_0\mu_0)^{-1/2}$.

The same factor Γ occurs now also in Maxwell's equations. We assert that these should be written:

$$\dot{\mathbf{B}} = -\Gamma \text{curl } \mathbf{E}, \quad \dot{\mathbf{D}} + \mathbf{J} = \Gamma \text{curl } \mathbf{H}. \quad (10)$$

If, as in §5, we proceed to Poynting's theorem (scalar multiplication of the first equation with \mathbf{H} , of the second equation with \mathbf{E}), we obtain

$$\mathbf{H} \cdot \dot{\mathbf{B}} + \mathbf{E} \cdot \dot{\mathbf{D}} + \mathbf{E} \cdot \mathbf{J} + \Gamma \text{div } \mathbf{E} \times \mathbf{H} = 0;$$

with the former definitions of the energy densities and of the Joule heat in (5.6) and (5.5) and with the definition of the energy flux suggested by (8a) this expresses the law of conservation of energy:

$$\dot{W}_m + \dot{W}_e + W_J + \text{div } \mathbf{S} = 0. \quad (11)$$

If, on the other hand, just as in §6, we integrate Eq. (10) for the case of the plane wave in vacuum propagated in the x -direction, we obtain the wave equation in the form

$$\epsilon\mu \ddot{\mathbf{E}} = -\Gamma^2 \text{curl curl } \mathbf{E} = \Gamma^2 \Delta \mathbf{E}. \quad (12)$$

Since this is supposed to represent a process with the velocity of propagation c , our expectation suggested by (9) is confirmed:

$$\frac{\Gamma}{\sqrt{\epsilon_0 \mu_0}} = c, \quad \sqrt{\epsilon_0 \mu_0} = \frac{\Gamma}{c}. \quad (12a)$$

The general form (10) of the Maxwell equations is not new. It was introduced by Emil Cohn, the friend and fellow student of Heinrich Hertz, and forms the basis of his important book¹ "Das elektromagnetische Feld." We have avoided Cohn's notation V , taking the place of our Γ , since we have otherwise disposed of V . It is true that Cohn does not work out the relationship of this constant with our unit P of pole strength, nor does he place dimensional considerations in the foreground as has been done here. Students of Cohn, in particular J. Zenneck, have used Cohn's system by preference.

H. A. Lorentz clearly recognized the advantages of Cohn's standpoint when, in 1902, he wrote his two great articles on Maxwell's theory and electron theory for the *Enzyklopädie der mathematischen Wissenschaften*. He wrote:² "Cohn's system has the advantage of easy transition to other systems, by specific choice of the values of V , ϵ_0 , and μ_0 . Eventual later advances in the understanding of the phenomena could be utilized for the ultimate determination of the units. On the other hand we could not bring ourselves to introduce indeterminate quantities into the formulas which are complex to begin with."

The "eventual later advances in the understanding of the phenomena" contemplated by Lorentz can only be expected when we have a *theory of the elementary particles* which now constitutes the greatest problem on the program of atomic physics; this would have to explain not only the magnetic moments, but also the possible masses and charges of the elementary particles. However, we can even now benefit by the flexibility of Cohn's system.

C. The Gaussian System of Only Three Units

We evidently return to our system with the four units MKSQ and our former form (4.4) of Maxwell's equations if we set

$$\Gamma = 1. \quad (13)$$

Then P has, according to (8), the dimension

$$P = Q \times \text{velocity}, \quad (13a)$$

¹ First Edition, Leipzig 1900, Second Edition, 1927.

² Vol. V, second part, p. 87.

in agreement with Ampère's hypothesis in (2.7). Furthermore, our specific choice of μ_0 and ϵ_0 in (7.16a) and (7.17) is evidently consistent with Eq. (12a) for these values of Γ and P .

We obtain another, also very simple, form of Maxwell's equations if we set

$$\Gamma = c. \quad (14)$$

Then, by (12a), the product $\epsilon_0\mu_0$ must be a pure number. It is tempting to make ϵ_0 and μ_0 separately pure numbers and to set

$$\mu_0 = 1, \quad \epsilon_0 = 1. \quad (14a)$$

In this manner we pass over to the *Gaussian system of units*. In view of (14) the Maxwell equations then become (we confine ourselves first to *nonconductors*):

$$\frac{1}{c} \dot{\mathbf{B}} = - \text{curl } \mathbf{E}, \quad \frac{1}{c} \dot{\mathbf{D}} = \text{curl } \mathbf{H}. \quad (15)$$

In view of (8) P and Q have now the same dimension. Hence, by Table (6), the dimensions of \mathbf{E} and \mathbf{B} , as well as those of \mathbf{D} and \mathbf{H} , also become mutually identical. (The same follows also from the form of Eqs. (15).) Furthermore the dimensions of the two pairs become the same, since now ϵ and μ , just as ϵ_0 and μ_0 in (14a), become pure numbers, equal to the pure numbers ϵ_{rel} and μ_{rel} introduced in (6.15). *The Gaussian system obscures the dimensional character of the four fundamental vectors \mathbf{E} , \mathbf{D} , \mathbf{B} , \mathbf{H} completely, while Cohn's system expresses it most clearly.*

The two Coulomb laws (7.8) and (7.12) were written in the *conventional form* (with the factor 4π suppressed). This has the result that the 4π do not occur in the Maxwell Eqs. (15) for nonconductors but *arise once more* in their integration. For, taking the divergence and integrating Eqs. (15) with respect to t leads to:

$$\text{div } \mathbf{B} = \text{const.}, \quad \text{div } \mathbf{D} = \text{const.}$$

The first constant is, of course, equal to zero; the second must now not be set equal to ρ , but equal to $4\pi\rho$:

$$\text{div } \mathbf{D} = 4\pi\rho, \quad (15a)$$

in order that the factors 4π cancel each other on the two sides of the equation if it is applied to a point charge $e = \int \rho \, d\tau$ and is integrated over a sphere about e . Only in this manner is the field strength $E_r = e/(er^2)$, obtained corresponding to the conventional form of the Coulomb force \mathbf{F} . From this follows also as the expression for the corresponding electrostatic potential $\Psi = e/(er)$, unlike Eq. (7.6), where the appropriate factor

4π appears on the left. Hence also (7.5) and (7.4a) must now be replaced by the less appropriate expressions

$$\epsilon\Psi = \int \frac{\rho}{r} d\tau, \quad \Delta\Psi = -4\pi\rho/\epsilon. \quad (15b)$$

The same follows from the form (7.12) of Coulomb's law for the magnetic density ρ_m and the magnetic potential Ψ_m :

$$\text{div } \mathbf{H} = 4\pi\rho_m, \quad \Psi_m = \int \frac{\rho_m}{r} d\tau, \quad \Delta\Psi_m = -4\pi\rho_m. \quad (15c)$$

We now extend Eq. (15) to the case of a *conductor*. Here we must temporarily multiply the conduction current \mathbf{J} , which is to be added to $\dot{\mathbf{D}}$, with a numerical factor γ which we shall determine in a moment. Hence we write in place of (15)

$$\frac{1}{c} \dot{\mathbf{B}} = -\text{curl } \mathbf{E}, \quad \frac{1}{c} (\dot{\mathbf{D}} + \gamma\mathbf{J}) = \text{curl } \mathbf{H}. \quad (16)$$

Taking the divergence of the second of these equations, as in (15a), and utilizing the definition of ρ given there leads to

$$4\pi \frac{\partial \rho}{\partial t} + \gamma \text{div } \mathbf{J} = 0. \quad (16a)$$

We must set $\gamma = 4\pi$ in order that this equation may express the conservation of charge, or in other words, the absence of sources of the total current \mathbf{C} ; only then does (16a) become the analogue (4.4c) or (3.6b) of the hydrodynamic equation of continuity.

Having entered this value of γ in (16), we seek the expression for the *Poynting theorem* by the procedure followed at the beginning of §5. Multiplying the two equations (16) scalarly with \mathbf{H} and \mathbf{E} respectively, and utilizing the transformation (5.2) we obtain

$$\frac{1}{c} \mathbf{H} \cdot \dot{\mathbf{B}} + \frac{1}{c} \mathbf{E} \cdot \dot{\mathbf{D}} + \frac{4\pi}{c} \mathbf{E} \cdot \mathbf{J} + \text{div } \mathbf{E} \times \mathbf{H} = 0. \quad (17)$$

We compare this with the earlier form (5.7) of the same theorem:

$$\dot{W}_m + \dot{W}_e + \text{div } \mathbf{S} = -W_J. \quad (17a)$$

Since we cannot disturb Ohm's law W_J is still given by the product $\mathbf{E} \cdot \mathbf{J}$. We must hence divide (17) by $4\pi/c$ in order that (17) may correspond with (17a). Then a comparison of the terms of (17) and (17a) leads to

$$\dot{W}_m = \frac{1}{4\pi} \mathbf{H} \cdot \dot{\mathbf{B}}, \quad \dot{W}_e = \frac{1}{4\pi} \mathbf{E} \cdot \dot{\mathbf{D}}, \quad (17b)$$

$$\mathbf{S} = \frac{c}{4\pi} \mathbf{E} \times \mathbf{H}, \text{ and } W_J = \mathbf{E} \cdot \mathbf{J} = \sigma \mathbf{E}^2 \text{ as before.} \quad (17c)$$

Integration of (17b) with respect to t , as on p. 27, yields (for isotropic and anisotropic media):

$$W_m = \frac{1}{8\pi} \mathbf{H} \cdot \mathbf{B}, \quad W_e = \frac{1}{8\pi} \mathbf{E} \cdot \mathbf{D}; \quad (17d)$$

They express the localization of energy in conventional units. Already in connection with Eq. (7.14) we pointed out the unsuitable form of the denominator 8π , as compared with the denominator 2 in our rational notation (5.6). The same applies for the factor $c/(4\pi)$ in the present expression (17c) for the energy flux. Even in the Maxwell equations (16) the suppression of 4π , carried out at the wrong place, avenges itself: These equations, in the form appropriate for both conductors and nonconductors, become:

$$\frac{1}{c} \dot{\mathbf{B}} = - \text{curl } \mathbf{E}, \quad \frac{1}{c} \dot{\mathbf{D}} + \frac{4\pi}{c} \mathbf{J} = \text{curl } \mathbf{H} \quad (18)$$

with the supplementary conditions, applying specifically for isotropic media

$$\mathbf{D} = \epsilon \mathbf{E}, \quad \mathbf{B} = \mu \mathbf{H}, \quad \mathbf{J} = \sigma \mathbf{E}. \quad (18a)$$

We hope that by this summary we have facilitated for the reader the laborious transition between our two systems of units

$$\text{MKSQ (rational)} \rightleftharpoons \text{cgs (Gauss, conventional)}$$

as far as possible. We have discussed the historical source of this annoyance at the end of §7. It is unavoidable in view of the present status of the question of units in electrical engineering, experimental physics, and theoretical physics. The following remarks may serve to clarify the situation.

H. A. Lorentz, when writing his articles for the *Enzyklopädie* in 1902, like Hertz, utilized the Gaussian system, postulating: *Electrical quantities* (including the electric current) *are measured electrically* (electrostatically), *magnetic quantities, magnetically*. Contrary to his original intention he decided, in the course of composing the articles, to convert the Gaussian system (unlike Gauss and Hertz) into *rational* units. In this manner the theoretical relationships became clearer and the 4π 's were eliminated from the Maxwell equations. Lorentz set for vacuum $\epsilon_0 = \mu_0 = 1$, as in our Eqs. (14a). In order to retain the rational form of the Coulomb force law he then had to introduce the 4π 's appearing in it into the definition of the unit charge and the unit pole strength, respectively. This somewhat artificial conversion of units¹ has not found wide acceptance, in spite of the authority of Lorentz.

¹ See table on p. 87 of Vol. 5, part 2, of the *Enzyklopädie*.

We have here—also against our original intention—arrived at the decision to write the Gaussian system, insofar as we shall use it, in *conventional units*. The reason is the following: Since the year 1902 *atomic physics* has come to be the most important branch of our science. It deals always with conventional units, e.g. with the electron charge $e = 4.80 \cdot 10^{-10}$ (electrostatic cgs-units) and with the electric potential, e.g. in the hydrogen atom, $\Psi = e/r$ (not $\Psi = e/(4\pi r)$). We consider it inadvisable to overturn this whole formalism anew by passing over to the rational form of the Gaussian system or even to our system of four units.

On the other hand Giorgi's system of the units MKSQ, freed of 4π 's, is most suitable for the macrophysical problems of this lecture. We are here in agreement with the international conventions, with the practice of engineering, and, in particular, with the textbooks of Mie (quoted on p. 10) and Pohl.¹ We regard the dogma of the scientific superiority of the *three* purely mechanical units cm, g, sec, which for example is supported in Kohlrausch, *Praktische Physik*, as outmoded.

D. Supplement Regarding Other Systems of Units

In the restriction to these two systems of units, the Gaussian system in conventional form and the MKSQ system, we follow the practice of the excellent textbook of Joos.² The Gaussian system (whether in rational or conventional form) is a *mixed* system, consisting of electrical (electrostatic) and magnetic cgs-units. There are however, as is well known, also a *purely electrical* and a *purely magnetic* system of units, of which the latter is particularly important, since the legal units volt, ampere, ohm, etc. are based on it.

The reason for setting up a separate *electrical system of units* rests on a certain quantitative difference between electrostatics and electrokinetics: Electrostatics deals with large voltages and small quantities of electricity, electrokinetics, with moderate voltages and large quantities of electricity. To give a comparison from hydrodynamics, the electric spark of a condenser discharge corresponds to a waterfall (great height, small quantity), the electric current, to a river (small grade, great flow), as is indicated in Fig. 7. Thus, for electrostatics, a small unit of charge and a large unit of field strength are suitable. The *electrostatic system* based on the electrical Coulomb law provides such units. In terms of this small unit of charge the charge of the electron (see above) has the relatively large value $4.80 \cdot 10^{-10}$ cgs-unit. The unit of charge in the *electromagnetic system* (equal to 10 coulombs), on the other hand, is larger by the factor c ; in terms of it, the charge of the electron appears smaller by a factor c , i.e. equal to $1.60 \cdot 10^{-20}$ cgs = $1.60 \cdot 10^{-19}$ coulomb (see p. 43). On the other hand, the unit of *field strength* in the electromagnetic system, according to the definition

¹ R. W. Pohl, *Elektrizitätslehre*, Springer, 8th and 9th Edition, 1943.

² G. Joos, *Theoretical Physics*, 2nd Ed., G. E. Stechert and Co., New York, 1950.

of the volt, is 10^{-8} volts/cm; that in the electrostatic system is c times as large, or 300 volts/cm. We shall return to this in §16D.

We have frightened generations of students with these two sets of values for charge and field strength (their number would be increased to 4 if, in addition to the usual conventional units, rational units would also be considered). It is, in our opinion, a special advantage of the introduction of our fourth unit of charge, Q , which is independent of all other units, that we need deal only with quite definite charges, expressed as multiples of Q .

FIG. 7. The hydrodynamic representation of a stationary electric current and of a condenser discharge.

We quote finally an informative analog to the double (electrostatic and electromagnetic) measure of charge which, like so many other clarifications in the question of units, we owe to J. Wallot.¹ Suppose that someone had decided to describe mechanical processes in terms of only *two* independent units, cm and sec. He eliminates the gram as unit by setting either the density δ or the modulus of elasticity E of some standard material such as copper arbitrarily equal to 1. He can then express the mass m of a given copper rod in two ways, either by a measurement of volume according to the formula

$$\delta = \frac{m}{V}, \text{ which, because of } \delta = 1, \text{ leads to: } m = m_1 = V$$

or by a vibration experiment with longitudinal waves according to the formula

$$c^2 = \frac{E}{\delta} = \frac{EV}{m}, \text{ which, because of } E = 1, \text{ leads to: } m = m_2 = V/c^2.$$

If he now divides one of the two values of m so found by the other he obtains—perhaps to his surprise—the square of the velocity of propagation c of elastic waves in copper. The analogy to electrodynamics is striking and requires no further explanation.

PART II

DERIVATION OF THE PHENOMENA FROM THE MAXWELL EQUATIONS

§9. *The Simplest Boundary-Value Problems of Electrostatics*

We have set up the fundamental equations of electrostatics in the beginning of §7 and have dealt with the resulting *summation problem* for a uniform medium in Eq. (7.5). We now turn to the *boundary-value problems* arising from the presence of *conductors* or *nonconductors* of different dielectric constant.

We think of the simplest electrostatic experiments: Let a metallic conductor of arbitrary shape, originally insulated, A, be connected to a source of potential V (with respect to ground) or B, be given a known charge (e.g. by a piezoquartz, see p. 78). We wish to know the field outside of the conductor. We describe this field by the potential Ψ associated with the field strength $\mathbf{E} = -\text{grad } \Psi$. Let Ψ be set equal to zero at infinity in both cases, A and B. In both cases $\Delta\Psi = 0$ outside of the conductor; on the surface, as well as in the interior of the conductor, we have $\Psi = \Psi_L = \text{const.}$

A. *Charging Problems*

In case A, $\Psi_L = V$ is given, in case B, Ψ_L must be found. According to (3.12a) the surface charge density at any point $d\sigma$ of the surface of L is given by

$$\omega = D_n = \epsilon E_n = -\epsilon \left(\frac{\partial \Psi}{\partial n} \right)_L. \quad (1)$$

ϵ is the dielectric constant outside of the conductor, n the outward normal to the surface of L . According to (1) the total charge on L is

$$q = \int \omega d\sigma = -\epsilon \int \frac{\partial \Psi}{\partial n} d\sigma. \quad (2)$$

In case A, q is sought; in case B, where q is given, (2) determines Ψ_L .

For the case of a *sphere*, of radius a , the appropriate solution of the differential equation $\Delta\Psi = 0$ may be written down immediately, in the form

$$\Psi = \frac{a}{r} \Psi_L. \quad (3)$$

This yields for A, since $\Psi_L = V$,

$$\Psi = \frac{a}{r} V. \quad (3a)$$

In case B, (2) and (3) lead to

$$q = 4\pi a^2 \frac{\epsilon \Psi_L}{a}, \Psi_L = \frac{q}{4\pi \epsilon a}, 4\pi \epsilon \Psi = \frac{q}{r}. \quad (3b)$$

The charge q , uniformly distributed over the spherical surface, thus acts at a distance like a point charge concentrated at the center.

It is also possible to guess the field of a conductor of the shape of a prolate spheroid (ellipsoid of revolution with long axis as axis of symmetry). For this it is merely necessary to stretch, so to speak, the center of the sphere, which appears in the last Eq. (3b) as locus of the total charge, into the connecting line of the two focal points of the generating ellipse and to distribute the charge q uniformly over this line. If we call the distance of the two focal points from the center of the ellipsoid c , the linearly distributed charge density becomes $q/(2c)$ and its potential becomes, by Eq. (7.5b):

$$\begin{aligned} 4\pi \epsilon \Psi &= \frac{q}{2c} \int_{-c}^{+c} \frac{d\zeta}{\sqrt{x^2 + y^2 + (z - \zeta)^2}} \\ &= \frac{q}{2c} \log \frac{z + c + \sqrt{x^2 + y^2 + (z + c)^2}}{z - c + \sqrt{x^2 + y^2 + (z - c)^2}} \end{aligned} \quad (4)$$

In Problem II.1 we will show that this expression assumes a constant value $\Psi = \Psi_L$ on each of the confocal ellipsoids pertaining to the given separation of foci and that therefore it solves our potential problem for each one of these ellipsoids. Since only the separation c of the focal points occurs in (4), this formula applies for all confocal ellipsoids of the family, in the sense that all of the equipotential surfaces of the confocal ellipsoids with the semiaxes $a_2 > a_1$, $b_2 > b_1$ are included among the equipotential surfaces of the ellipsoid with the semiaxes a_1 , b_1 . The ellipsoid $a = c$, $b = 0$, which degenerates to a straight line of length $2c$, also belongs to this family. In II.2 the limiting case of a paraboloid of revolution, and its degeneration, the field of a semi-infinite glass rod uniformly charged by friction, are studied from this point of view.

B. Induction Problems and Method of Reciprocal Radii

The "induction problem," which we shall specialize to an inducing point charge, is more complex than the "charging problem" treated thus far. Here also we can distinguish between two cases: A. The (otherwise arbitrarily shaped) conductor is grounded and B., it is insulated. The generally

accepted meaning of "grounding" is a conducting connection with an infinitely distant surface at the potential $\Psi = 0$. "Insulation" signifies, for an originally uncharged conductor, that even after induction the total charge q continues to be zero.

Problem A is solved by *Green's function* $G(P, Q)$ —more exactly, "Green's function of the potential equation for the exterior of the conductor L ." Q is the "source point," which will be assumed to represent a "unit source," P , the "reference point." G is defined by the following conditions:

$$\begin{aligned} \Delta G &= 0 \text{ for all } P \neq Q \text{ outside of } L, \\ G &\rightarrow 1/(4\pi r_{PQ}) \text{ for } P \rightarrow Q \text{ (definition of unit source),} \\ G &= 0 \text{ on the surface of } L, \\ G &\rightarrow 0 \text{ for } P \rightarrow \infty. \end{aligned} \quad (5)$$

Green's function plays a central role not only in potential theory, but generally in the theory of linear differential equations, to be treated in Vol. VI. Here we shall merely point out its significance for our special problem. If Q represents the position of the inducing charge e , the solution of problem A is given by

$$\Psi(P, Q) = \frac{e}{\epsilon} G(P, Q) \quad (6)$$

and that of B by

$$\Psi(P, Q) = \frac{e}{\epsilon} G(P, Q) + \alpha \Psi; \quad (6a)$$

here Ψ is the solution of our "charging problem" A for the same conductor L , α , a parameter which, according to Eq. (2), is determined by the condition

$$\int \frac{\partial \Psi(P, Q)}{\partial n} d\sigma = 0. \quad (6b)$$

As special case we consider once more a sphere of radius a . Its Green's function can be written down in closed form by the ingenious method of the young William Thomson, later Lord Kelvin, which will be treated in detail in Vol. VI, §23. With Q as source point and Q' as "electrical image of Q with reference to the sphere of radius a " this solution is:

$$4\pi G(P, Q) = \frac{1}{r_{PQ}} - \frac{a}{\rho} \frac{1}{r_{PQ'}}. \quad (7)$$

$\rho = OQ$ is the separation of the source point Q from the center of the sphere, $\rho' = OQ'$, that of its image point Q' . They are related by the condition of "reciprocal radii":

$$\rho\rho' = a^2, \quad (8)$$

from which Thomson's procedure has been given the name "method of reciprocal radii." It is immediately evident that our formula (7) satisfies the first, second, and last condition (5); the fulfilment of the third condition (5) can be demonstrated by elementary geometry.

According to (6), Eq. (7) yields for induction on the grounded sphere:

$$4\pi\epsilon\Psi(P, Q) = \frac{e}{r_{PQ}} - \frac{e'}{r_{PQ'}}, e' = \frac{a}{\rho} e \quad (8a)$$

and for the insulated sphere, by (6a, b) and (3b):

$$4\pi\epsilon\Psi(P, Q) = \frac{e}{r_{PQ}} - \frac{e'}{r_{PQ'}} + \frac{e'}{r_{PO}}, e' = \frac{a}{\rho} e. \quad (8b)$$

The last term in this formula corresponds to the added term $\alpha\Psi$ in (6a). It has the effect of raising the potential of our insulated sphere to the

FIG. 8. Two charges $\pm e$ moving toward infinity and their electric images at a conducting sphere of radius a produce a uniform electric field and an electric dipole at the center of the sphere.

value $V = e'/(4\pi\epsilon a)$ and of making the total charge on its surface $q = 0$, as it should be.

C. Conducting Sphere in a Uniform Field

For the practically unlimited possibilities of application of spherical images in potential theory we refer to the portion of Vol. VI cited above. Here we shall treat only the simple case of the sphere in a *uniform field*, whose lines of force may, for example, be parallel to the x -axis. In the absence of the conducting sphere the uniform field is given by

$$\Psi = -Fx, E_x = -\frac{\partial\Psi}{\partial x} = F, E_y = E_z = 0. \quad (9)$$

We imagine this field as resulting from the superposition of two fields, originating in the infinitely distant source points Q, \bar{Q} (see Fig. 8) on the

x -axis, with the charges $\pm e$; their coordinates are $x = \pm \rho$ ($\rho \rightarrow \infty$), $y = z = 0$. The superposition leads to the potential

$$\begin{aligned} 4\pi\epsilon\Psi &= \frac{e}{r_{PQ}} - \frac{e}{r_{P\bar{Q}}} = e\{(\rho - x)^2 + y^2 + z^2\}^{-1/2} \\ &\quad - e\{(\rho + x)^2 + y^2 + z^2\}^{-1/2} = e\{\rho^2 + x^2 + y^2 + z^2\}^{-1/2} \quad (9a) \\ &\quad \cdot \left(1 + \frac{\rho x}{\rho^2 + \dots} - 1 + \frac{\rho x}{\rho^2 + \dots}\right) \rightarrow \frac{2ex}{\rho^2}. \end{aligned}$$

We have thus in fact a uniform field of the same form as (9) provided that we let e become infinite as ρ^2 . To obtain quantitative agreement with (9) we must put

$$\frac{2e}{\rho^2} \rightarrow -4\pi\epsilon F. \quad (9b)$$

In Fig. 8 we have also shown the sphere of radius a and the appropriate spherical images of the source points Q, \bar{Q} constructed for it:

$$Q' = \rho', 0, 0 \text{ and } \bar{Q}' = -\rho', 0, 0.$$

They approach each other as the charges $\pm e$ move apart and form in the limit an electric dipole with the moment

$$M = 2\rho'e'. \quad (10)$$

Here we substitute from Eq. (8) $\rho' = a^2/\rho$ and from Eq. (8a, b) $e' = ea/\rho$. In view of (9b), Eq. (10) then states that the moment M assumes in the limit for $\rho \rightarrow \infty$ the finite value

$$M = 2 \frac{a^2}{\rho} \frac{ea}{\rho} = -4\pi\epsilon F a^3. \quad (10a)$$

We conclude therefore that the boundary value problem for the homogeneous field is solved by placing a virtual electric dipole of the finite moment M at the center of the sphere. The homogeneous field (9) is then replaced by the inhomogeneous field¹

$$\Psi = -Fx + \frac{M}{4\pi\epsilon} \frac{\partial}{\partial x} \frac{1}{r}, \quad (11)$$

which contains the distortion created by the dipole. Since, now, r represents the distance from the center of the sphere,

$$r = (x^2 + y^2 + z^2)^{1/2}, \text{ so that } \frac{\partial}{\partial x} \frac{1}{r} = -\frac{x}{r^3}.$$

Eq. (11) hence becomes

$$\Psi = -Fx \left(1 + \frac{M}{4\pi\epsilon F} \frac{1}{r^3}\right). \quad (11a)$$

¹ The denominator $4\pi\epsilon$ is to be added here for the same reason as the factor $4\pi\epsilon$ on the left side of (9a).

If we substitute here the value of M from (10a), we obtain

$$\Psi = -Fx \left(1 - \frac{a^3}{r^3}\right). \quad (11b)$$

On the surface of the sphere, $r = a$, Ψ assumes the constant value $\Psi_L = 0$. The value of M found in (10a) by the method of reciprocal radii is thus confirmed for the *conducting sphere*.

D. Dielectric Sphere in a Uniform Field

We shall now show that the formula (11), with the value of M undetermined, has a much greater range of validity, i.e. will also fulfill the boundary conditions for a *non-conducting sphere of arbitrary dielectric constant*. If we distinguish the exterior and the interior of the sphere by the indices 1 and 2 (see Fig. 9), these conditions require that

$$\Psi_1 = \Psi_2, \quad \epsilon_1 \frac{\partial \Psi_1}{\partial n} = \epsilon_2 \frac{\partial \Psi_2}{\partial n} \quad \text{for } r = a. \quad (12)$$

The first of these guarantees the continuity of the *tangential* components of \mathbf{E} ; the second indicates the continuity of the *normal* component of \mathbf{D} , which, for an originally uncharged, nonconducting sphere, is equivalent to the absence of surface charge, $\omega = 0$ (Eq. (3.11)). We assert that both equations may be satisfied if for Ψ_1 (exterior of sphere, $r > a$) we use formula (11a) and for Ψ_2 (interior of sphere, $r < a$) we assume a *homogeneous field*, in the same direction as, but differing in strength from, the exterior primary field.

With $x = r \cos \theta$ (θ = geographic latitude on the sphere, measured from the field direction) we write tentatively

$$\Psi_1 = -F \left(r + \frac{M}{4\pi\epsilon_1 F} \frac{1}{r^2} \right) \cos \theta, \quad \Psi_2 = -F_2 r \cos \theta \quad (13)$$

and, according to (12), we must demand that for $r = a$ ($\cos \theta$ cancels in both Eqs. (12)):

$$\begin{aligned} F \left(1 + \frac{M}{4\pi\epsilon_1 F} \frac{1}{a^3} \right) &= F_2, \\ F \left(1 - \frac{2M}{4\pi\epsilon_1 F} \frac{1}{a^3} \right) &= \frac{\epsilon_2}{\epsilon_1} F_2. \end{aligned} \quad (13a)$$

From this we find, with $\epsilon = \epsilon_2/\epsilon_1$ as *relative dielectric constant*:

$$\frac{F_2}{F} = \frac{3}{\epsilon + 2}, \quad \frac{M}{4\pi\epsilon_1 F} = -\frac{\epsilon - 1}{\epsilon + 2} a^3. \quad (14)$$

Thus our assumption of a homogeneous field within the sphere has proved adequate. This field F_2 is weaker than the primary external field F if

$\epsilon > 1$, as, for example, if the sphere is in air. The lines of force penetrate the interior of the sphere (see Fig. 9); although they are curved outside by the action of the (virtual) dipole moment they are straight and parallel to the x -axis within the sphere.

To understand this figure properly it should be noted that it does not represent the lines of force E , but the lines of induction D . The two systems of lines have the same direction but different density both inside and outside of the sphere (see the remarks on magnetic lines of force or better tubes of force on p. 11), and hence behave differently at the surface. The D -lines are *source-free* not only within and outside of the sphere but also at its surface, because of the vanishing surface divergence (D_n is continuous); this does not apply to the E -lines (E_n is discontinuous). The fact that Fig. 9 represents the D -lines is evident from the fact that just one line passes through every point of the spherical surface. In the

FIG. 9. A dielectric sphere in a uniform electric field. The excitation lines within and outside of the sphere.

case of the E -lines, more lines would arrive at the surface on the outside than leave it on the inside.

We consider two limiting cases, $\epsilon \rightarrow \infty$ and $\epsilon \rightarrow 0$. The first proves to be identical with that of the *conducting* sphere. Eqs. (14) yields then

$$M = -4\pi\epsilon_1 Fa^3, \quad F_2 = 0, \quad (14a)$$

in agreement with Eq. (10a) and with the fact that the interior of the sphere is field-free. This appears to contradict Fig. 9a, which shows a finite field inside of the sphere. We must note again, however, that this figure, as limiting case of Fig. 9, represents the D -field and that " $D = \epsilon E = \text{finite}$ " is consistent with passing to the limit $\epsilon \rightarrow \infty$, $E \rightarrow 0$.

The limiting case $\epsilon \rightarrow 0$ cannot be realized electrostatically,¹ but only

¹ Or only by assuming $\epsilon_2 \ll \epsilon_1$, i.e. considering a spherical cavity in a medium of very high dielectric constant. Then indeed the interior of the sphere is *relatively* free of D -lines, as is shown in Fig. 9b.

by placing a nonconductor in the stationary current field of a conductor. The magnetic analog would be a superconductor; hydrodynamically it represents the case of a rigid sphere immersed in a liquid whose flow is nonturbulent, incompressible and in parallel lines at infinity. In contrast with (14a) we have now

$$M = 2\pi\epsilon_1 F a^3, F_2 = \frac{3}{2} F. \quad (14b)$$

In spite of the finite value of F_2 the magnetic induction lines in the case of the superconductor and the hydrodynamic flow lines do not penetrate into

FIG. 9a. A conducting sphere in a uniform electric field. Representation of the excitation lines.

FIG. 9b. Stream lines about a rigid sphere. At the same time, magnetic lines of force about a superconducting sphere.

the interior of the sphere, as shown in Fig. 9b; they are pushed out of the interior since they must run tangential to the surface.

In the other limiting case, $\epsilon \rightarrow \infty$, the lines of force are perpendicular to the surface,¹ as for a conductor. In Problem II.3 we shall indicate the close relationship between Figs. 9 and 9a. We shall return to these important formulas and figures in §11.

¹ The force lines at the upper and lower pole of the sphere (in three dimensions at the diametral plane passing through the poles) form an exception. They make an angle of 45° with the surface of the sphere (see figure), an angle of 90° with each other. This may for example be seen from the fact that the Taylor expansion of Ψ (Eq. (11b)) begins with a term of the second order. Maxwell calls such a point a "point of equilibrium" (see art. 112 of the Treatise).

E. Reflection and Refraction of Lines of Force at the Boundary of a Semi-infinite Dielectric

For the sake of completeness a rather trivial problem will be dealt with here, namely induction in a dielectric bounded by a plane (see Fig. 10): Let a unit electric charge Q be at the point $x = a$ in the right halfspace, $x > 0$; it brings about a state of induction in the left halfspace, $x < 0$; ϵ is the *relative* dielectric constant of the left halfspace referred to the right halfspace. As in (12), the boundary conditions are

$$\Psi_1 = \Psi_2, \quad \frac{\partial \Psi_1}{\partial x} = \epsilon \frac{\partial \Psi_2}{\partial x} \quad \text{for} \quad x = 0. \quad (15)$$

A solution may be obtained with the aid of the simple reflection method familiar from optics: a virtual charge Q' of opposite sign is imagined at the point $x = -a$, which has an effect in medium 1, but has no effect in medium

FIG. 10. In the right-hand halfspace (air) at point Q is a point charge producing induction in the left halfspace (dielectric). Representation of the excitation lines. In the right halfspace they are curved; their continuations (dotted in the figure) pass through the image point Q' of Q . In the left halfspace they are straight lines whose (dotted) continuations pass through Q .

2, in view of the finiteness of the field throughout this medium; here all effects appear to proceed from the primary charge. Introducing the two disposable parameters e'/e and e''/e we write tentatively:

$$4\pi\epsilon_0\Psi_1 = \frac{e}{r} + \frac{e'}{r'}, \quad 4\pi\epsilon_0\Psi_2 = \frac{e''}{r}. \quad (16)$$

In the boundary plane $x = 0$, $r = r_{PQ}$ and $r' = r_{PQ'}$ are identical; at the same time

$$\frac{\partial}{\partial x} \frac{1}{r} = -\frac{x-a}{r^3}, \quad \text{and} \quad \frac{\partial}{\partial x} \frac{1}{r'} = -\frac{x+a}{r^3}$$

are equal and opposite, that is, are respectively equal to $\pm a/r^3$. Hence conditions (15) require

$$\begin{aligned} e + e' &= e'' \\ e - e' &= \epsilon e' \end{aligned} \quad \begin{aligned} e' &= \frac{1-\epsilon}{1+\epsilon} e, & e'' &= \frac{2}{1+\epsilon} e. \end{aligned} \quad (16a)$$

Employing optical terminology, e'' might be called the "refracted" charge; the "reflected" charge e' of course becomes zero for $\epsilon = 1$ (uniform dielectric, no discontinuity at $x = 0$). In the limiting case $\epsilon \rightarrow \infty$ (conductor) $e' = -e$, $e'' = 0$, so that $\Psi_2 = 0$; this corresponds to the requirement of a constant potential for $x < 0$. For $\epsilon \rightarrow 0$ the second condition (15) becomes $\partial\Psi_1/\partial x = 0$ and leads to $e' = +e$. See in this connection Fig. 10 (arbitrary $\epsilon > 1$), Fig. 10a ($\epsilon \rightarrow \infty$), and Fig. 10b ($\epsilon \rightarrow 0$, i.e. $\epsilon_{\text{right}} \gg \epsilon_{\text{left}}$).

FIG. 10a. Limiting case $\epsilon \rightarrow \infty$: the left halfspace is a conductor.

FIG. 10b. Limiting case $\epsilon \rightarrow 0$; dielectric constant of the right halfspace very large compared with that of the left halfspace.

§10. Capacity and its Connection with Field Energy

We consider two conductors of arbitrary shape L_1 and L_2 and give them charges $+q$ and $-q$ respectively. Such a system is called a *condenser* because the field between them is concentrated and limited to their neighborhood. The lines of force pass from L_1 to L_2 without diverging to infinity. Let the potential Ψ have the constant values Ψ_1 and Ψ_2 on L_1 and L_2 . The potential difference between them is then

$$V = \Psi_1 - \Psi_2 = \int_{L_1}^{L_2} \mathbf{E} \cdot d\mathbf{s}. \quad (1)$$

In this line integral we are permitted to leave the shape of the path indefinite; every path from L_1 to L_2 (it need by no means be a line of force) yields, as we know, the same value of the potential difference for a lamellar electrostatic field.

The ratio q/V is called the *capacity*, i.e. the ability of the system to take up charge. We employ for it the letter K (instead of the often-employed symbol C , which we use so often with the meaning "constant"):

$$K = \frac{q}{V}. \quad (2)$$

The unit of capacity is the "farad":

$$1 \text{ farad} = 1 \frac{\text{coulomb}}{\text{volt}} = 1 \frac{Q^2}{\text{joule}}; \quad (3)$$

FIG. 11. The pair of conductors L_1, L_2 with the charges $\pm q$ and the potentials ψ_1, ψ_2 form an electric condenser.

which is thus defined in our system without the appearance of inconvenient powers of ten. On the other hand, in electromagnetic cgs-units, according to (3),

$$1 \text{ farad} = \frac{10^{-1}}{10^9} \text{ cgs} = 10^{-9} \text{ cgs}; \quad (3a)$$

thus the so-called absolute cgs-unit of capacity would be $=10^9$ farad. The microfarad ($=10^{-6}$ farad) is employed more often than the farad.

According to (3) and (4.6a) the dielectric constant of vacuum has the dimension farad/ M and, according to (7.18), it has the magnitude

$$\epsilon_0 = \frac{10^{-9}}{36\pi} \frac{\text{farad}}{M} = \frac{10^{-9}}{36\pi} \frac{\text{microfarad}}{M}. \quad (3b)$$

However, if one chooses to give the capacity in "absolute electrostatic units" not only is the numerical value of the capacity different but also its dimensions (here cm!) are changed and a very confusing state of affairs results.

We shall consider, as simplest example,

A. The Plate Condenser

This condenser is to consist of two conducting plates with (large) area F , which are placed parallel and facing each other with (small) separation

a. We imagine their charges $\pm q$ to be distributed over F with uniform surface density ω . Hence we have for $x = \pm a/2$

$$\omega = \mp \frac{q}{F}, \quad \text{and also } \omega = D_n \text{ (Eq. (3.12a))}. \quad (4)$$

We regard the field between the plates as homogeneous, neglecting as we already have in (4), the perturbation at the edge zones. The lines of force are then normal to the plates *throughout*, and we find, with the value of D given by (4)

$$E_x = \frac{\omega}{\epsilon} = \frac{q}{F\epsilon}. \quad (4a)$$

It follows hence that

$$V = \int_{-a/2}^{+a/2} E_x dx = \frac{qa}{F\epsilon} \quad (4b)$$

and thus, from (2)

$$K = \frac{F\epsilon}{a}. \quad (5)$$

This is the "rational" value of our capacity, previously given in (7.15).

FIG. 12. The plate condenser with the field E , D between plates considered as uniform.

If, for example, we consider $F = 20 \cdot 20 \text{ cm}^2$, $a = 1 \text{ mm}$, and $\epsilon = 2\epsilon_0$ (paraffin filling) we find, with the value (3b) of ϵ_0 in our system of units,

$$K = \frac{80}{36\pi} 10^{-9} \text{ farad} = \frac{2}{9\pi} \cdot 10^{-8} \text{ farad} = \frac{2}{9\pi} \cdot 10^{-2} \text{ microfarad}. \quad (5a)$$

Thus, to obtain a capacity comparable with a microfarad, a very large number of condensers of the type considered have to be added together.

The neglected edge correction and the resulting inhomogeneity of the field will be treated in Problem II.4.

B. Spherical Condenser

This is to consist of an inner sphere of radius r_1 and an outer sphere of radius r_2 . The spheres need not be conductors throughout; it suffices if the outer surface of the inner sphere, and the inner surface of the outer sphere are "coated with tin foil." (The same remark applies for the plate condenser.) Let the inner sphere have the charge $+q$, the outer sphere,

the charge $-q$. The field is spherically symmetrical— E and D depend only on r and are directed radially. Hence for every r between r_1 and r_2

$$\int D, d\sigma = 4\pi r^2 D = q, \quad (6)$$

$$E_r = \frac{D}{\epsilon} = \frac{q}{4\pi\epsilon r^2}.$$

From E_r we obtain

$$V = \int_{r_1}^{r_2} E_r dr = \frac{q}{4\pi\epsilon} \left(\frac{1}{r_1} - \frac{1}{r_2} \right) = \frac{q}{4\pi\epsilon} \frac{r_2 - r_1}{r_1 r_2}. \quad (7)$$

This leads to

$$K = \frac{q}{V} = 4\pi\epsilon \frac{r_1 r_2}{r_2 - r_1}. \quad (8)$$

FIG. 13. The spherical condenser with its radial field E , D and a voltage $V = \Psi_1 - \Psi_2$.

If we allow r_2 to become infinite we obtain

$$K = 4\pi\epsilon r_1, \quad (8a)$$

i.e. the value for the capacity for this limiting form of spherical condenser which was designated as "rational" in Eq. (7.15a). If, on the other hand, both radii in (8) are permitted to approach infinity while yet their difference $r_2 - r_1 = a$ remains finite, and if only a finite segment F of the two spherical surfaces $4\pi r_1^2$ and $4\pi r_2^2$ is considered, the capacity of this segment becomes according to (8)

$$K = \frac{F\epsilon}{a} \quad (8b)$$

i.e., identical, as it should be, with that of the plate condenser in Eq. (5).

The cylindrical condenser (Leyden jar¹) will be treated in Problem II.5.

C. Capacity of an Ellipsoid of Revolution and of a Straight Piece of Wire

In Eq. (9.4) we have given the potential Ψ of an ellipsoid with the charge q . If we substitute for x, y, z the coordinates of any point of its surface, e.g. one of the two endpoints of its major axis $x = y = 0, z = a$, Ψ assumes the value V , where V is its potential relative to an infinitely distant ground ($\Psi = 0$). If, at the same time, we introduce the minor axis b in place of half the focal separation c , we obtain $c = \sqrt{a^2 - b^2}$. Eq. (9.4) thus becomes²

$$\begin{aligned} \frac{V}{q} = \frac{1}{K} &= \frac{1}{8\pi\epsilon\sqrt{a^2 - b^2}} \log \frac{a + \sqrt{a^2 - b^2}}{a - \sqrt{a^2 - b^2}} \\ &= \frac{1}{4\pi\epsilon\sqrt{a^2 - b^2}} \log \frac{a + \sqrt{a^2 - b^2}}{b}. \end{aligned} \quad (9)$$

For $b \rightarrow a$, in the limit, the capacity (8a) of the sphere is obtained. In a similar manner the capacity of the axially symmetric *ellipsoidal condenser*, consisting of an inner and an outer ellipsoid of the confocal family, may be derived.

On the other hand, if we let $b \rightarrow 0$, our ellipsoid degenerates into a *straight segment* of length $l = 2c$ (focal separation). This may be thought of as representing a straight wire³ of radius $b \rightarrow 0$. Its capacity becomes, according to (9)

$$K = 2\pi\epsilon l / \log \frac{l}{b}. \quad (9a)$$

We will obtain a similar logarithmic formula for the selfinduction of a straight piece of wire (see §15).

D. Energetic Definition of Capacity

The usual elementary definition (2) of capacity may appear rather arbitrary and formal. We attain a physically more significant understanding of it by considering the *energy of the electrostatic field*.

¹ Also known as "Kleist jar," since it was built by the pastor of Kleist in Cammin (Pomerania) and first demonstrated at the Danzig Scientific Society in December 1745. At the beginning of the next year it was demonstrated in Leyden and has hence become internationally famous. In this manner it acquired its present customary name, which is thus purely accidental in origin.

² Compare Kohlrausch, *Praktische Physik*, 12th Ed., p. 631. The factor 4π is missing here (conventional system of units). Obviously the last formula in Eq. (9) results from the preceding one by rationalization of the denominator.

³ Not, it is true, a cylindrical wire, but one getting thinner toward the ends.

We utilize Green's theorem in the form (3.16) of Vol. II:

$$\int \text{grad } U \cdot \text{grad } V \, d\tau + \int U \Delta V \, d\tau = \int U \frac{\partial V}{\partial n} \, d\sigma. \quad (10)$$

U and V are two arbitrary continuous functions. The integration on the left side is extended over an arbitrary region of space, the integration on the right, over its surface; n is the normal to the surface of the space, pointing outward. We put $U = V = \Psi$ and obtain, because of $\Delta \Psi = 0$, $\mathbf{E} = -\text{grad } \Psi$, from (10)

$$\int \text{grad } \Psi \cdot \text{grad } \Psi \, d\tau = \int \mathbf{E}^2 \, d\tau = \int \Psi \frac{\partial \Psi}{\partial n} \, d\sigma. \quad (10a)$$

Let the volume integration on the left be carried out through the region exterior to the two conductors L_1 and L_2 in Fig. 11, the surface integration on the right, over the two conductor surfaces and a sphere K with the very large radius $r = R$. The integral over K vanishes.¹ (10a) then leads to

$$\int \mathbf{E}^2 \, d\tau = \Psi_1 \int_{L_1} \frac{\partial \Psi}{\partial n} \, d\sigma + \Psi_2 \int_{L_2} \frac{\partial \Psi}{\partial n} \, d\sigma. \quad (10b)$$

After multiplication with $\epsilon/2$ we can write instead

$$\frac{1}{2} \int \mathbf{E} \cdot \mathbf{D} \, d\tau = -\frac{1}{2} \left(\Psi_1 \int_{L_1} D_n \, d\sigma + \Psi_2 \int_{L_2} D_n \, d\sigma \right) = \frac{q}{2} (\Psi_1 - \Psi_2) = \frac{1}{2} qV.$$

At the left end of this multiple equation we have the total energy of the volume considered, which we shall call W :

$$W = \int W_e \, d\tau.$$

We then find, with the definition (2) of K ,

$$W = \frac{1}{2} qV = \frac{K}{2} V^2 = \frac{q^2}{2K}. \quad (11)$$

¹ We have, by Gauss's theorem, for an arbitrary system of n conductors L_1, L_2, \dots, L_n , since $\text{div } \mathbf{D} = 0$,

$$0 = \int_K D_n \, d\sigma + \int_{L_1} D_n \, d\sigma + \dots + \int_{L_n} D_n \, d\sigma = \int_K D_n \, d\sigma - \sum_{i=1}^n q_i.$$

If Ψ on K is put equal to Ψ_∞ , it follows that

$$\int_K \Psi \frac{\partial \Psi}{\partial n} \, d\sigma = -\frac{\Psi_\infty}{\epsilon} \int_K D_n \, d\sigma = -\frac{\Psi_\infty}{\epsilon} \sum q_i.$$

In the present case this vanishes because of $q_1 = q, q_2 = -q$. In general, with $\sum q_i \neq 0$, it is only necessary to put $\Psi_\infty = 0$, i.e. to refer the potentials Ψ_i to the zero level at infinity, to make it possible to carry over the following formulas also to unneutral systems. This is to be remembered for section E.

This fundamental relation is reminiscent of the expression for the kinetic energy of a particle in rectilinear motion in terms of its velocity v and its momentum $p = mv$:

$$W = \frac{1}{2} vp = \frac{p^2}{2m} = \frac{m}{2} v^2. \quad (11a)$$

In both cases the energy is factored (see p. 11) into the product of an entity of quantity and one of intensity or expressed by the square of one of these two quantities. The quantity is in one case q , in the other, v , the intensity, V and p , respectively. Comparison of (11) and (11a) shows that the capacity K corresponds to the reciprocal mass $1/m$, which we might call "compliance," in contrast with the "inertia" m . However, the analogy is not very profound and will have to be modified in §33.

We can call (11) an energetic definition of capacity, just as (11a) may serve as energetic definition of inertia.

E. The Capacities of an Arbitrary System of Conductors

If we pass from two conductors L_1, L_2 with charges $\pm q$ to an arbitrary number of conductors L_1, L_2, \dots, L_n with charges q_1, q_2, \dots, q_n , where once more the total charge $\sum_{i=1}^n q_i$ is assumed to be zero, Green's theorem (10a, b) shows directly that the total energy W of the system is the sum of n terms, according to the formula

$$W = \frac{1}{2} \sum_{i=1}^n \Psi_i q_i. \quad (12)$$

Here Ψ_i denotes the constant value of the potential on the conductor L_i . Now, however, Ψ_i depends not only on q_i , but depends *linearly* on all the q_j as well. This follows from the general representation (7.5) of the potential.

In order to perceive this, we rewrite (7.5) in terms of the surface charge ω_j , whose distribution on every conductor L_j we can assume as known, in place of the volume charge ρ , and put $\omega_j = q_j \omega'_j$, where ω'_j is the distribution of unit charge on L_j (in the presence of the remaining conductors!). Then (7.5) becomes

$$\Psi_i = \sum_{j=1}^n q_j H_{ij}. \quad (13)$$

The coefficients which appear here,

$$H_{ij} = \frac{1}{4\pi\epsilon} \int \frac{\omega'_j}{r_{ij}} d\sigma_j, \quad (13a)$$

are purely geometrical quantities, which depend only on the location of the L_j relative to each other and relative to L_i ; they are independent

of the choice of the origin $r_{ij} = 0$ on L_i , since Ψ_i has the same value for every choice of this point. Eqs. (13) and (13a) thus confirm the linear relation between the Ψ_i and q_i .

The solution of the system (13) of n equations for the n charges q_i yields

$$q_i = \sum_{j=1}^n K_{ij} \Psi_j \quad \text{with} \quad K_{ij} = \frac{\Delta_{ij}}{\Delta}. \quad (14)$$

Δ_{ij} is the sub-determinant of the $n \cdot n$ row determinant Δ of the H_{ij} associated with the term i, j . Maxwell calls the H_{ij} "potential coefficients" of the system in art. 87 of his Treatise and the K_{ij} , "capacity coefficients."

Substituting the relations (13) and (14) in (12) yields the *multiple equation*

$$W = \frac{1}{2} \sum \Psi_i q_i = \frac{1}{2} \sum \sum H_{ij} q_i q_j = \frac{1}{2} \sum \sum K_{ij} \Psi_i \Psi_j. \quad (15)$$

which generalizes our earlier Eq. (11). Since W is a quantity determined by the state of the system (the work done in charging the system must be independent of the "path," i.e. the sequence of the individual processes), the K and H fulfill the reciprocity relations

$$K_{ij} = K_{ji}, \quad H_{ij} = H_{ji}. \quad (15a)$$

Capacity and potential coefficients play a role in communications, where complicated systems of interacting conductors are of frequent occurrence. Their theoretical calculation is difficult since it presupposes the solution of the potential problem of the multiconductor system in question. As we have seen, even for two conductors the solution is possible only for particularly simple shapes of the conductors (plane, sphere, ellipsoid). In general approximations are required.

In Problem II.6 we shall discuss the (somewhat complicated) relation between these coefficients and the elementary definition of capacity in Eq. (2).

§11. General Considerations on the Electric Field

The following statements and concepts apply not only to electrostatic, but also to arbitrarily varying fields.

A. The Law of Refraction for the Lines of Force

The boundary conditions applying at the interface between two insulators of different dielectric constant,

$$E_{\text{tang}} \text{ continuous and } D_{\text{norm}} \text{ continuous} \quad (1)$$

(the latter in the absence of surface charge, Eq. (3.11)) show directly that the "angle of incidence" α_1 and the "angle of refraction" α_2 , both measured with respect to the normal to the interface and given by

$$\tan \alpha_1 = \left(\frac{E_{\text{tang}}}{E_{\text{norm}}} \right)_1, \quad \tan \alpha_2 = \left(\frac{E_{\text{tang}}}{E_{\text{norm}}} \right)_2,$$

are related by

$$\frac{\tan \alpha_1}{\epsilon_1} = \frac{\tan \alpha_2}{\epsilon_2}. \quad (2)$$

This "law of refraction of the electric lines of force" deviates from the optical law of refraction not only in the appearance of the tangent instead of the sine, but also in the direction of refraction: *In entering into the electrically denser medium a line of force is refracted away from the normal to the interface.* We here describe the medium with the higher dielectric constant as "electrically denser." If this is medium 2, then it follows from Eq. (2) that

$$\tan \alpha_2 > \tan \alpha_1.$$

Examples of this phenomenon are shown in Figs. 10 (refraction at a plane) and 9 (refraction at a sphere). The conductor (limiting case $\epsilon_2/\epsilon_1 = \infty$) satisfies this law of refraction inasmuch as here generally $\alpha_1 = 0$ (lines of force normal to surface of conductor).

B. On the Definition of the Vectors \mathbf{E} and \mathbf{D}

Now we do not accept the "positivistic" standpoint, according to which only observables may be employed in theoretical physics, but instead are of the opinion that the introduction of not directly observable quantities is justified whenever the resulting conclusions agree with experiment (as in the kinetic theory of gases). Nevertheless we demand that the concepts introduced in a hypothesis may be based at least on an imaginary experiment, i.e. an observational method, even if it cannot be carried out in practice.

In §2 we defined the electric field strength dynamically as the force on a unit test charge. This force can, however, only be measured in air (more generally, in a fluid) by the motion produced by it. Thus the definition fails in the solid body.

In order to define the component of \mathbf{E} at a given point in a given direction s within the solid body we proceed as follows: We drill a *tube* with the direction s in the body at the point in question. The tube is so narrow and so short that it does not appreciably disturb the field elsewhere; it remains empty or is filled with air. According to the boundary condition (1) the field-strength component E_s is the same within it as in the surrounding solid body and as it was originally in the tube. Thus E_s can be measured within the tube on a test body which has been introduced, and by varying the direction of the tube all three components of the vector \mathbf{E} can be ob-

tained. If the field is not stationary, but variable, we must measure more rapidly than the field changes.

Our definition of D in §2 requires supplementation in even greater degree. We described, in Eq. (4), D as the quantity of electricity which, at a given point, has passed through an area F during the excitation of the field, divided by the magnitude of F . More precisely, we obtain in this manner the component D_n of D in the direction of the normal n to F . This explanation is unsatisfying since it does not contain specific directions for measurement. We can, however, obtain such directions by the following imaginary experiment:

We place at the point in question a plate condenser,¹ whose surfaces F are made normal to the n -direction; the space between the plates is to be filled with the surrounding dielectric (if we are dealing with a solid body a slit must be cut into it into which the condenser fits exactly). In view of the boundary condition (1) the value of D_n in the condenser is equal to that in its surroundings and hence also equal to the value of D_n which prevailed before the introduction of the condenser at the point in question. We can now measure D_n on our condenser directly as the surface charge ω on that coating toward which the prescribed direction n points.

In this manner the displacement D also becomes, in a sense, an "observable quantity."

C. The Concept of Electric Polarization; the Clausius-Mossotti Formula

We give up temporarily the purely phenomenological point of view of Maxwell's theory and attempt to construct a molecular model of the dielectric. A molecule consists of positive and negative charges (protons and electrons), but acts as a neutral entity in the absence of a field. With the application of the field the charges are separated and form a dipole.² The induced moment m is proportional to the external field and is a characteristic of the molecule.

Such a moment has the dimension charge · lever arm = QM . If we pass from the single molecule to the sum of the molecular moments "per unit volume" the dimension

$$\frac{QM}{M^3} = \frac{Q}{M^2}$$

¹ If the field is inhomogeneous the condenser must be made adequately small. Its metallic coatings distort the field, but do not disturb the measurement of D_n between the plates.

² We think here of *nonpolar molecules*. The *polar molecules*, which have been studied with great success, both experimentally and theoretically, by Debye, have a dipole even in the absence of a field. The formulas of the text would have to be altered for polar molecules and would show a dependence on temperature. For details see Debye: *Polar Molecules*, Dover, New York, 1945. In analogy to paramagnetism, polar molecules may be called *paraelectric*.

is obtained. It corresponds to the dimension (2.4) of \mathbf{D} . We shall designate this sum $\Sigma \mathbf{m}$ divided by the volume with \mathbf{P} and call it the *polarization*.¹

We shall divide \mathbf{D} into one part which is present even in the absence of the molecules, and another part which is produced by the molecules. The first corresponds to the case of vacuum and is $\mathbf{D}_0 = \epsilon_0 \mathbf{E}$, where \mathbf{E} is the applied, macroscopically measurable field; the second is our polarization \mathbf{P} . Hence we write

$$\mathbf{D} = \mathbf{D}_0 + \mathbf{P} = \epsilon_0 \mathbf{E} + \mathbf{P}. \quad (3)$$

\mathbf{D} is the macroscopically measurable excitation and is hence equal to $\epsilon \mathbf{E}$. Accordingly (3) leads to

$$\mathbf{P} = (\epsilon - \epsilon_0) \mathbf{E}. \quad (4)$$

We also wish to determine \mathbf{P} from the behavior of the molecules in the electric field. In agreement with the notation of Eqs. (9.9)ff. we call this field \mathbf{F} and indicate by this that it differs from the macroscopic field \mathbf{E} . The difference between them results from the effect of the polarized molecules according to the formula

$$\mathbf{F} = \mathbf{E} + \frac{1}{3} \frac{\mathbf{P}}{\epsilon_0}. \quad (5)$$

In order not to interrupt our train of thought we defer proof of this expression to section *D*. The moment \mathbf{m} acquired by the individual molecule is proportional to this \mathbf{F} . We put

$$\mathbf{m} = \alpha \epsilon_0 \mathbf{F}, \quad (6)$$

where α is a constant characteristic of the molecule. Here the molecule is assumed to be isotropic; otherwise \mathbf{m} and \mathbf{F} would not have to have the same direction.

If N is the number of molecules per unit volume, we obtain from (6) and (5):

$$\mathbf{P} = \sum_{\text{unit volume}} \mathbf{m} = N \alpha \epsilon_0 \mathbf{F} = N \alpha \left(\epsilon_0 \mathbf{E} + \frac{1}{3} \mathbf{P} \right). \quad (7)$$

If we substitute here expression (4) for \mathbf{P} and cancel the common factor \mathbf{E} , we find

$$\epsilon - \epsilon_0 = N \alpha \left(\epsilon_0 + \frac{\epsilon - \epsilon_0}{3} \right) = \frac{N \alpha}{3} (\epsilon + 2 \epsilon_0)$$

or, if we pass to the relative dielectric constant ϵ/ϵ_0 :

¹ Every individual moment has the direction of its lever arm as axis. Hence the direction of \mathbf{P} is obtained by the geometric addition of all the \mathbf{m} in the volume considered and passing to the limit of a sufficiently small volume.

$$\frac{\epsilon_{\text{rel}} - 1}{\epsilon_{\text{rel}} + 2} = \frac{N\alpha}{3} \quad (8)$$

This is the Clausius-Mossotti formula. In optics, where ϵ_{rel} is the square of the refractive index, it is known as the Lorenz-Lorentz formula.

To clarify the physical content of Eq. (8), we multiply numerator and denominator with m , the mass of the individual molecule. Thus we obtain, in the product Nm , the mass of unit volume of the dielectric or its *density* and, at the same time, in the quotient α/m , a new constant characteristic of the molecule. Then in Eq. (8) the left side is *proportional to the density*. This assertion can be tested directly on compressed gases for which ϵ_{rel} differs appreciably from 1. For highly diluted gases, where $\epsilon_{\text{rel}} \sim 1$, $\epsilon_{\text{rel}} + 2 \sim 3$, Eq. (8) leads to

$$\epsilon_{\text{rel}} - 1 = N\alpha = \rho \frac{\alpha}{m}. \quad (8a)$$

Historically it may be mentioned that Mossotti, in his paper dating as far back as 1850, treated the molecules as *conducting* spheres, which were assumed to be distributed in some fashion in the imponderable "ether." We know from §9 that an external field F induces a moment M in such a sphere whose magnitude is given by (Eq. (9.10a))

$$M = 4\pi\epsilon_0 a^3 F.$$

Our molecular constant α has then, according to the definition (6), the value

$$\alpha = 4\pi a^3. \quad (9)$$

If this expression is substituted in (8) the right side becomes

$$\frac{4\pi}{3} a^3 N. \quad (9a)$$

This is simply the ratio of the volume of the spheres contained in unit volume to unit volume (dimensionless, as it should be).

We summarize what we have learned about the concept of dielectric displacement which was inadequately explained in §2. D is composed of two parts, a vacuum portion $D_0 = \epsilon_0 E$ and a portion arising from matter P :

$$D = D_0 + P. \quad (10)$$

We call P the polarization of the matter; it is also the electric moment per unit volume of the dielectric. Similarly, the dielectric constant is made up of two parts, its vacuum component ϵ_0 and its component arising from matter $\epsilon_0 \eta$:

$$\epsilon = \epsilon_0(1 + \eta). \quad (11)$$

The material constant η , which is defined as a pure number, is called the *electric susceptibility*. It is pleasant to note that in both Eqs. (10) and (11) the factor 4π , which otherwise occurs in \mathbf{P} and η , is absent as the result of the rational character of our MKSQ-system. In determining \mathbf{P} and η we had to differentiate between the field strength \mathbf{F} acting on the molecule and the macroscopically defined field strength \mathbf{E} ; the difference between them arises from the field of the neighboring molecules.

As already noted on p. 9, the designation "dielectric displacement" for \mathbf{D} really fits only its polarization component \mathbf{P} . In vacuum there is no charge which can be displaced and \mathbf{D} is nevertheless by no means equal to zero. This is the reason why we have preferred (see p. 8) the term "excitation" for \mathbf{D} .

D. Supplement to the Calculation of the Polarization

We are here concerned with the proof of Eq. (5). We consider an arbitrary molecule, surround it with a small sphere whose radius b is nevertheless very great compared to the molecular radius, and remove from the sphere all matter except the one molecule at the center; this molecule is therefore in vacuum. It is thus acted upon by the field strength \mathbf{E} , corresponding to the first term on the right side of (5). The removal of the molecules from the interior of the sphere does not result in a change of the field resulting from the matter present, provided that the molecules were distributed randomly, i.e. that they were not oriented in any way by the molecule under consideration. If we limit ourselves to isotropic dielectrics we can assume this.¹

After exclusion of this sphere we can treat the remaining dielectric as a continuous medium, i.e. neglect its molecular structure and proceed according to Maxwell's phenomenological theory. Hence we shall replace the action of the residual dielectric by charge densities ω on the elements $d\sigma$ of the inner bounding sphere of the cavity of radius b ; here we shall have to determine ω not from the complete \mathbf{D} , but only from its molecular component \mathbf{P} in Eq. (3). Since \mathbf{P} differs from zero only for $r > b$ (in vacuum, for $r < b$, $\mathbf{P} = 0$), ω is not given by the difference of two \mathbf{P} -values (as in (3.11) by that of two \mathbf{D} -values), but directly by $\omega = P_n$. In view of the fact that \mathbf{P} has the same direction as the primary field \mathbf{E} , which shall have the x -direction, we find

$$\omega = P_n = P_x \cos \theta \text{ with } \theta = \text{angle of } n \text{ with respect to } x. \quad (12)$$

According to Coulomb's law (7.7) the contribution of $\omega d\sigma$ to the field strength acting on our molecule at $r = 0$ in the direction of the radius vector is

¹ H. A. Lorentz has proved this also for crystals of cubic structure; for other symmetries, as well as for associating liquids, the assumption in the text is unproved.

$$dF = \frac{\omega d\sigma}{4\pi\epsilon_0 b^2} = \frac{P_z \cos \theta}{4\pi\epsilon_0 b^2} d\sigma \quad (13)$$

and its z -component, with which alone we are concerned,

$$dF_z = \frac{P_z \cos^2 \theta}{4\pi\epsilon_0 b^2} d\sigma. \quad (13a)$$

Integration over the whole sphere, with $d\sigma = b^2 \sin \theta d\theta d\phi$ leads to

$$F_z = \frac{P_z}{4\pi\epsilon_0} \cdot 2\pi \int_0^\pi \cos^2 \theta \sin \theta d\theta = \frac{1}{3} \frac{P}{\epsilon_0}. \quad (14)$$

This corresponds to the second term of the right side of Eq. (5), which is proved herewith.

E. Permanent Polarization

We have assumed so far that the polarization is caused by an external field and vanishes with it. That is not the case in general. We have already noted (p. 73, footnote 2) that permanent electric moments exist on a *molecular* scale. It is true that they compensate each other, particularly in the liquid or gaseous state, because of the thermal disorder in *any finite volume*, so that here also the resulting polarization vanishes with the external field E . However, if a substance made up of such polar molecules (a wax or resin) is liquefied by heating and exposed to a strong electric field, the latter forces the molecular moments largely into its direction. After solidification the substance retains its polarization for a time even if the field is subsequently removed. If the environment could be made completely insulating a substance would be obtained with a macroscopically *permanent electric field*.

Heaviside has christened a substance treated in this manner with the rather forced name "electret," in view of its analogy to the permanent magnet.

The assumption of a completely insulating environment is, however, never satisfied. Even pure, highly diluted air is, because of radioactive emanation and, in particular, because of cosmic radiation, always somewhat ionized and hence conducting. An electret hence tends to lose its effectiveness to the outside in the course of hours or days.

There are however also natural substances with similar properties. We find these among crystals which are asymmetric in structure (crystals with a polar axis). The most familiar example is *tourmalin*. A crystal is in general made up of positively and negatively charged ions which, if there is an imperfect symmetry of structure, have an electric moment in any elementary domain. Depending on the lattice of the crystal, the elementary moments may combine to form a macroscopic moment, which then produces an electric field in its neighborhood.

Such a field can in fact be detected on *fresh fragments* of tourmalin. Since the environment, as noted above, never insulates perfectly, the field decays in the course of a few hours. Surface charges are built up by the conduction currents at the entrance and exit points of the lines of force which then compensate the external field of the interior electric moment. The difference between the electric and magnetic permanent moment consists merely in the fact that there are no such conduction currents in the magnetic field. Hence a steel magnet shows no appreciable change in its field in the course of decades. This difference between electret and magnet is not fundamental, but only quantitative.

The polar asymmetry existing in tourmalin may be produced artificially in other, less asymmetric¹ crystals by subjecting them to a deformation. This distorts the crystal lattice and impresses an electric moment proportional to the deformation. The crystal thus becomes *piezoelectric*. Quartz is the typical representative of this class of substances. It was used by Pierre Curie, as "piezo-quartz," to produce well-defined quantities of electric charge. It is true that here also, because of imperfect insulation, the electric charge decays with a certain finite relaxation time. Of even greater importance in more recent times has been the role of the quartz crystal when vibrating with its characteristic frequency and producing a corresponding oscillatory electric field. Inversely, by applying an alternating field of this frequency it is possible to maintain the characteristic vibration of the quartz at a constant amplitude. In this manner one obtains (Cady) an ideal microscale of time, which plays its well known role in present-day radio engineering.

In all these cases (electret, tourmalin, piezoquartz) the external electric field may be calculated from the inner moment which is assumed to be known. We will omit this, however, since the calculation is quite similar to that of the external field of a permanent magnet, which is carried out below.

§12. *The Field of the Permanent Bar Magnet*

The forces which emanate from certain forms of iron have excited the popular imagination since the earliest times. The Greeks called the carriers of such effects *magnets*.² The Chinese were the first to utilize their interaction with the great magnet "Earth" for geographic orientation on the

¹ The degree of the required asymmetry may be predicted exactly by means of the general rules of Voigt. See Vol. II, §40.

² Apart from *steel* the metals *cobalt* and *nickel*, which are related to iron, show permanent magnetism, similarly the *Heusler alloys*, containing manganese, which adjoins iron in the periodic system. The iron ore $\text{Fe}_3\text{O}_4 \cdot \text{FeO}$ which, crystallizes in a cubic lattice, is known as *magnetite*, the hexagonal FeS (with admixture of Fe_2S_3), as *pyrrhotin* or *magnetic gravel*; both are characterized by permanent magnetism and magnetic anisotropy.

broad expanses of their country. In the 18th Century it was fashionable to attribute all mysterious processes in the human body to "animal magnetism" (Mesmer). Today the importance of the natural or *permanent magnets* is outdistanced by that of the *electromagnets*. In spite of this we shall begin with some consideration of permanent magnets; we shall then be in a position to cover briefly the general properties of the magnetostatic field, in analogy to those of the electrostatic field in §13.

It is true that the nature of the permanent magnets lies outside the range of the Maxwell theory and can be understood only with the aid of atomic physics. It is based on the spin of the electron and its magnetic moment, of which the Maxwell theory is, of course, ignorant. The same remark applies eventually to the electromagnet: the electric currents which produce the electromagnet, unless they are generated electro-dynamically by induction, have their origin in electrochemical processes, which are foreign to the Maxwell theory; only the magnetic fields proceeding from the electromagnet are described by the latter. In similar manner, the fields proceeding from permanent magnets fit into the framework of the Maxwell theory.

We commence with the *magnetization*, which we shall call \mathbf{M} or, to begin with, \mathbf{M}^* , as counterpart to the electric polarization \mathbf{P} ; the analog of our equation of definition (11.3) for \mathbf{P} ,

$$\mathbf{D} = \epsilon_0 \mathbf{E} + \mathbf{P}. \quad (1)$$

would be, from our point of view,

$$\mathbf{H} = \frac{1}{\mu_0} \mathbf{B} + \mathbf{M}^*. \quad (1a)$$

(Here \mathbf{H} and \mathbf{M}^* are "quantities" like \mathbf{D} and \mathbf{P} , \mathbf{B} is an "intensity" like \mathbf{E} ; $1/\mu_0$ corresponds to ϵ_0 , as emphasized in Eq. (4.7)). Solved for \mathbf{B} , Eq. (1a) yields

$$\mathbf{B} = \mu_0(\mathbf{H} - \mathbf{M}^*). \quad (1b)$$

The customary definition of magnetization is, on the other hand, contained in the equation

$$\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M}), \quad (2)$$

which we shall utilize from here on. We shall return to Eq. (1b) in §13D, in discussing diamagnetism. As defined by (2), \mathbf{M} signifies the *part of the excitation derived from matter* and is at the same time the *sum*, referred to unit volume, of the *moments of elementary magnets*, just as \mathbf{P} was a corresponding sum of electrical elementary moments. In the following we shall imagine the distribution of \mathbf{M} within the magnet to be given arbitrarily and shall calculate from the Maxwell equations the corresponding fields of the vectors \mathbf{B} and \mathbf{H} .

We know from §7 that \mathbf{H} is throughout *lamellar*, \mathbf{B} throughout *solenoidal* (free of sources). In view of the absence of sources of \mathbf{B} Eq. (2) leads to the condition

$$\operatorname{div} \mathbf{H} = -\operatorname{div} \mathbf{M}. \quad (3)$$

At a surface of discontinuity of \mathbf{M} the Eq. $\operatorname{div} \mathbf{B} = 0$, which presupposes that \mathbf{B} is continuous and differentiable, is replaced by the condition that the "surface divergence" of \mathbf{B} vanishes; i.e.

$$B_n + B_{n'} = 0, \quad (3a)$$

where n and n' , as in (3.7), denote the normals of the surface of discontinuity pointing toward opposite sides. Applied to the surface of a magnet, at which \mathbf{M} jumps from the external value $\mathbf{M} = 0$ to a value of \mathbf{M} which, in general, differs from zero, (3a) yields in view of (2)

$$H_n + H_{n'} = -M_n. \quad (3b)$$

If, now, $\mathbf{H} = -\operatorname{grad} \Psi$ is substituted in Eqs. (3) and (3b), the differential equation of the problem

$$\Delta \Psi = \operatorname{div} \mathbf{M}, \quad (4)$$

and the surface condition

$$\frac{\partial \Psi}{\partial n} + \frac{\partial \Psi}{\partial n'} = M_n \quad (4a)$$

are obtained. We add, as boundary condition at infinity

$$\Psi = 0. \quad (4b)$$

Since, in the two Eqs. (4) and (4a), the right sides can be assumed to be known, we are dealing here not with a boundary value problem, but, in the sense of §7, Eqs. (10) and (10a), with a simple summation problem. The solution is

$$4\pi\Psi = -\int \frac{\operatorname{div} \mathbf{M}}{r} d\tau - \int \frac{M_n}{r} d\sigma. \quad (5)$$

The first term sums all magnetic volume densities ρ_m in the *interior* of the magnet, the second all surface densities ω_m on its *boundary*. The negative signs result from the fact that, according to (4) and (4a)

$$\rho_m = -\operatorname{div} \mathbf{M}, \quad \omega_m = -M_n.$$

(If we had continued to employ $\mathbf{M}^* = -\mathbf{M}$ in our calculation, the signs would have been positive, as in electrostatics.) We consider two special cases: *a.* homogeneous magnetization parallel to the bar axis, *b.* magnetization increasing from zero toward the center, also parallel to the bar axis.

For *a* the first integral on the right in Eq. (5) vanishes because of $\text{div } \mathbf{M} = 0$, for *b*, the second one because of $M_n = 0$.

a. Only the two end surfaces contribute to the surface integral in (5) since the normal component of \mathbf{M} vanishes, by assumption, on the sides. The pole strengths of the magnet are thus, in a sense, uniformly distributed over the end surfaces; if the cross-section area is F the two total pole strengths are $\pm P = \pm FM$.

Approximate integration of (5) for *large* distance of the reference point from the magnet (see Fig. 14: p , r_1 , r_2 distance of reference point from bar axis and from the centers of the end surfaces, respectively, z , coordinate

FIG. 14. Bar magnet, magnetized longitudinally. Point of reference on the outside.

of the reference point parallel to the bar axis, measured from its center, $2l$, length of bar) leads to

$$4\pi\Psi = -MF \left(\frac{1}{r_1} - \frac{1}{r_2} \right) \text{ with } \begin{aligned} r_1^2 &= (z - l)^2 + p^2 \\ r_2^2 &= (z + l)^2 + p^2 \end{aligned} \quad (6)$$

Series expansion yields

$$\begin{aligned} \frac{1}{r_1} &= \frac{1}{r_0} \left(1 + \frac{1}{2} \frac{2zl + l^2}{r_0^2} + \dots \right), \\ \frac{1}{r_2} &= \frac{1}{r_0} \left(1 - \frac{1}{2} \frac{2zl + l^2}{r_0^2} + \dots \right), \end{aligned}$$

with $r_0 = \sqrt{z^2 + p^2}$ = distance of reference point from center of bar. Hence, according to (6),

$$4\pi\Psi = -2lP \frac{z}{r_0^3} = 2lP \frac{\partial}{\partial z} \frac{1}{r_0}. \quad (6a)$$

As was to be expected, the external action of the magnet for distances $\gg 2l$ is that of a dipole with the lever arm $2l$ and pole strength $P = MF$.

The same representation by the surface integral in Eq. (5) applies for the interior of the bar, but this requires a more careful evaluation. For the sake of brevity we limit ourselves to the center line of the bar and

FIG. 15. Demagnetization of a uniformly magnetized bar. In the drawing it is assumed that $a = l/4$.

assume the cross section to be circular (a = radius, ρ = distance of the point of integration from the center of the end surfaces). We then find

$$4\pi\Psi = 2\pi M \left\{ \int_0^a \frac{\rho d\rho}{r_1} - \int_0^a \frac{\rho d\rho}{r_2} \right\}, \quad (7)$$

$$r_1^2 = (l - z)^2 + \rho^2, \quad r_2^2 = (l + z)^2 + \rho^2.$$

The evaluation yields, since $0 \leq |z| \leq l$:

$$\Psi = \frac{M}{2} [\{ (l - z)^2 + a^2 \}^{\frac{1}{2}} - \{ (l + z)^2 + a^2 \}^{\frac{1}{2}} + 2z], \quad (7a)$$

$$H = -\frac{\partial\Psi}{\partial z} = \frac{M}{2} \left[\frac{l - z}{\{ (l - z)^2 + a^2 \}^{\frac{1}{2}}} + \frac{l + z}{\{ (l + z)^2 + a^2 \}^{\frac{1}{2}}} - 2 \right] \quad (7b)$$

Since l is in any case many times larger than a , we obtain

$$H \sim 0, \quad \frac{\partial H}{\partial z} \sim 0 \quad \text{for } z = 0$$

$$H = -\frac{M}{2}, \quad \frac{\partial H}{\partial z} = \mp \frac{M}{2} \frac{1}{a} \quad \text{for } z = \pm l;$$

as shown in Fig. 15, there is a sharp decrease of $-H$ at the two ends of the bar and a vanishing of a high order at the center of the bar. The sign of H

is opposite to that of \mathbf{M} ; \mathbf{H} has what is commonly expressed as a "demagnetizing action." This is seen also in the pattern of \mathbf{B} . Though \mathbf{B} attains almost the full magnitude $\mu_0 \mathbf{M}$ at the center of the bar, it is only half as large at the ends, the same of course, inside and outside of the bar.

b. Let \mathbf{M} be constant in every cross section of the bar, but be dependent on z in such fashion that \mathbf{M} vanishes at the ends $z = \pm l$ and increases parabolically toward the center:

$$M = \frac{C}{2} \left(1 - \frac{z^2}{l^2}\right), \quad \text{div } \mathbf{M} = -\frac{Cz}{l^2}. \quad (8)$$

As already mentioned, the surface integral in (5) vanishes here, and only the volume integral remains to be calculated.

With ξ, ρ, ψ for the coordinates of the point of integration, and z, p, φ for the coordinates of the reference point Eq. (5) yields:

$$4\pi\Psi = \frac{C}{l^2} \iiint \frac{\xi}{r} d\xi d\sigma, \quad (9)$$

$$r^2 = (z - \xi)^2 + p^2 + \rho^2 - 2p\rho \cos(\varphi - \psi), \quad d\sigma = \rho d\rho d\psi.$$

The field at a distance here, just as in case *a*, is that of a dipole. If the average magnetization \bar{M} is computed for the length of the bar and if as in *a*, we put $\bar{M}l = P$, the moment of the dipole field becomes, as in (6a), $2lP$.

Within the bar, in particular on the bar axis $p = 0$, we obtain from (9), by carrying out the integrations with respect to ρ and ψ

$$\begin{aligned} \Psi &= \frac{C}{2l^2} \int_{-l}^{+l} \xi d\xi \left[\{(z - \xi)^2 + a^2\}^{\frac{1}{2}} - |z - \xi| \right] \\ &= \frac{C}{2l^2} \int_{-l}^{+l} \xi d\xi \{(z - \xi)^2 + a^2\}^{\frac{1}{2}} - \frac{C}{2l^2} \left(\frac{1}{3} z^3 - zl^2 \right) \end{aligned} \quad (10)$$

and

$$\begin{aligned} H &= -\frac{\partial \Psi}{\partial z} = \frac{C}{2l^2} \int_{-l}^{+l} \xi d\xi \frac{\partial}{\partial \xi} \{(z - \xi)^2 + a^2\}^{\frac{1}{2}} + \frac{C}{2l^2} (z^2 - l^2) \\ &= \frac{C}{2l} \left[\{(z - l)^2 + a^2\}^{\frac{1}{2}} + \{(z + l)^2 + a^2\}^{\frac{1}{2}} + \frac{z^2 - l^2}{l} \right] \\ &\quad - \frac{C}{2l^2} \int_{-l}^{+l} |(z - \xi)^2 + a^2|^{\frac{1}{2}} d\xi. \end{aligned} \quad (11)$$

The symbol $||$ in the last integral indicates that the sign of this square-root, just as that of the preceding ones, is to be positive.

We will show that, just as in the case of uniform magnetisation, \mathbf{H} is *nearly zero* (of the order a/l) everywhere except at the ends of the bar. Ex-

clusion of the bar ends signifies $a \ll l - |z|$. We may then neglect a in (11) and obtain

$$H = \frac{C}{2l} \left[l - z + l + z + \frac{z^2 - l^2}{l} - \frac{z^2 + l^2}{l} \right], \quad (11a)$$

i.e. zero (more exactly, vanishing to the order Ca/l). For $z = \pm l$, i.e. at the bar ends, H is small to the same order of magnitude. This does not apply, however, to dH/dz . This is given by¹

$$\frac{dH}{dz} = \frac{C}{2l} (1 + \dots). \quad (12)$$

Thus H has *positive* values, appreciably differing from zero, only in a small region near the two ends of the bar. This is illustrated by Fig. 16.

FIG. 16. Demagnetization of a bar magnetized according to the formula $M = \frac{C}{2} \left(1 - \frac{z^2}{l^2} \right)$. As in Fig. 15, $a = l/4$.

Also here H has a "demagnetizing action," i.e. is opposite to the impressed moment M . B/μ_0 approximates the full value of M in the whole middle portion of the bar and deviates from it slightly only at the ends.

The fact that H always acts in the direction of demagnetization (for arbitrary distribution of the magnetization and for any shape of the magnet) may be recognized from the following: The lines of force (B -lines) are closed

¹ Differentiation of (11) leads to the exact elementary formula

$$\frac{dH}{dz} = \frac{C}{2l^2} \left\{ \frac{z(z-l) + a^2}{\sqrt{(z-l)^2 + a^2}} - \frac{z(z+l) + a^2}{\sqrt{(z+l)^2 + a^2}} + 2z \right\}$$

from which (12) is readily derived. The dots in (12) indicate terms of the order a/l . The upper positive sign in (12) refers to $z = +l$ and positive dz ; the gradient of H toward the *interior* of the bar (negative dz) is thus *negative*, just as at the other end of the bar.

because of $\text{div } \mathbf{B} = 0$ and part of their path lies in the interior, and part lies in the region outside of the magnet. We carry out a line integral of \mathbf{H} over such a closed line of force in the positive \mathbf{B} -direction. Then we obtain, because of the lamellar character of \mathbf{H} , as for any closed path,

$$\oint \mathbf{H} \cdot d\mathbf{s} = 0. \quad (12a)$$

The part of the integral over the path *outside* of the magnet, where the directions of \mathbf{H} and \mathbf{B} coincide, is *positive*; hence the part of the integral over the path *within* the magnet must be negative:

$$\int_{\text{inside}} \mathbf{H} \cdot d\mathbf{s} < 0 \quad (12b)$$

On the other hand, the integral of \mathbf{B} over the same part is, by assumption, positive. Eq. (2) shows that this applies even more to the integral of \mathbf{M} :

$$\int_{\text{inside}} \mathbf{M} \cdot d\mathbf{s} = \frac{1}{\mu_0} \int_{\text{inside}} \mathbf{B} \cdot d\mathbf{s} - \int_{\text{inside}} \mathbf{H} \cdot d\mathbf{s} > 0. \quad (12c)$$

The two inequalities (12b, c) for \mathbf{H} and \mathbf{M} show together that \mathbf{H} has within the magnet, along any line of force, on the *average* the *opposite* direction of \mathbf{M} .

We have dealt with the preceding rather arbitrarily selected problem in such detail because most textbooks contain little of a quantitative nature regarding the vectors \mathbf{B} , \mathbf{H} , and \mathbf{M} in the interior of a magnet. We have seen that if \mathbf{M} is known \mathbf{H} may in principle be evaluated, in accord with the rules of potential theory, by a simple summation, whereupon \mathbf{B} is also known. It is true that the assumption of a known distribution of \mathbf{M} is not fulfilled in practice. Bar magnets are therefore unsuited for a practical study of ferromagnetism: we shall return to this later.

Although our calculation was limited to the center line of the bar magnet, Figs. 17 and 18 give quantitative information¹ regarding the shape of the lines of force and lines of excitation throughout the interior of a uniformly magnetized bar magnet: The \mathbf{B} -lines are drawn into the interior, the \mathbf{H} -lines pushed out of it. On the outside the two sets of lines coincide, of course, since $\mathbf{B} = \mu_0 \mathbf{H}$.

The *ring magnet*, provided with a narrow gap, is both simpler and of greater practical importance than the bar magnet. Because of the equivalence of all cross sections the magnetization may here be regarded as uniform, so that $\text{div } \mathbf{M} = 0$, and \mathbf{M} is everywhere parallel to the center line.

¹ These figures were kindly prepared by Prof. J. Jaumann, by a graphical method which was developed by Maxwell for the numerous line-of-force patterns at the end of his *Treatise* and which is widely employed by electrical engineers; see also art. 123 of the *Treatise*.

A "magnetic coating" exists only on the gap faces; between them a magnetic field is formed which is similar in geometry to the electric field in a plate condenser. This applies not only to a permanent ring magnet, but almost identically to the ring-shaped electromagnet with an iron core.

Referring once more to Eq. (12a), we consider the line integral of the excitation H carried out over the center line of the ring. It may be divided into two parts, the short section through the air gap of thickness a , which we shall traverse in the positive direction of the magnetic condenser field

FIG. 17. Lines of force of a uniformly magnetized bar magnet; they are drawn into the interior.

FIG. 18. Lines of excitation of a uniformly magnetized bar magnet; they are pushed out of the interior.

which exists there, and the long part through the ring-shaped iron core of length l , on which the integration is to be carried out in the same sense. We put $H = H_0$ in the gap and $H = H_r$ in the iron core, respectively. Eq. (12a) yields

$$l \cdot H_r = -a \cdot H_0.$$

Thus a "demagnetization" of the iron core goes with the magnetization of the air gap. We have here the same state of affairs as in Figs. 15 and 16, only in a much simpler and more obvious form.

We return once more to the bar magnet and to the definition of its pole strength P . From our point of view it is a *quantity* of magnitude

$$P = \oint H_n d\sigma, \quad (13)$$

where the closed surface σ envelops, starting from the center of the bar, the one or the other half of the bar in arbitrary manner. This definition of P corresponds to the definition (7.2) of the magnetic volume density $\rho_m = \text{div } \mathbf{H}$ and states that P is equal to the sum of all magnetic quantities $\rho_m d\tau$ which are present in the half of the bar in question.

In contrast to this the pole strength is often defined as *intensity* in the literature and described in terms of the magnetic flux. We shall call the pole strength so defined \bar{P} and write

$$\bar{P} = \int B_n d\sigma \quad (14)$$

The surface σ cannot now be closed since otherwise, in view of $\text{div } \mathbf{B} = 0$, $\bar{P} = 0$. Rather, the cross section q passing through the center of the bar must be *excluded* from the integration; or, as an alternative, the integration is carried out *only* over this cross section with reversed sign of the normal n :

$$\bar{P} = \int B_n dq. \quad (14a)$$

It may readily be shown with the aid of (13) and (14) that then, very nearly,

$$\bar{P} = \mu_0 P \quad (15)$$

where μ_0 is the permeability of the surroundings.¹ In fact, we convinced ourselves above that \mathbf{H} very nearly vanishes in the central cross section, so that the closed integration in (13) may be replaced by the open integration in (14), where we may put $H_n = B_n/\mu_0$. The definitions (13) and (14) would thus be practically equivalent in the presence of a plane of symmetry (which, incidentally, exists also for the horseshoe magnet). However, for asymmetric shape or asymmetric magnetization relation (14) fails and only definition (13) remains meaningful. It is also recommended by the fact that it exactly corresponds to the definition of charge:

$$e = \oint D_n d\sigma.$$

¹ While P , according to (13), may be regarded as an *internal* property of the magnet, \bar{P} also depends, according to (15), on its surroundings. This evidently arises from the fact that an environment differing from vacuum contains itself magnetic moments which, quite understandably, are included in \bar{P} . See in this respect Phys. Z. 1935, p. 424.

§13. General Considerations on Magnetostatics and Its Boundary-Value Problems

While, in §12, we have considered only the proper field of permanent magnets, we shall now approach the behavior of *arbitrary bodies* in an *outside field*, arising from either permanent magnets or electromagnets. The laws which apply here closely parallel those of electrostatics; however, contrary to our classification of the field vectors into entities of quantity and intensity, \mathbf{H} here corresponds to \mathbf{E} , \mathbf{B} to \mathbf{D} . This follows from the familiar fundamental equations, e.g. (7.2), (7.9), and (7.9a)

$$\text{curl } \mathbf{H} = 0, \quad \mathbf{H} = -\text{grad } \Psi, \quad (1)$$

$$\text{div } \mathbf{B} = 0, \quad \text{div } \mathbf{H} = \rho_m \quad (2)$$

and the boundary conditions at an interface:

$$\text{continuity of the tang. comp. of } \mathbf{H} \text{ and the normal comp. of } \mathbf{B}. \quad (3)$$

The line integral of the magnetic excitation, which, by (1), is independent of the path, i.e. depends only on the endpoints A, B , we shall call magnetomotive force and designate by U_{AB} , in analogy to V_{AB} in §2, U_{AB} bears following relation to the magnetic potential:

$$U_{AB} = \int_A^B H_s ds = \Psi_A - \Psi_B. \quad (4)$$

The "loop magnetomotive force" is given by

$$U_{A \rightarrow B} = \oint H_s ds = 0, \quad (5)$$

irrespective of the manner in which the closed path is traversed, whether it passes through magnetized material or through air.

We designate the "induction" or the "flux" through an arbitrarily shaped surface σ by the usual symbol Φ :

$$\Phi = \int B_n d\sigma. \quad (6)$$

In view of (2), Φ depends only on the boundary curve of the surface σ , i.e. is identical for all surfaces passing through the same boundary curve. For a closed surface it vanishes, of course:

$$\Phi = \oint B_n d\sigma = 0. \quad (6a)$$

We shall now discuss briefly the magnetic analogs of the topics dealt with in §§11, 10, and 9.

A. The Law of Refraction of the Lines of Magnetic Excitation

The law of refraction (11.2) of the magnetic lines of *force* may be carried over to the lines of magnetic *excitation*, but applies also to the magnetic lines of *force* because of the identical direction of \mathbf{H} and \mathbf{B} . If the angles α_1 and α_2 have the same meaning as before,

$$\frac{\tan \alpha_1}{\mu_1} = \frac{\tan \alpha_2}{\mu_2}. \quad (7)$$

We prefer to speak here of the lines of *force* because they, unlike the lines of *excitation*, are individually continued into the second medium. We may therefore say: Every individual \mathbf{B} -line is refracted away from the normal in entering the more permeable medium (e.g. $\mu_2 > \mu_1$).

B. Definition of the Vectors \mathbf{H} and \mathbf{B} , Particularly in Solid Bodies

To measure the component of \mathbf{H} in a given direction at a given point by means of an imaginary experiment a short narrow tube must be drilled, to measure \mathbf{B} , a thin slit must be cut. Within the cavity (vacuum or filled with air) so prepared a deflection experiment can be carried out and \mathbf{B} or $\mathbf{H} = \mathbf{B}/\mu_0$, respectively, be determined from the force, so measured, acting on a test body.¹

C. The Magnetization \mathbf{M} in Any Non-Ferromagnetic Substance

As in Eq. (12.2) we define \mathbf{M} by

$$\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M}) \quad (8)$$

and set

$$\mathbf{M} = \kappa \mathbf{H}. \quad (8a)$$

κ is a material constant, the *magnetic susceptibility* of the substance. Physically more significant is the *molar susceptibility*

$$\chi = \kappa M / \rho, \quad (8b)$$

where M is the mass of a mole, the so-called molecular weight of the substance, and ρ is its density. (As we know, the proportionality between \mathbf{M} and \mathbf{H} does not in general apply for ferromagnetic materials). $\mathbf{B} = \mu \mathbf{H}$ and Eqs. (8) and (8a) lead to

$$\frac{\mu}{\mu_0} = 1 + \kappa, \quad \kappa = \frac{\mu - \mu_0}{\mu_0}. \quad (9)$$

¹ A magnet needle, a wire traversed by current, or, eventually, a bismuth spiral; from our standpoint such an experiment yields the intensity \mathbf{B} directly; from it is determined, in the tube experiment, the proportional quantity \mathbf{H} . For details see also §11B.

The conventional form of Eqs. (8) and (9) is marred by the appearance of 4π as factor of \mathbf{M} and κ (see our corresponding remark regarding \mathbf{P} and η in connection with Eq. (11.3)). We must hence note that in the use of experimental data employing conventional notation the factor 4π must be added. That is indicated in the small table in the following section D.

D. Dia- and Paramagnetism

Diamagnetism corresponds to *dielectricity*; like the latter it is a general property of ponderable matter and *independent of temperature*. Both owe their origin to the electronic (and nuclear) structure of matter. *Paramagnetism* occurs only for magnetically polar molecules, i.e. molecules which have a magnetic moment of their own. (Electrically polar molecules were discussed on p. 73.) Paramagnetism is temperature-dependent and hence has a statistical origin. This phenomenon, like ferromagnetism, lies outside of Maxwell's theory. The paramagnetic susceptibility obeys the *law of Curie and Langevin*:

$$\chi = \frac{C}{T}, \quad \begin{array}{l} C = \text{Curie constant} \\ T = \text{absolute temperature} \end{array} \quad (10)$$

This dependence on the temperature indicates that increasing thermal agitation interferes with the alignment of the magnetic moments in the field direction, decreasing thermal agitation favors it.

In the diamagnetic case we have

$$\mu < \mu_0, \quad \kappa < 0 \quad (11)$$

This apparent difference from the dielectric case

$$\epsilon > \epsilon_0, \quad \eta > 0 \quad (11a)$$

is explained in the manner already indicated following Eq. (4.7): the true analog of ϵ is not μ , but $1/\mu$. The magnetic parallel of the statement $\epsilon > \epsilon_0$ is thus

$$\frac{1}{\mu} > \frac{1}{\mu_0}, \quad \mu < \mu_0, \quad \kappa < 0$$

corresponding to (11). The negative sign of \mathbf{M}^* in Eq. (12.1b) is also related to this. For, if we put $\mathbf{M}^* = \kappa^* \mathbf{H}$, the susceptibility κ^* so defined becomes, in view of $\mathbf{M}^* = -\mathbf{M} = -\kappa \mathbf{H}$,

$$\kappa^* = -\kappa > 0$$

in the diamagnetic case corresponding to $\eta > 0$ in (11a). The introduction of \mathbf{M}^* , which was suggested previously but immediately given up above, thus corresponds in fact to the inner relationship of dielectricity and diamagnetism.

For paramagnetism, we have, in contrast with (11),

$$\mu > \mu_0, \quad \kappa > 0. \quad (11b)$$

The numerical value of κ is very small for both paramagnetic and diamagnetic materials. The following represent extreme values:

Paramagnetism	Diamagnetism
$\kappa = +4\pi \cdot 1.8 \cdot 10^{-6}$ for O_2	$\kappa = -4\pi \cdot 0.007 \cdot 10^{-6}$ for N_2
$\kappa = +4\pi \cdot 782 \cdot 10^{-6}$ for Pd	$\kappa = -4\pi \cdot 160 \cdot 10^{-6}$ for Bi

The paramagnetic values refer here to 18°C .

The Clausius-Mossotti law, Eq. (11.8), with ϵ replaced by μ , gives the dependence on density.

E. Soft Iron as Analog to the Electric Conductor

With certain restrictions soft iron may be classified with the paramagnetic substances. The initial value of the permeability (referred to the value for vacuum) is several thousandfold, according to the variety of iron; for increasing H , B approaches a saturation value in the neighborhood of 21,000 gauss. The equation $B = \mu H$ must hence be replaced by the functional relationship $B = B(H)$, as was mentioned already on p. 21.

Just as we noted on p. 61, that the electric conductor corresponds, with respect to the electrostatic boundary conditions and boundary-value problems, to the limiting case $\epsilon \rightarrow \infty$ of a dielectric, so we may regard soft iron ($\mu \rightarrow \infty$) as the magnetostatic analog of the electric conductor. Eq. (7) shows, in fact, that the magnetic lines of force are perpendicular to the surface of soft iron ($\alpha_1 \rightarrow 0$ follows from $\mu_2 \rightarrow \infty$). If two such pieces of soft iron Fe_1 and Fe_2 are placed at different magnetic potentials (e.g. if they are placed on the poles of a horseshoe magnet), the H -lines between them are similar to the E -lines in Fig. 11. Thus, in a sense, a magnetic condenser is obtained.

In engineering applications it is also convenient to introduce the concept of "magnetic resistance" and to employ a "magnetic Ohm's law."

F. Specific Boundary-Value Problems

The methods of solution developed in §9 may be taken over directly into magnetostatics; an example is the imaging at a plane, where it makes no difference whether the induction in halfspace 2 in Fig. 10 is produced by a single pole or a dipole in halfspace 1. The same remark applies for the method of reciprocal radii as applied to a sphere (previously regarded as a conductor, here as consisting of soft iron).

We refer in particular to the sphere in a uniform magnetic field. Within there is a uniform field F_2 , while outside the field becomes nonuniform, through the superposition on the original field F of the field of a virtual

magnetic moment M at the center of the sphere, with its axis in the field direction. ("Field" here denotes "excitation field".) The values of F_2 and M are, by (9.14),

$$F_2 = \frac{3}{\mu + 2} F, \quad M = -\frac{\mu - 1}{\mu + 2} a^3 \cdot 4\pi\mu_0 F. \quad (12)$$

Here a = radius of sphere, $\mu = \mu_2/\mu_0$ = relative permeability of the sphere referred to its surroundings (air). F_2 is stronger than F for diamagnetic substances, weaker for paramagnetic materials. In the interior of soft iron $H \cong 0$, just as in the electric conductor.

G. The Uniform Field within an Ellipsoid of Revolution

The solution (9.13) for the sphere, translated into magnetic terms, becomes, after substitution of the values (12)

$$\Psi_1 = -F \left(r - \frac{\mu - 1}{\mu + 2} \frac{a^3}{r^2} \right) \cos \theta, \quad \Psi_2 = -\frac{3}{\mu + 2} F r \cos \theta. \quad (13)$$

This solution satisfied the boundary conditions

$$\Psi_1 = \Psi_2, \quad \frac{\partial \Psi_1}{\partial r} = \mu \frac{\partial \Psi_2}{\partial r} \quad (13a)$$

because the factor $\cos \theta$, which varies over the sphere, factors out of these equations. We will show that a solution of the same form is valid for the ellipsoid.

In passing from the sphere to the ellipsoid we must first replace the spherical polar coordinates r, θ by corresponding elliptical coordinates, which we shall call u, v . We proceed here from the well-known parametric representation of the ellipse (instructions for Problem II.1), in which we write for the principal axes a and b

$$\begin{aligned} a &= c \cosh u, & b &= c \sinh u, \\ c &= \sqrt{a^2 - b^2} = \text{independent of } u. \end{aligned} \quad (14)$$

Rotation about the long axis (z -axis, angle of rotation φ) produces a family of elongated confocal ellipsoids of revolution, corresponding to Eq. (19.17a) in Vol. II:

$$\frac{z^2}{c^2 \cosh^2 u} + \frac{x^2 + y^2}{c^2 \sinh^2 u} = 1. \quad (14a)$$

Let the ellipsoid considered by us be one of these, namely that with the parameter $u = u_0$. The relation between x, y, z and the elliptical coordinates u, v, φ is the following:

$$\begin{aligned}
 z &= c \cosh u \cos v, \\
 x &= c \sinh u \sin v \cos \varphi, \\
 y &= c \sinh u \sin v \sin \varphi.
 \end{aligned}
 \tag{15}$$

The expression for the line element ds consequently is given by

$$\frac{ds^2}{c^2} = (\cosh^2 u - \cos^2 v)(du^2 + dv^2) + \sinh^2 u \sin^2 v d\varphi^2. \tag{15a}$$

According to the rule (3.9b) in Vol. II the potential equation in these coordinates, becomes:

$$\frac{\partial}{\partial u} \left(\sinh u \sin v \frac{\partial \Psi}{\partial u} \right) + \frac{\partial}{\partial v} \left(\sinh u \sin v \frac{\partial \Psi}{\partial v} \right) = 0 \tag{16}$$

if the potential is independent of the cyclic coordinate φ .
One solution is the uniform field, parallel to the major axis,

$$\Psi = \frac{z}{c} = \cosh u \cos v. \tag{17}$$

We seek a second solution of such form that the factor $\cos v$ which varies over the surface of the ellipsoid corresponding to the factor $\cos \theta$ giving geographic latitude on the sphere, is cancelled out in the boundary conditions. We write for this second solution

$$\Psi = f(u) \cos v \tag{17a}$$

and obtain from (16) for the differential equation

$$\frac{d}{du} (\sinh u f'(u)) - 2 \sinh u f(u) = 0 \tag{17b}$$

which is evidently satisfied by the uniform field $f = \cosh u$. Following a general rule,¹ we place the desired second solution equal to the product of the known first solution and an unknown function $U(u)$:

$$f(u) = \cosh u U(u). \tag{18}$$

The resulting differential equation for $U(u)$

$$U'' + \frac{3 \sinh^2 u + 1}{\sinh u \cosh u} U' = 0$$

can be integrated directly and yields, with A and B as integration constants,

¹ It corresponds to the method of solving an algebraic equation with one known root.

$$U'(u) = \frac{A}{\sinh u \cosh^2 u}, \quad U(u) = \frac{A}{2} \log \frac{\cosh u - 1}{\cosh u + 1} + \frac{A}{\cosh u} + B,$$

$$f(u) = A \left(1 + \frac{\cosh u}{2} \log \frac{\cosh u - 1}{\cosh u + 1} \right). \quad (18a)$$

In the last formula we have omitted the term multiplied with B , since this corresponds to our known solution representing a uniform field.

We now complete our expression (17) for the external field by the addition of (18a) and retain the uniform-field expression (17) for the internal field:

$$\Psi_1 = F \cosh u \cos v + A \left(1 + \frac{\cosh u}{2} \log \frac{\cosh u - 1}{\cosh u + 1} \right) \cos v, \quad (19)$$

$$\Psi_2 = F_2 \cosh u \cos v.$$

We regard the constant F of the external field, which has been added, as known; the two constants A and F_2 are to be determined from the boundary conditions. These are identical with (13a), with dr replaced by du (more exactly, by ds_u , the line element in the direction of the normal to the ellipsoid,

$$ds_u = c \sqrt{\cosh^2 u - \cos^2 v} du,$$

where, however, the square root cancels out in the second Eq. (13a)). The boundary conditions demand hence for $u = u_0$

$$F + A \left(\frac{1}{\cosh u_0} + \frac{1}{2} \log \frac{\cosh u_0 - 1}{\cosh u_0 + 1} \right) = F_2, \quad (19a)$$

$$F + A \left(\frac{\cosh u_0}{\sinh^2 u_0} + \frac{1}{2} \log \frac{\cosh u_0 - 1}{\cosh u_0 + 1} \right) = \mu F_2. \quad (19b)$$

Subtraction yields the somewhat simpler relation

$$A = \cosh u_0 \sinh^2 u_0 (\mu - 1) F_2$$

and substitution thereof in (19a)

$$F_2 \left\{ 1 - (\mu - 1) \sinh^2 u_0 \left(1 + \frac{1}{2} \cosh u_0 \log \frac{\cosh u_0 - 1}{\cosh u_0 + 1} \right) \right\} = F. \quad (20)$$

The field strength F_2 inside is thus expressed in terms of the known strength of the original external, homogeneous field.

If we utilize Eqs. (14) and denote by a, b, c the principal axes and focal distance from the center of our ellipsoid $u = u_0$, we may write instead of (20)

$$F_2 \left\{ 1 - (\mu - 1) \frac{b^2}{c^2} \left(1 + \frac{1}{2} \frac{a}{c} \log \frac{a - c}{a + c} \right) \right\} = F \quad (20a)$$

or, in terms of the numerical eccentricity $e = c/a$ and the magnetic susceptibility $\kappa = \mu - 1$:

$$F_z \left\{ 1 + \kappa \frac{1 - e^2}{e^3} \left(\frac{1}{2} \log \frac{1 + e}{1 - e} - e \right) \right\} = F. \quad (21)$$

We note here that:

a. for $\kappa = 0$ we have of course

$$F_z = F; \quad (21a)$$

b. for $e \rightarrow 0$ series expansion of (21) leads to

$$F_z = F / \left(1 + \frac{\kappa}{3} \right). \quad (21b)$$

The field inside is *weaker* than outside for paramagnetic bodies, stronger for diamagnetic bodies.

c. The same applies for $e \rightarrow 1$. If we put $\eta = 1 - e$, (21) yields

$$F_z = F / \left\{ 1 + \kappa \eta \left(\log \frac{2}{\eta} - 2 \right) \right\}. \quad (21c)$$

In the limiting case b the ellipsoid becomes nearly *spherical*; in fact, (21b) is identical with Eq. (12) for the sphere. In the limiting case c the ellipsoid degenerates to a *thin rod*.

The problem treated here is usually related to a famous formula of Dirichlet for the gravitational potential of a triaxial ellipsoid uniformly filled with matter. This procedure is mathematically more elegant than ours, but is rather indirect. We have preferred the direct method of the magnetic boundary-value problem because it appears to give us more profound insight into the physical conditions.

Our solution of the magnetic problem is of course transferable without change to the corresponding electrostatic problem.

H. The So-Called Demagnetization Factor

The ellipsoid and its limiting forms (sphere, rod) is the *standard shape* of the magnetic test body because it alone possesses a uniform and easily calculable internal field when introduced into an originally uniform external field. For other shapes the determination of the internal field leads to a practically insoluble *boundary-value problem*; the internal field is by no means uniform, but varies from point to point.

It is clear, however, that all questions concerned with the magnetic properties of the material depend on the internal field F_i . This field interacts with the molecular components of the material directly, while the *external* field F has no direct effect on them. Accordingly we may express our Eq. (8a) more precisely by

$$M = \kappa F_i. \quad (22)$$

Such questions become particularly important with *ferromagnetic* materials, where the differences between the external and the internal field (F and F_i in our present notation) are extremely large; for para- and diamagnetic materials they are negligible because of the smallness of κ . Since for ferromagnetic, as for paramagnetic, materials $F_i < F$, we write, with P denoting a numerical factor,

$$F_i = F - PM \quad (22a)$$

or, in view of (22),

$$F_i = F - \kappa P F_i, \quad (22b)$$

$$F_i(1 + \kappa P) = F. \quad (22c)$$

The numerical factor P is a measure for the attenuation of the external field by the presence of the magnetizable material and is hence called the *demagnetization factor*. A comparison of (22c) and (21) yields for its value

$$P = \frac{1 - \epsilon^3}{\epsilon^3} \left(\frac{1}{2} \log \frac{1 + \epsilon}{1 - \epsilon} - \epsilon \right). \quad (23)$$

It is purely geometric in character. For the two limiting cases of (21b) and (21c) we have

$$P = 1/3 \text{ for } \epsilon \rightarrow 0, \text{ sphere,}$$

$$P = \eta \left(\log \frac{2}{\eta} - 2 \right) \rightarrow 0 \text{ for } \eta \rightarrow 0, \text{ rod.}$$

Intermediate values are readily calculated from (23) (log always signifies in this book the natural logarithm) and are tabulated for example, by Kohlrausch.¹

It is clear that this factor P has a legitimate meaning only for the ellipsoid and its degenerate forms, since only here we are dealing with the ratio of one uniform field to another. Clearly the boundary-value problem for other body-shapes cannot be circumvented by the employment of a numerical factor which is guessed in some manner. In practice the procedure consists of measuring the value of B experimentally with an induction coil at some characteristic points (e.g. the center of the test body).

§14. Some Remarks on Ferromagnetism

This section does not pretend to be an introduction to the broad field of ferromagnetism, but merely intends to mention certain important features

¹ F. Kohlrausch, *Praktische Physik*, 12th Ed., p. 540. It should be noted that the factor 4π , by which Kohlrausch's Eq. (4) differs from our Eq. (23), is, with us, included in the definition of κ . See the remark at Eq. (9) above.

which, since they lie outside our subject, will be indicated rather than logically derived. As has already been noted at the beginning of §12, ferromagnetism is not based on Maxwell's phenomenological theory, but on the more profound laws of atomic physics and on the statistical behavior of electrons.

A. The Weiss Domains

The sign of the ferromagnetic susceptibility and its temperature dependence indicate that it, like the paramagnetic susceptibility, results from the alignment of elementary magnets in a magnetic field. The fact that it differs from the paramagnetic susceptibility in order of magnitude shows, however, that we are here dealing not with individual, freely mobile, magnets, but with whole groups of them which, perfectly aligned within the group, have different preferential directions. The individual group is "saturated" internally even in the absence of an external field, while in a macroscopic block of ferromagnetic material saturation occurs only at a field excitation of 10 to 1000 oersted.

This concept of the ferromagnetic state is illustrated by a model constructed by Ewing. Magnet needles are arranged in a lattice on a board. With the earth's field compensated by a current loop, they arrange themselves in groups or rows in which they are parallel. This state is stable against external disturbances, such as shaking of the board. A weak external field produces only a slight deflection from the equilibrium position since the internal aligning field is much stronger than the external field. Complete alignment in the direction of the external field, i.e. saturation of the entire system, takes place only at a very much higher field strength.

Pierre Weiss has elaborated this interpretation of ferromagnetism in all directions, both experimentally and theoretically, and has, together with Langevin, given it a thermodynamic basis. The individual groups are known as *Weiss domains*. Their size is estimated at about 10^{-6} cm in linear dimension, corresponding to $5 \cdot 10^8$ Fe-atoms. The smallest ferromagnetically active domains are however certainly very much smaller and contain fewer than 100 Fe-atoms.¹ It is tempting to identify them with the single crystals of which a polycrystal of the material is composed on a microscopic scale. However, it is necessary to assume such a subdivision into Weiss domains even for the macroscopic single crystal, since its behavior is qualitatively similar to that of the polycrystal. (It is true that quantitatively the shape of the hysteresis loop, discussed below, differs from that for the polycrystal; it has a rectangular shape.)

¹ See H. König, *Naturwiss.* 1946, p. 1.

B. The Electron Spin as Elementary Magnet

All ferromagnetic materials are conductors of electricity, i.e. contain *free electrons*.¹ We have very definite reasons for regarding these electrons as the elements whose alignment causes ferromagnetism. These are the so-called "gyromagnetic effects": *magnetization by rotation* of a bar of a material of the iron group (J. S. Barnett 1914) and *rotation by magnetization* of a small ferromagnetic rod suspended on a torsion fiber (Einstein and de Haas 1915). In both cases measurements gave as ratio of the mechanical to the magnetic moment *half the value* to be expected if the effects resulted from the electron *orbits* in the atom. It must therefore be concluded that it is not the charge of the revolving electron and the magnetic field produced by it that are responsible, but the inner structure of the electron itself. The electron possesses, apart from its charge, an inner mechanical moment, a "*spin*," and a *magnetic moment* which is *twice as large* as the magnetic moment which would be assigned classically to its spin. This *magnetic anomaly* of the electron is the general result which may be deduced from the total observed data on the anomalous Zeeman effects (Goudsmit and Uhlenbeck 1925). It explains directly the observed results of the two gyro-magnetic effects and proves at the same time that the electron spin plays the role of the magnetic needles in Ewing's model.

On the basis of this discovery Heisenberg, in 1928, with the aid of modern electron statistics, was able to proceed toward a true physical understanding of ferromagnetism and to calculate qualitatively the extraordinary magnitude of the inner magnetic field in a Weiss domain. We see from this how long the road is from the Maxwell theory to the actual theory of ferromagnetism and it becomes evident that we cannot travel this road.

C. Hysteresis Loop and Reversible Magnetization

The figure which represents the magnetization M of a ferromagnetic material as function of the excitation H with increasing and decreasing H is well known. If the material is originally unmagnetized, the "virginal curve" is first traversed, beginning in the origin $H = 0, M = 0$ and passing over into the horizontal asymptote $M = M_s$ of *saturation* for sufficiently large H . If, from this point, H is permitted to decrease, the characteristic lies above the virginal curve and cuts the ordinate axis in a point $H = 0, M = M_r$, which indicates the *remanent magnetization*. If H is permitted to decrease still further, i.e. is reversed in direction, a region is entered in which B and H have opposite directions. The iron specimen has then become a "permanent magnet". With further decrease of H the hysteresis loop cuts the axis of abscissas in a point $H = -H_c, M = 0$, where the

¹ Atomic theory has not demonstrated fully why just the atoms of the iron group are ferromagnetically active.

remanent magnetization is just nullified. H_c is called the "coercive force". If H is decreased further, the negative saturation $M = -M_s$ is approached. If, now, H is once more increased, the gradually rising characteristic remains below the descending branch and below the virgin curve. It does not pass through the origin, but cuts the axis of abscissas in a point $H = +H_c$, $M = 0$. The ascending branch is symmetrical through the origin to the descending branch and approaches finally once more the positive saturation $M = +M_s$.

As a rule M_R is approximately $\frac{1}{2}M_s$. In order that the magnet may retain its remanence for all opposing fields which occur it is important that H_c may be as large as possible. This is the case for hard steel (tungsten steel has $H_c \sim 70$ oersteds).

The ascending and descending branches form together the *hysteresis loop*; its area is the magnetic work $\oint \mathbf{H} \cdot d\mathbf{B}$, which is performed on the material in a complete cycle. If the increase of H is stopped, in traversing the virgin curve, before reaching saturation, e.g. for $H_1 < H_s$, and H is then permitted to decrease to $H = -H_1$, then to increase to $H = +H_1$, a smaller hysteresis loop is obtained, which lies inside of the one previously described. For very small $H_1 = \delta H$ the loop degenerates into a twice traversed line; its area becomes zero and the process is *reversible*. The ratio $\delta M / \delta H$ defines the *initial susceptibility* κ_0 . It is possible to carry out such a reversible process not only at the origin, but at any arbitrary point of the cycle and to define for every such point a *reversible susceptibility* κ_{rev} .

With reversible magnetization the elementary magnets are *deflected* only slightly out of their original position in the direction of the external field. With irreversible magnetization some *reorientations* take place as well. In both cases changes occur in the boundaries of the Weiss domains, which are described as wall displacements; they are small for reversible, large for irreversible processes. In an induction coil with telephone connection they become acoustically noticeable by noises (clicks) and can be made visible on an oscilloscope as *Barkhausen jumps*. In fact, for sufficient oscillographic magnification, the apparently continuous course of the hysteresis loop resolves itself, particularly in the descending branch, into a sequence of small steps.

The individual processes which go to make up the magnetization curves are thus of varied nature. They depend on the composition of the iron specimen and on its microcrystalline structure; even for the single crystal they depend on the orientation relative to the magnetic field. It is the problem of the metallurgist to find the alloy (permalloy, permivar, cobalt steel) suited for each purpose (transformer laminations, communications engineering).

D. Thermodynamics

Ferromagnetism is even more dependent on temperature than paramagnetism. Above a certain critical temperature ferromagnetism ceases and passes over into ordinary paramagnetism. This critical temperature is designated with θ and is called the *Curie point*. On the centigrade scale ($\theta = \theta_{\text{cent}} + 273$) we have:

	for iron	cobalt	nickel
$\theta_{\text{cent}} =$	770	1120	358

For $T > \theta$ we have in place of Curie's law (13.10) the Curie-Weiss law

$$\chi = \frac{C}{T - \theta}. \quad (1)$$

This suggests that there may be no difference in principle between paramagnetism and ferromagnetism, that, in other words, the Curie point, in the former case, lies close to absolute zero. With this assumption a region of ferromagnetic behavior near $T = 0$ is to be expected also for ordinary paramagnetic materials. It then seems reasonable to transfer Langevin's statistical and thermodynamic theory of paramagnetic materials to the conditions of ferromagnetism.

In fact Weiss in this manner arrived at a representation of the whole complex of ferromagnetic phenomena which, in its main features, is satisfactory. However, this representation utilizes concepts with which we will only be able to deal in Volume V. Also detailed questions of atomic physics play here a role, such as the question of the atomic unit of magnetic moment (Bohr's magneton as compared with the Weiss magneton, which is smaller by a factor of five) and the question to what extent, in addition to the spin moment of the free electrons, the orbital moment of the electrons bound in the atom, which is twice as large, must be considered. The standard textbook¹ of R. Becker and W. Döring gives complete information on all relevant questions.

§15. Stationary Currents and Their Magnetic Field. Method of the Vector Potential

Since the assumption of stationary fields demands $\partial/\partial t = 0$ throughout, the Maxwell equations (4.4) reduce to

$$\text{curl } \mathbf{E} = 0, \quad \mathbf{J} = \text{curl } \mathbf{H}. \quad (1)$$

¹ *Ferromagnetismus*, Springer, Berlin 1939. For a less detailed treatment, see F. Bitter, *Introduction to Ferromagnetism*, McGraw-Hill, New York, 1937.

The second of these leads to

$$\operatorname{div} \mathbf{J} = 0. \quad (2)$$

For the *surface* of a conductor carrying current we have therefore

$$J_n = 0. \quad (2a)$$

(2) states that the electricity within a conductor behaves like an incompressible fluid (increase and decrease of current density for a narrowing and broadening of the conductor, respectively). Also *Kirchhoff's branching laws for linear conductors*, which Kirchhoff worked out as solution to a seminar problem given by F. Neumann (see p. 1), rest in the final analysis on (2) and the existence of the electrical potential (see below).

Eqs. (1) state that \mathbf{E} has *everywhere* a potential, $\mathbf{E} = -\operatorname{grad} \Psi_e$, while \mathbf{H} has a scalar potential, $\mathbf{H} = -\operatorname{grad} \Psi_m$, only *outside* of the current-carrying conductors. We will deal with this scalar potential in §16. Here we shall give a representation of \mathbf{B} (and hence also one of \mathbf{H}) which is valid both *inside* and *outside* of the conductors. We recall here Helmholtz's representation of the velocity field \mathbf{v} for given distribution of turbulence ω in Vol. II, Eq. (20.13). In Helmholtz's analogy the electric current density \mathbf{J} corresponded¹ to the second, the magnetic excitation \mathbf{H} , to the first. Just as there, we introduce a *vector potential* \mathbf{A} , by setting:²

$$\mathbf{B} = \operatorname{curl} \mathbf{A}. \quad (3)$$

The second Eq. (1) then becomes

$$\operatorname{curl} \frac{1}{\mu} \operatorname{curl} \mathbf{A} = \mathbf{J}. \quad (4)$$

For constant μ we can write instead

$$\operatorname{curl} \operatorname{curl} \mathbf{A} = \mu \mathbf{J}. \quad (4a)$$

¹ But for a factor $\frac{1}{4\pi}$ whose suppression was justified in Vol. II, p. 15 by the requirements of electrodynamics.

² It is customary to write instead $\mathbf{H} = \operatorname{curl} \mathbf{A}$, which, however, assumes the complete absence of sources of \mathbf{H} , a condition which is not fulfilled in regions of non-vanishing magnetic density ρ_m . Our formula (3) is more satisfactory, since $\operatorname{div} \mathbf{B} = 0$ throughout; in addition, it will generally simplify our formulas, particularly in Part III. Incidentally, both formulas amount to much the same thing if the assumption is made that μ is constant everywhere, which occurs already in Eq. (4a) of the text. For nonconstant μ the summation problem to be solved in (7) would have to be supplemented by a magnetostatic *boundary-value problem* (determination of the discontinuity of B_{tang} at the boundary between media of different permeability for our expression for \mathbf{A} and determination of the magnetic surface densities appearing there for the usual expression for \mathbf{A} , respectively).

We here employ the general transformation (6.2) with the restriction to Cartesian coordinates which is there emphasized and obtain instead of (4a) the form which is more convenient for integration:

$$\Delta A - \text{grad div } A = -\mu J. \quad (4b)$$

This may be simplified by the supplementary condition

$$\text{div } A = 0, \quad (5)$$

which transforms (4b) into

$$\Delta A = -\mu J. \quad (6)$$

The condition (5) may be added since A , for given B , is determined by Eq. (3) with the exception of the gradient of a scalar function. The latter may be utilized to satisfy (5). For, if A_1 is any solution of (3),

$$A = A_1 + \text{grad } f \quad (6a)$$

is similarly a solution; if we now write

$$\text{div grad } f = \Delta f = -\text{div } A_1, \quad (6b)$$

which, according to the well-known integration procedure of Poisson's equation is always possible, we find $\text{div } A = 0$.

This method of integration yields at the same time as the solution of (6):

$$4\pi A_P = \int \frac{\mu J_Q d\tau_Q}{r_{PQ}}. \quad (7)$$

Here the point of integration $Q = \xi, \eta, \zeta$ traverses the entire interior of the conductors; $P = x, y, z$ is the reference point for which the Cartesian components A_x, A_y, A_z are to be calculated. It was shown in Vol. II, §20, Nr. 2a that this representation satisfies (5) provided that J is solenoidal, in accord with (2), and that μ is constant. The integration in Eq. 7 is to be extended over the *closed* current field J (just as in Vol. II over the *closed* vortex rings).

The current density J appearing in (7) may be obtained as solution of a potential problem. Since $J = \sigma E$ the potential equation applies, for constant σ , just as much for J as for E :

$$\Delta J = 0. \quad (8)$$

For varying σ Eq. (8) takes on a somewhat more complicated form. The total current I is obtained from J by integration over any cross section of the conductor:

$$I = \int J_n d\sigma. \quad (9)$$

The familiar fact that I has a fixed value independent of position and shape of the cross section follows from integration of Eq. (2) over a segment of the conductor bounded by two arbitrary cross sections as for the analogous spatial law of conservation of vortex theory (see Vol. II, p. 136, Fig. 24).

We shall now give some applications of our representation (7).

A. The Law of Biot-Savart

We subdivide the three-dimensional conductor into current tubes with the cross section dq , normal to the tube axis, and the element of length ds ; the current $J_n dq$ in such a tube element, which has the same dimension as the total current I , we shall also call I , for the present. We then can set

FIG. 19. The law of Biot-Savart, derived from the vector potential of an element of current.

$\mathbf{J} d\tau = I ds$, where the direction of the current flow \mathbf{J} is indicated by the vectorial character of ds . By (7) the contribution of our tube element to \mathbf{A} then becomes

$$4\pi d\mathbf{A} = \frac{\mu I ds}{r}$$

and, by (3), the corresponding contribution to \mathbf{B} is,

$$4\pi d\mathbf{B} = \text{curl} \frac{\mu I ds}{r}. \quad (10)$$

We shorten the remaining calculation by employing the symbolic vector ∇ :

$$\text{curl} \frac{\mu I ds}{r} = \nabla \times \frac{\mu I ds}{r} = \left(\text{grad} \frac{1}{r} \right) \times \mu I ds. \quad (11)$$

For $I ds$ is dependent on x, y, z in direction, but not in magnitude; $1/r$ depends on x, y, z in magnitude, but not in direction (being a scalar). We see furthermore from Fig. 19 that

$$\text{grad} \frac{1}{r} = -\frac{\mathbf{r}}{r^2} = -\frac{\mathbf{e}}{r^2}, \quad (11a)$$

where \mathbf{r} denotes the radius vector from the current element to the reference point and \mathbf{e} the corresponding unit vector. Substitution of (11) and (11a)

in (10) yields

$$4\pi d\mathbf{B} = \frac{-\mu I}{r^2} \mathbf{e} \times d\mathbf{s}, \quad 4\pi |d\mathbf{B}| = \frac{\mu I ds}{r^2} \sin \vartheta. \quad (12)$$

ϑ signifies the angle between the vectors \mathbf{e} and $d\mathbf{s}$; the direction of $d\mathbf{B}$, in view of the negative sign in (12) and the meaning of the vector product, is that of a left-hand screw for the direction of rotation $\mathbf{e} \rightarrow d\mathbf{s}$. Let us imagine a magnetic unit pole at the reference point and let the vector $d\mathbf{B}$ act on it; $d\mathbf{B}$ then represents the *Biot-Savart force* exerted on the unit pole by the current element $I d\mathbf{s}$. The corresponding line of force then surrounds the current element, in a *right-hand* screw direction, as shown in the figure and as expected. Evidently the first Eq. (12) is the more complete one, since it expresses the dependence on direction which is characteristic of the magnetic field in the simplest and most appropriate manner; we have added the second form merely because it is the historically more familiar one.

B. The Magnetic Energy of the Field of Two Conductors

If we denote the energy integrated over space by W we obtain, for the magnetic energy density W , from Eq. (5.6)

$$2W = \int \mathbf{H} \cdot \mathbf{B} d\tau = \int \mathbf{H} \cdot \text{curl } \mathbf{A} d\tau. \quad (13)$$

For the evaluation we utilize the vector formula (5.2), previously derived in connection with the Poynting theorem, which we rewrite in terms of our present symbols (\mathbf{A} , \mathbf{H} in place of \mathbf{U} , \mathbf{V}) as follows:

$$\mathbf{H} \cdot \text{curl } \mathbf{A} = \mathbf{A} \cdot \text{curl } \mathbf{H} + \text{div } \mathbf{A} \times \mathbf{H}. \quad (14)$$

We assert that the second term on the right vanishes in the integration over infinite space. According to Gauss's theorem this term yields

$$\int \text{div } \mathbf{A} \times \mathbf{H} d\tau = \int (\mathbf{A} \times \mathbf{H})_n d\sigma, \quad (14a)$$

where the integration on the right is to be carried out over a surface bounding the region at a great distance, e.g. a sphere of radius R . Let the two conductors, whose total magnetic energy is to be determined, be entirely confined to a finite region. The distance of all their points from the infinitely distant element of area $d\sigma$ of the bounding sphere may then be set equal to the constant value R . By Eq. (7) \mathbf{A} approaches zero on $d\sigma$ as $1/R$ and, by the law of Biot-Savart, \mathbf{H} approaches zero as $1/R^2$. Since $d\sigma = R^2 d\Omega$ ($d\Omega$ = solid angle intercepted by $d\sigma$), the right side of (14a) approaches zero as R^2/R^3 .

In view of (1), (14) and (13) lead to

$$2W = \int \mathbf{A} \cdot \text{curl } \mathbf{H} \, d\tau = \int \mathbf{A} \cdot \mathbf{J} \, d\tau. \quad (15)$$

The integration is now to be carried out only over the conductors 1 and 2, since \mathbf{J} is zero everywhere outside of them. If we designate the point of integration in (15) by P ($d\tau_P$ instead of $d\tau$) and if we substitute $\mathbf{A} = \mathbf{A}_P$ from (7), the simple volume integral is replaced by a double volume integral:

$$\frac{2W}{\mu} = \frac{1}{4\pi} \iint \mathbf{J}_P \cdot \mathbf{J}_Q \frac{d\tau_P \, d\tau_Q}{r_{PQ}}. \quad (16)$$

In evaluating this integral we have to distinguish four cases, depending on the position of P and Q on conductors 1 and 2:

- | | |
|------------------------|------------------------|
| a. P and Q on 1, | b. P and Q on 2, |
| c. P on 1, Q on 2, | d. P on 2, Q on 1; |

the cases c and d are however alike in view of the symmetry of (16) with respect to P and Q . We can write the result in the form

$$W = \frac{1}{2}(L_{11} I_1^2 + L_{22} I_2^2 + 2L_{12} I_1 I_2), \quad (17)$$

$$L_{11} = \frac{\mu}{4\pi} \iint \mathbf{j}_1 \cdot \mathbf{j}_1' \frac{d\tau_1 \, d\tau_1'}{r_{11}'}, \quad L_{22} = \frac{\mu}{4\pi} \iint \mathbf{j}_2 \cdot \mathbf{j}_2' \frac{d\tau_2 \, d\tau_2'}{r_{22}'}, \quad (17a)$$

$$L_{12} = \frac{\mu}{4\pi} \iint \mathbf{j}_1 \cdot \mathbf{j}_2 \frac{d\tau_1 \, d\tau_2}{r_{12}}. \quad (17b)$$

The factor 2 in the product term in (17) results from the equality of cases c and d , which causes the coefficient L_{21} also to be given by (17b), i.e. $L_{21} = L_{12}$. I_1 , I_2 are the total currents in conductors 1 and 2, which, as noted at (9), are independent of the place in the conductor. 1 , $1'$ are two points on the conductor 1; 2 , $2'$ two points on conductor 2. Division of the current densities \mathbf{j}_1 , \mathbf{j}_2 by I_1 , I_2 leads to the purely geometrically defined "current-line density vectors"

$$\mathbf{j}_1 = \frac{\mathbf{J}_1}{I_1}, \quad \mathbf{j}_2 = \frac{\mathbf{J}_2}{I_2}. \quad (17c)$$

The L 's are called *induction coefficients*: L_{11} , L_{22} are the *coefficients of self-induction*, L_{12} is the *coefficient of mutual induction*. Maxwell uses the letter M in place of L_{12} .

The unit of the coefficients L (or M) is the *henry*.¹ In accord with (17)

¹ Joseph Henry, 1792–1878, American physicist, discovered almost simultaneously with Faraday the appearance of an electromotive force in a coil when the magnetic field in its interior is changed.

this unit is fixed in value and dimension by the statement

$$1 \text{ henry} = 1 \frac{\text{joule}}{\text{I}^2} = 1 \frac{\text{joule S}^2}{\text{Q}^2}. \quad (18)$$

Converted into electromagnetic cgs-units we find, since

$$\begin{aligned} \text{Q} &= 10^{-1} \text{ cm}^{\frac{1}{2}} \text{g}^{\frac{1}{2}}, & 1 \text{ joule} &= 10^7 \text{ cm}^2 \text{g sec}^{-2}, \\ 1 \text{ henry} &= 10^9 \text{ cm} = 1 \text{ quadrant of the earth.} \end{aligned} \quad (18a)$$

From our standpoint we can, however, attach no significance to this apparently so simple dimension and this relationship to the earth's circumference, since it rests on the arbitrary assumptions of the electromagnetic system of units. At the same time we are glad to point out the following relation between the henry and the permeability in vacuum given by (7.16a):

$$\mu_0 = 4\pi \cdot 10^{-7} \frac{\text{joule} \cdot \text{S}^2}{\text{Q}^2 \text{M}} = 4\pi \cdot 10^{-7} \frac{\text{henry}}{\text{M}}. \quad (18b)$$

Compare with this the analogous relation between the dielectric constant of vacuum and the farad as given by Eq. (10.3b).

C. Neumann's Potential as the Coefficient of Mutual Induction

In (17b) it is possible to pass to the limiting condition of linear conductors, i.e. infinitely thin wires. In (17a) this is not permitted since r'_{11} (or r'_{22}) would vanish as the two integration points approach each other and the convergence of the integrals would be destroyed.

We write in (17b)

$$d\tau_1 = dq_1 ds_1, \quad d\tau_2 = dq_2 ds_2 \quad (19)$$

and combine dq_1 and j_1 , dq_2 and j_2 . The products $j_1 dq_1$ and $j_2 dq_2$ then have, by (17c), unit magnitude and their scalar product is equal to the cosine of the angle θ_{12} between the two directions of flow ds_1 and ds_2 . Hence:

$$\frac{4\pi}{\mu} L_{12} = \int ds_1 \int ds_2 \frac{\cos \theta_{12}}{r_{12}} = \iint \frac{ds_1 \cdot ds_2}{r_{12}}. \quad (20)$$

This amazingly simple and beautiful representation was discovered¹ by Franz Neumann as early as 1845. It is known as *Neumann's potential*; according to (17) it represents that portion of the magnetic energy which results from the interaction of the two circuits. A relative displacement or rotation of the two circuits with the currents I_1 and I_2 left unaltered hence is accompanied by a change in energy δW in the amount

$$\delta W = I_1 I_2 \delta L_{12}. \quad (20a)$$

¹ Abhandl. Preuss. Akad., reprinted in Ostwald's *Klassiker*, Nr. 10.

The *work* which must be done in a displacement or rotation, as well as the *force* or *torque* which one circuit exerts on the other, are related to this.

In spite of the simplicity of expression (20) the actual calculation of the mutual induction coefficient is rather inconvenient. To begin with we work out a formal mathematical example, i.e. two straight parallel wires of length l separated by distance a . The condition of closed circuits stated in Eq. (7) is temporarily not fulfilled here. We shall take due account of it only

FIG. 20. The coefficient of mutual induction of two straight, parallel segments of wire of length l . The finite cross section of the wires is indicated at the bottom of the figure.

when we reach Eq. (24). Referring to Fig. 20, we have ($dy_1 dy_2$ in place of $ds_1 ds_2$, $\cos \theta_{12} = 1$):

$$\frac{4\pi}{\mu} L_{12} = \int_0^l dy_1 \int_0^l \frac{dy_2}{\sqrt{a^2 + (y_2 - y_1)^2}}. \quad (21)$$

The formula of integration already employed in (9.4) yields for the second integral

$$\begin{aligned} \int_0^l \frac{dy_2}{\sqrt{a^2 + (y_2 - y_1)^2}} \\ = \log(l - y_1 + \sqrt{a^2 + (l - y_1)^2}) - \log(-y_1 + \sqrt{a^2 + y_1^2}). \end{aligned} \quad (22)$$

A further formula, which may readily be checked by differentiation,

$$\int^z \log(\xi + \sqrt{a^2 + \xi^2}) d\xi = z \log(z + \sqrt{a^2 + z^2}) - \sqrt{a^2 + z^2} + \text{const}$$

yields for the integration of the first term on the right of (22)

$$\begin{aligned} \int_0^l dy_1 \log(l - y_1 + \sqrt{a^2 + (l - y_1)^2}) \\ = l \log(l + \sqrt{a^2 + l^2}) - \sqrt{a^2 + l^2} + a \end{aligned}$$

and for the integration of the second term

$$\begin{aligned}
 - \int_0^l dy_1 \log(-y_1 + \sqrt{a^2 + y_1^2}) \\
 = -l \log(-l + \sqrt{a^2 + l^2}) - \sqrt{a^2 + l^2} + a.
 \end{aligned}$$

A simple transformation under the logarithm sign yields for the sum of the two

$$\frac{4\pi}{\mu} L_{12} = 2l \log \frac{l + \sqrt{a^2 + l^2}}{a} - 2 \sqrt{a^2 + l^2} + 2a. \quad (23)$$

We assume $l \gg a$, and obtain as a first approximation

$$\frac{4\pi}{\mu} L_{12} = 2l \left(\log \frac{2l}{a} - 1 \right). \quad (24)$$

It is worth noting in this result that we have not obtained simple proportionality to l , since the parenthesis depends on l logarithmically. Accordingly we can not speak of a mutual induction coefficient per unit length of our wires.

The reason for this is the following: Our derivation assumes, as has been stressed repeatedly, two *closed* circuits, while our example deals with two circuit segments. Our result (24) is nevertheless meaningful. For example, it is possible to determine with its aid the mutual inductance of two parallel rectangles such as occur in Ampere's basic experiments. For such a pair of rectangles (the second rectangle is supposed to be obtained from the first by a parallel displacement perpendicular to its plane) only parallel pairs of sides contribute; for mutually perpendicular sides the product $ds_1 \cdot ds_2$ occurring in Eq. (20) is equal to zero. The mutual inductance of two such rectangles becomes equal to the sum of four terms of the form of (24).

D. The Coefficient of Selfinduction

As already noted we cannot in this case pass to the limit of the linear conductor, but must return to the double volume integrals in (17a). We can readily convince ourselves, however, that then any convergence difficulty is avoided. For if, for an arbitrary position of 1, we employ polar coordinates r, ϑ, φ with this point as origin to locate the point 1', $d\tau_1' = r^2 dr \sin \vartheta d\vartheta d\varphi$ and the denominator $r_{11}' = r$ cancels one of the factors r in $d\tau_1'$. However the carrying out of the integrations becomes now, in general, even more awkward than in C.

We therefore limit ourselves to a simple mathematical example, namely a straight wire of the (great) length l and the (small, but finite) cross section q . We consider two current filaments parallel to the axis of the wire

(y -axis) and employ once again Fig. 20, where now the two linear currents are assumed to refer to the same wire of cross section q . Let dq_1, dq_2 be the cross sections of the two current filaments; their separation, formerly denoted by a , will now be called ρ since it is variable, depending on the position of the two current filaments within q . The volume elements are once again given by (19), with $ds_1 = dy_1, ds_2 = dy_2$, and the vectors defined in (17c) become

$$j_1 = j_2 = \frac{l}{q}.$$

The defining equation (17a) for the selfinductance then takes the form

$$\frac{4\pi}{\mu} L = \iint \frac{dq_1 dq_2}{q^2} \int_0^l \int_0^l \frac{dy_1 dy_2}{\sqrt{\rho^2 + (y_2 - y_1)^2}}. \quad (25)$$

The second double integral has exactly the same form as (21). We can utilize the approximate evaluation (24) here also and obtain

$$\begin{aligned} \frac{4\pi}{\mu} L &= \frac{2l}{q^2} \iint dq_1 dq_2 \left(\log \frac{2l}{\rho} - 1 \right) \\ &= \frac{2l}{q^2} \left\{ \iint dq_1 dq_2 (\log 2l - 1) - \iint dq_1 dq_2 \log \rho \right\}. \end{aligned}$$

In the first term on the right the integration with respect to dq_1 and dq_2 can be carried out easily; the second term requires more detailed discussion because of the variability of $\rho = \rho_{12}$ = separation of our two current filaments. We note the preliminary result

$$\frac{4\pi}{\mu} L = 2l \{ \log 2l - 1 - \log \bar{\rho} \}, \quad \log \bar{\rho} = \frac{1}{q^2} \int dq_1 \int dq_2 \log \rho_{12}. \quad (26)$$

Maxwell calls the quantity $\bar{\rho}$ here introduced the *mean geometric separation* of the elements dq_1, dq_2 within the cross section q .¹ It can be determined more elegantly by an electrostatic consideration than by direct calculation.

In terms of polar coordinates the two-dimensional potential equation becomes

$$\Delta \Phi = \frac{\partial^2 \Phi}{\partial x^2} + \frac{\partial^2 \Phi}{\partial y^2} = \frac{1}{\rho} \frac{d}{d\rho} \rho \frac{d\Phi}{d\rho} + \frac{1}{\rho^2} \frac{\partial^2 \Phi}{\partial \varphi^2} = 0. \quad (27)$$

¹ Treatise, art. 691 ff. In explanation of the notation we remark: The integral to be evaluated in (26) is the arithmetic mean of all values of $\log \rho$ occurring on our surface q . In view of the relation

$$\sum \log \rho_i = \log \Pi \rho_i$$

this arithmetic mean of the logarithms is at the same time the logarithm of the *geometric* mean of all the ρ_i .

Apart from a multiplying and an additive constant the solution which is independent of φ is known to be the "logarithmic potential"

$$\Phi = \log \rho.$$

This signifies, in two dimensions, a negative charge concentrated at the point $\rho = 0$. If the charge is distributed over the area q with a positive surface density f , and with the surface element of q being designated with dq_1 , Green's theorem yields for its potential at the reference point 1.

$$2\pi\Phi_1 = - \int_q f \log \rho_{12} dq_1. \quad (28)$$

This is the two-dimensional analog to the familiar Eq. (7.5). If, in (28), we put $f = -2\pi$, we obtain the inner integral in (26),

$$\Phi_1 = \int_q \log \rho_{12} dq_1 \quad (28a)$$

and our desired mean geometric separation may be written

$$\log \beta = \frac{1}{q^2} \int \Phi_1 dq_1. \quad (28b)$$

The integral (28b) can be readily evaluated in the case that q is a circle, e.g. of radius b , and the point 1 coincides with the center of the circle. We then have $\rho_{12} = \rho$, i.e. equal to the polar coordinate employed previously, and $dq_1 = \rho d\rho d\varphi$. We denote by Φ_0 the corresponding specific value of Φ_1 . Eq. (28a) then takes the form

$$\Phi_0 = \int_0^{2\pi} d\varphi \int_0^b \log \rho \rho d\rho. \quad (29)$$

The integral with respect to ρ can readily be evaluated by integration by parts; thus

$$\int_0^b \log \rho \rho d\rho = \frac{\rho^2}{2} \log \rho \Big|_0^b - \int_0^b \frac{\rho}{2} d\rho = \frac{b^2}{2} (\log b - \frac{1}{2}).$$

Hence (29) leads to

$$\Phi_0 = \pi b^2 (\log b - \frac{1}{2}). \quad (29a)$$

Furthermore Φ_1 , as the potential for a known surface distribution, can be calculated for arbitrary location of point 1 directly from Poisson's equation, which, in analogy to (7.4a), in two dimensions takes the form

$$\Delta\Phi_1 = -f,$$

where f is the surface density. In our special case ($f = -2\pi$, circle q of radius b , Φ_1 a function of ρ only) it becomes

$$\frac{1}{\rho} \frac{d}{d\rho} \rho \frac{d\Phi_1}{d\rho} = 2\pi. \quad (30)$$

Integrated twice this yields

$$\rho \frac{d\Phi_1}{d\rho} = \pi\rho^2 + A, \quad \Phi_1 = \frac{\pi\rho^2}{2} + A \log \rho + B.$$

In order that this expression for Φ_1 may pass over, for $\rho = 0$, into the expression (29a) for Φ_0 , we must set

$$A = 0, \quad B = \Phi_0, \quad \text{hence} \quad \Phi_1 = \pi b^2 \left(\log b - \frac{1}{2} + \frac{1}{2} \frac{\rho^2}{b^2} \right). \quad (31)$$

If we substitute this expression for Φ_1 in (28b) we obtain

$$\begin{aligned} \log \bar{\rho} &= \frac{1}{q} \int dq_1 (\log b - \tfrac{1}{2}) + \frac{1}{2q} \int dq_1 \frac{\rho^2}{b^2} \\ &= \log b - \tfrac{1}{2} + \frac{1}{b^2} \int_0^b \rho^2 d\rho = \log b - \tfrac{1}{2}. \end{aligned} \quad (32)$$

For $\bar{\rho}$ itself we obtain from this the peculiar value

$$\bar{\rho} = b/\sqrt[4]{e}. \quad (32a)$$

Here the proportionality with b is rather obvious in view of the definition of the geometric mean (see last footnote); however the numerical factor is to be found only by detailed analysis, which following Maxwell, we have here based on potential theory. It may be mentioned that Maxwell carried out these considerations even for cross sections of arbitrary shape.

To pursue our real goal, the calculation of the selfinductance L , we return to (26). We then find, utilizing (32)

$$\frac{4\pi}{\mu} L = 2l \left\{ \log 2l - \log b - \frac{3}{4} \right\} = 2l \left\{ \log \frac{2l}{b} - \frac{3}{4} \right\}. \quad (33)$$

This formula confirms our original expectation that the transition to the linear conductor ($b \rightarrow 0$) is not permissible for the selfinductance. Regarding the dependence on l we must make the same remark as at the end of section C: We cannot, by division of l , obtain the *selfinductance per unit length of an infinitely long wire*; however, we can, as for the *mutual inductance*, piece together the selfinductance of any *closed* circuit, made up of straight wires, by adding up terms of the form of (33).

We shall further answer a rather obvious objection which may be raised against the somewhat indirect derivation of (33). The magnetic field of an

infinitely long wire is known from Fig. 4 and the corresponding equations (10) to (13) on p. 24. Cannot the energy and selfinduction of the straight wire be calculated much more directly from them?

With I as current we found (writing now b, c in place of the earlier a, b)

$$r < b: H = \frac{r}{b} \frac{I}{2\pi b}; \quad r > b: H = \frac{I}{2\pi r}.$$

Hence the contribution of the interior of the wire to the energy per unit length is

$$\frac{\mu}{2} 2\pi \int_0^b H^2 r \, dr = \frac{\mu}{4\pi} \frac{I^2}{b^4} \int_0^b r^3 \, dr = \frac{\mu}{16\pi} I^2 \quad (33a)$$

and the contribution of the exterior:

$$\frac{\mu}{2} 2\pi \int_b^c H^2 r \, dr = \frac{\mu}{4\pi} I^2 \int_b^c \frac{dr}{r} = \frac{\mu}{4\pi} I^2 \log \frac{c}{b}. \quad (33b)$$

From this we find for the selfinductance per unit length, from the energetic formula of definition (17),

$$\frac{\mu}{2\pi} \left(\frac{1}{4} + \log \frac{c}{b} \right). \quad (33c)$$

This expression becomes logarithmically infinite if we let $c \rightarrow \infty$, i.e. pass over to the single wire without return conductor. Our intended simplified derivation hence fails—quite understandably—as the result of the unphysical assumptions of the problem, which must lead to an infinite energy content of space for any unit length of the wire as we pass to the limit $c \rightarrow \infty$.

E. Selfinductance of the Two-Wire Line

The system of two straight parallel wires traversed by current in opposite directions plays an important role in electric power transmission and is known, in Hertz's experiments with high frequency waves, as a Lecher system. We shall determine the selfinductance per unit length of such a system (with appropriate restriction to the direct-current case).

So as to be able to utilize Fig. 20, we shall call the (very great) length of the wires l , their separation a , and their radius b . We proceed from the energetic formula (17), where we put

$$I_1 = I, \quad I_2 = -I, \quad L_{11} = L_{22} = L.$$

We then obtain

$$W = \frac{1}{2} L_D I^2, \quad L_D = 2(L - L_{12}). \quad (34)$$

We can designate L_D , introduced here, as inductance of the *line*, regarded as a uniform system.¹ Substitution from (33) and (24) yields:

$$L_D = \frac{\mu}{\pi} l \left(\log \frac{2l}{b} - \frac{3}{4} - \log \frac{2l}{a} + 1 \right).$$

In evaluating the logarithmic terms the two terms $\pm \log 2l$ drop out and the following simple formula remains:

$$\frac{L_D}{l} = \frac{\mu}{\pi} \left(\log \frac{a}{b} + \frac{1}{4} \right). \quad (35)$$

L_D/l is the desired selfinductance per unit length of the two-wire line, which evidently is independent of l . Hence the transition to $l \rightarrow \infty$, which, according to (33) and (24), was inappropriate in the expressions for L/l and L_{12}/l because of the term $\log 2l$, is now feasible. This is obviously related to the fact that the field of a two-wire line traversed by oppositely directed currents corresponds to that of a circuit closed at infinity. On the other hand the transition to the linear two-wire line ($b \rightarrow 0$), which was possible in the expression for the mutual inductance, cannot be carried out even now.

F. General Theorem Regarding Energy Transmission by Stationary Currents

We consider the section of an arbitrarily shaped wire between two cross sections F_1 and F_2 . Let it contain a "load" in which electrical energy is translated into work or some other form of energy, e.g. a light bulb. We ask what *power* is supplied to the load (the Joule heat generated in our section of wire to be counted as part of the load).

We extend the cross sections F_1, F_2 to a closed surface F and calculate the power N as the inward-directed energy flux through this surface. According to Poynting's theorem (5.7a) and the meaning of Joule heat (5.5) we obtain under stationary conditions

$$N = \int_V S_n dF = \int_V \mathbf{E} \cdot \mathbf{J} dV. \quad (36)$$

V is the volume enclosed by F . Under stationary conditions we have everywhere within V

$$\text{curl } \mathbf{E} = 0, \quad \mathbf{E} = -\text{grad } \Psi, \quad \text{hence } \mathbf{E} \cdot \mathbf{J} = -\text{grad } \Psi \cdot \mathbf{J}.$$

We transform this with the aid of the obvious and universally valid identity

$$\text{div}(\Psi \mathbf{J}) = \text{grad } \Psi \cdot \mathbf{J} + \Psi \text{div } \mathbf{J}$$

¹ A similar definition is employed in electrical engineering for multiple conductor systems with the designation "operating selfinductance," if under the conditions of operation all circuit currents are determined by one of them.

where \mathbf{J} is any vector, Ψ , any scalar. For our meaning of \mathbf{J} the last term vanishes. We hence deduce from (36)

$$N = - \int \operatorname{div}(\Psi \mathbf{J}) dV \quad (37)$$

and, by application of Gauss's theorem

$$N = \int_r \Psi J_n dF. \quad (38)$$

This integral need only be carried out over the surfaces of entry and exit, F_1 and F_2 , of the current, since only here J_n differs from zero. It is most convenient to choose F_1 and F_2 as the equipotential surfaces $\Psi = \Psi_1$ and $\Psi = \Psi_2$. We then obtain from (38)

$$N = \Psi_1 \int_{F_1} J_n dF_1 + \Psi_2 \int_{F_2} J_n dF_2. \quad (39)$$

With the convention regarding the direction of \mathbf{n} established above

$$\int J_n dF_1 = - \int J_n dF_2 = I$$

and hence, by (39),

$$N = (\Psi_1 - \Psi_2)I = VI. \quad (40)$$

V is the voltage drop between F_1 and F_2 (in volts) and I , the current entering and leaving (in amperes).

This fundamental formula, which expresses the power directly in watts (joules/S), has here been derived for stationary conditions; in §18 it will be found applicable also to "quasistationary" states. To avoid misunderstandings it should be noted that Eq. (40) makes no statement regarding the brightness of the light bulb or the energy radiated by it. This phenomenon lies outside of the domain of Maxwell's theory and rests on atomic processes which are made possible by the Joule heat supplied to the filament, but whose energy balance has nothing to do with Eq. (40). Our Eq. (40) follows the energy conversion only up to the generation of the Joule heat, not beyond it.

§16. *Ampère's Method of the Magnetic Double Layer*

In the last paragraph we had to introduce the concept of the *vector potential* in order to arrive at a representation of the magnetic field without and within the current-carrying conductor. If we content ourselves with a representation which applies only *outside* of the conductor we can get along with the ordinary *scalar* magnetic potential Ψ .

Outside of the conductors we have, by (15.1),

$$0 = \text{curl } \mathbf{H}, \quad \mathbf{H} = -\text{grad } \Psi. \quad (1)$$

If we add the condition $\text{div } \mathbf{B} = 0$ and assume uniform permeability, e.g. $\mu = \mu_0$, outside, we have furthermore

$$\text{div grad } \Psi = \Delta \Psi = 0. \quad (2)$$

This potential Ψ is *not*, however, a *unique* function of position, as in the magnetostatic case. For every closed loop about a conductor carrying I it changes by the amount I , independently of the shape and length of the path:

$$\Psi_1 - \Psi_2 = \oint \mathbf{H} \cdot d\mathbf{s} = \pm I. \quad (3)$$

Here Ψ_1 and Ψ_2 are the values of Ψ at the starting point 1 and the coinciding endpoint 2 of the loop. The upper or lower sign of I applies depending on whether the loop forms a right or left screw with the direction of the current. On the other hand, for every closed path which does not link such a conductor:

$$\Psi_1 - \Psi_2 = \oint \mathbf{H} \cdot d\mathbf{s} = 0. \quad (3a)$$

The proof of both Eqs. (3) and (3a) follows again from (15.1). An arbitrary surface σ bounded by the path of integration cuts the conductor in question in the first instance; in the second it can always be placed so that it cuts no conductor. If the component of Eq. (15.1) normal to every surface element $d\sigma$ is formed and integrated over all $d\sigma$, we obtain

$$\int_{\sigma} J_n d\sigma = \int_{\sigma} \text{curl}_n \mathbf{H} d\sigma.$$

By (15.9) the left side is the total current traversing the surface σ , i.e. I for Eq. (3) and 0 for (3a). The right side may be transformed by Stokes's theorem into the line integral over s .

For multiple loops about the conductors in one or the other direction a change in Ψ is obtained which is equal to the sum of the changes corresponding to individual circuits:

$$\Psi_1 - \Psi_2 = \sum n_k I_k.$$

Here n_k denotes the number of circuits about the k th conductor. Thus Ψ is infinitely multivalued. Any two "branches" of Ψ differ by a constant which is a sum of the currents I_k multiplied by integer coefficients n_k .

A. The Magnetic Shell for Linear Conductors

To give a prescription for the computation of Ψ which is unique in spite of this multiplicity we must confine ourselves to the limiting case of linear conductors (cross section $\rightarrow 0$); furthermore, it will suffice for the present to consider a single conductor. Let it be Λ . Through Λ as boundary we place an otherwise arbitrarily shaped "branch cut" surface S and forbid passage through S . In this manner we select, from the infinitely many-valued potential, a "function branch." Carrying over the already somewhat daring language of the *Riemannian surfaces* into three dimensions, we could also say: Of the "Riemannian space," whose infinite number of "leaves" have the branch line Λ in common and are joined in the branch cut S , we separate out one leaf as alone physically significant. This leaf has become "singly connected."

The calculation of Ψ may now be carried out by simple application of Green's theorem:

$$\int (u\Delta v - v\Delta u) d\tau = \int \left(u \frac{\partial v}{\partial n} - v \frac{\partial u}{\partial n} \right) d\sigma. \quad (4)$$

Here we put,

$$u = \Psi, \quad v = \frac{1}{r}, \quad r = r_{PQ} \quad (4a)$$

and carry out the volume integral on the left over all points P of our physical leaf, excluding a sphere of radius $\rho \rightarrow 0$ about the source point Q and a sphere of radius $R \rightarrow \infty$ cutting off the infinite; the latter sphere may have an arbitrary point O as center, which may for example be situated on S . Correspondingly, the surface integral on the right is to be carried out over the two spherical surfaces K_ρ and K_R , as well as the two "sides" of the branch cut S . Since on the sphere K_ρ ,

$$u \frac{\partial v}{\partial n} = -\Psi_Q \left(\frac{d}{dr} \frac{1}{r} \right)_{r=\rho} = \frac{1}{\rho^2} \Psi_Q$$

integration over $d\sigma$ here yields evidently

$$4\pi\Psi_Q. \quad (5)$$

The sphere K_R contributes

$$-\frac{1}{R^2} \int \Psi d\sigma - \frac{1}{R} \int \frac{\partial \Psi}{\partial n} d\sigma.$$

According to the law of Biot-Savart H decreases with increasing R as $1/R^2$. Hence the second of the above integrals is finite and, with its factor, vanishes as $1/R$. The first integral becomes infinite only in proportion to

R and yields similarly a vanishing contribution when multiplied with $1/R^2$. Thus the contribution of K_s is zero. We could confirm this result which is here based on the law of Biot-Savart, i.e. the method of the vector potential, also by the method of this paragraph.

Finally, we must consider the two sides 1 and 2 of the branch cut. In view of the opposite direction of n on the two sides we have

$$\left(\frac{\partial v}{\partial n}\right)_1 = -\left(\frac{\partial v}{\partial n}\right)_2. \quad (6)$$

Since

$$\frac{\partial u}{\partial n} = \frac{\partial \Psi}{\partial n} = -H_n$$

is a physical quantity which has nothing to do with the mathematical fiction of our branch cut we have, in addition to (6),

$$\left(\frac{\partial u}{\partial n}\right)_1 = -\left(\frac{\partial u}{\partial n}\right)_2. \quad (6a)$$

The sum of the contributions of the two sides of the branch cut to the right side of (4) may hence be written

$$\int \left\{ (u_1 - u_2) \left(\frac{\partial v}{\partial n}\right)_1 - (v_1 - v_2) \left(\frac{\partial u}{\partial n}\right)_1 \right\} d\sigma. \quad (6b)$$

Here $v_1 - v_2$ vanishes because of the meaning of $v = 1/r$, but, by Eqs. (3) and (4a), $u_1 - u_2 = \pm I$. Hence (6b) takes the form

$$\pm \int I \frac{\partial}{\partial n_1} \frac{1}{r} d\sigma. \quad (7)$$

To fix the sign, consider Fig. 21. Here 1 is to denote that side of S on which the normal n_1 directed toward S forms a *right screw* with the direction of current flow. The loop from 1 to 2 shown in the figure then forms a *left screw* with the direction of the current. Hence by prescription (3) we must choose the negative sign in formula (7). If we now write n for n_1 and place the factor I , which is a constant for all pairs of points 1, 2, ahead of the integral sign, this becomes

$$-I \int_s \frac{\partial}{\partial n} \frac{1}{r} d\sigma. \quad (7a)$$

Together with (5) we then obtain as the value of the right side of (4):

$$4\pi\Psi_0 - I \int_s \frac{\partial}{\partial n} \frac{1}{r} d\sigma.$$

Since the left side of (4) vanishes because $\Delta u = \Delta v = 0$, we obtain as the final representation of Ψ :

$$4\pi\Psi_Q = I \int_S \frac{\partial}{\partial n} \frac{1}{r} d\sigma. \quad (8)$$

The integral on the right has a very simple geometrical significance: It is the *solid angle* Ω intercepted by the circuit A at the point Q . In fact the integrand in Eq. (8)

$$\frac{\partial}{\partial n} \frac{1}{r} d\sigma = \frac{1}{r^2} \cos(n, r) d\sigma = \frac{d\sigma_n}{r^2}$$

is the surface element df of the unit sphere about Q cut out by the radii directed toward the boundary of $d\sigma$; $d\sigma_n$ is the corresponding surface element of a sphere of radius r . Hence

$$\Omega = \int_S df \quad (8a)$$

is the total area cut out on the unit sphere by the cone of radii directed toward the boundary of S , i.e. the above mentioned solid angle.

FIG. 21. The magnetic line integral about the conductor A , extended from side 1 to side 2 of the branch cut S .

The potential jump at the branch cut, $\Psi_1 - \Psi_2$, now also acquires a certain simple meaning. For if we place our point Q on side 1 of S the cone of radii degenerates into a flat fan and the solid angle Ω to 2π ; on the other hand, if we place it on side 2, the solid angle becomes $\Omega = -2\pi$. If we form the difference of Eq. (8) for the two cases we find

$$4\pi(\Psi_1 - \Psi_2) = I(2\pi - [-2\pi]),$$

i.e. the potential jump demanded by (3).

We will supplement this *geometrical* interpretation of the expression (8) by a *magnetic* interpretation: We speak of a *double layer* on the branch cut S with the *magnetic surface densities* $\pm \omega_m$, which we think of as distributed parallel to S at a distance dn from each other. We regard the current I as the moment per unit area of this magnetic double layer:

$$I = \omega_m dn. \quad (9)$$

Eq. (8) may then be written

$$4\pi\Psi = \int_s \omega_m dn \frac{\partial}{\partial n} \frac{1}{r} d\sigma. \quad (9a)$$

If we designate by r_{\pm} the distances of the point Q from the positive and the negative layer respectively we have

$$\frac{\partial}{\partial n} \frac{1}{r} dn = \frac{1}{r_+} - \frac{1}{r_-} \quad \text{and} \quad 4\pi\Psi = \int \frac{\omega_m d\sigma}{r_+} - \int \frac{\omega_m d\sigma}{r_-}. \quad (9b)$$

Accordingly Eq. (8) is in fact the potential of a *magnetic double layer* whose moment has the constant value I over its entire surface. Following Ampère we call the carrier of this double layer a *magnetic shell*; the linear conductor A forms the *boundary* of this shell.

In this connection we state a generally valid law of potential theory for simple and double layers: A simple layer of the type (7.5a)

$$4\pi\Psi = \int \frac{\omega}{r} d\sigma$$

leaves the *potential* Ψ *continuous* in passing through the carrier surface σ , but leads to a *discontinuous* normal component of the potential *gradient*, since

$$\left(\frac{\partial\Psi}{\partial n}\right)_1 - \left(\frac{\partial\Psi}{\partial n}\right)_2 = \omega;$$

on the other hand, a double layer of the type (8)

$$4\pi\Psi = \int I \frac{\partial}{\partial n} \frac{1}{r} d\sigma$$

makes the *potential discontinuous*, but leaves its *gradient continuous*. We have here

$$\Psi_1 - \Psi_2 = I, \quad \text{but } H_1 - H_2 = 0.$$

B. Magnetic Energy and Magnetic Flux

The calculation of the magnetic energy of a linear conductor in a medium of uniform permeability, i.e. the carrying out of the integration in the expression defining this energy:

$$W = \frac{1}{2} \int \mathbf{H} \cdot \mathbf{B} d\tau = \frac{\mu}{2} \int \mathbf{H}^2 d\tau, \quad (10)$$

becomes particularly simple by the above method. We utilize here the so-called "second form of Green's theorem" (Vol. II, Eq. 3.16) which

becomes,

$$\int u \Delta u \, d\tau + \int \text{grad } u \cdot \text{grad } u \, d\tau = \int u \frac{\partial u}{\partial n} \, d\sigma \quad (11)$$

if the two functions u and v occurring there are set equal to each other. We set $u = \Psi$ and extend the integration on the left over the entire exterior of our linear conductor, having made the potential Ψ unique with the aid of the branch cut S . The integral on the right is then to be carried out over the two sides 1 and 2 of S . We can omit the integration over the surface bounding the space considered at infinity in view of our knowledge regarding the behavior of Ψ at infinity.

The first term on the left of (11) vanishes since $\Delta\Psi = 0$; the second is identical with $2W/\mu$ since $\text{grad } \Psi = -\mathbf{H}$. Summing over sides 1 and 2 with due regard of the opposite signs of $\partial\Psi/\partial n$, the right side of (11) becomes

$$\int (\Psi_1 - \Psi_2) \frac{\partial \Psi}{\partial n} \, d\sigma = I \int H_n \, d\sigma, \quad (11a)$$

where the established rule regarding the correlation of the sign of the normal n and the direction of the current is to be observed. We thus obtain from (11)

$$W = \frac{\mu}{2} I \int H_n \, d\sigma = \frac{1}{2} I \Phi; \quad (12)$$

Here Φ is the flux of the magnetic induction through our conductor Λ .

A particularly simple definition of the coefficient of selfinduction L may be deduced from (12). For, if we compare (12) with the equation of definition (15.17) specialized for a single conductor,

$$W = \frac{1}{2} LI^2 \quad (13)$$

we find directly

$$\Phi = LI; \quad L = \Phi/I. \quad (14)$$

We now pass from the single linear conductor considered so far to two linear conductors Λ_1 and Λ_2 . We must then make space "singly connected" by means of two branch cuts S_1 and S_2 , which are bounded by the currents I_1 and I_2 . We shall call the normals correlated to I_1 and I_2 by the right screw rule n_1 and n_2 . By superposition the magnetic fields of I_1 and I_2 form the total field $\mathbf{H} = \mathbf{H}_1 + \mathbf{H}_2$. In the integration over S_1 and S_2 , to be carried out as in (11a), there appear the expressions

$$I_1 \int_{S_1} (\mathbf{H}_1 + \mathbf{H}_2)_{n_1} \, d\sigma_1 \text{ and } I_2 \int_{S_2} (\mathbf{H}_1 + \mathbf{H}_2)_{n_2} \, d\sigma_2.$$

Thus (12) is replaced by an energy expression of four terms, which we shall write, as in (15.17),

$$W = \frac{1}{2}(L_{11}I_1^2 + (L_{12} + L_{21})I_1I_2 + L_{22}I_2^2), \quad (15)$$

$$L_{11} = \frac{\mu}{I_1} \int_{S_1} H_{1n_1} d\sigma_1, \quad L_{22} = \frac{\mu}{I_2} \int_{S_2} H_{2n_2} d\sigma_2, \quad (15a)$$

$$L_{12} = \frac{\mu}{I_2} \int_{S_1} H_{2n_1} d\sigma_1, \quad L_{21} = \frac{\mu}{I_1} \int_{S_2} H_{1n_2} d\sigma_2. \quad (15b)$$

If \mathbf{H} is expressed by Ψ , and Ψ by (8), it will be recognized that also with this definition

$$L_{12} = L_{21}.$$

We then obtain

$$4\pi L_{12} = \mu \int_{S_1} d\sigma_1 \int_{S_2} d\sigma_2 \frac{\partial^2}{\partial n_1 \partial n_2} \frac{1}{r_{12}}, \quad (16)$$

where r_{12} is the distance between any one point on S_1 and any second point on S_2 . Since the right side of (16) is symmetrical with respect to the indices 1 and 2 it represents also L_{21} .

By the representation in (15a, b) the magnetic fluxes Φ_1 and Φ_2 through S_1 and S_2 may be written

$$\begin{aligned} \Phi_1 &= \mu \int_{S_1} (\mathbf{H}_1 + \mathbf{H}_2)_{n_1} d\sigma_1 = L_{11} I_1 + L_{12} I_2, \\ \Phi_2 &= \mu \int_{S_2} (\mathbf{H}_1 + \mathbf{H}_2)_{n_2} d\sigma_2 = L_{21} I_1 + L_{22} I_2. \end{aligned} \quad (17)$$

The magnetic flux is thus now expressed by two elements (for n linear conductors by n elements) in terms of the two (or n) currents.

C. Application to the Selfinductance of a Two-Wire Line

As in §15E we regard conductor and return conductor as *one* closed circuit and designate, just as there, the separation of the wires with a , the radius with b . Since we cannot proceed to the limit $b \rightarrow 0$ our method of the scalar potential, which is restricted to linear conductors, is strictly inapplicable. However, we may regard Eq. (14), quite apart from its origin in this method, as the definition of the selfinductance L , or, more exactly, of that part of L which has its origin in the exterior of the wires (see Fig. 22).

The portion of the branch cut S which is of importance to us has here been shaded. It extends in the xy -plane (the plane containing the two axes of the wires) from the periphery of one wire to that of the other and is to have the length 1 in the y -direction. The magnetic field \mathbf{H} results, in gen-

eral, from the *vectorial* superposition of the magnetic fields H_1 and H_2 of the two wires. On the plane area S , H_1 and H_2 have, however, the same direction, since $I_1 = -I_2$, and are perpendicular to S . With x and $a - x$,

FIG. 22. Selfinductance of a two-wire line, computed from the magnetic flux through the branch cut S .

respectively, indicating the distance of the reference point on S from the conductor and the return conductor we obtain

$$H_x = \frac{I}{2\pi} \left(\frac{1}{x} + \frac{1}{a-x} \right);$$

hence we find from (14) for unity length of the two-wire line

$$L_a = \frac{\mu}{2\pi} \int_b^{a-b} \left(\frac{1}{x} + \frac{1}{a-x} \right) dx. \quad (18)$$

The subscript a of L indicates "external selfinductance". The evaluation of (18) yields:

$$L_a = \frac{\mu}{2\pi} \left(\log \frac{a-b}{b} - \log \frac{b}{a-b} \right) = \frac{\mu}{\pi} \log \frac{a-b}{b} \sim \frac{\mu}{\pi} \log \frac{a}{b}, \quad (19)$$

the last since $b \ll a$. If we compare this with (15.35), we see that the first part of the earlier formula corresponds to our "external" selfinductance and conclude from this that the second part will signify the "inner" selfinductance L_i .

We confirm this in the following manner: Employing the energetic definition of selfinductance in (15.17) we put

$$W_i = \frac{1}{2} L_i I^2. \quad (20)$$

W_i is the magnetic energy within a unit segment of our two-wire line. Within the individual wire the magnetic field is given, as in (15.33a), by

$$H = \frac{r}{b} \frac{I}{2\pi b},$$

if we neglect the magnetic field of the other single wire, which is weak in comparison. Hence the energy content of unit length of the individual wire becomes as in (15.33a)

$$\frac{\mu}{2} \int_0^b \int_0^{2\pi} H^2 r \, dr \, d\varphi = \mu\pi \int_0^b \left(\frac{r}{b} \frac{I}{2\pi b} \right)^2 r \, dr = \frac{\mu I^2}{4\pi b^4} \int_0^b r^3 \, dr = \frac{\mu I^2}{16\pi}.$$

This is one half of the energy W_i in (20). It hence follows from (20) that

$$L_i = \frac{\mu}{4\pi}. \quad (20a)$$

Together with (19) this confirms our earlier result (15.35).

D. Application to the Electromagnetic Current Measurement of Wilhelm Weber

We proceed from Eq. (8) and assume to begin with that the surface S bounded by the current I is *plane*; the reference point for which Ψ is to be computed is supposed to be at a *great* distance from S . Then the direction of dn and the magnitude of $1/r$ become the same for all elements $d\sigma$ of S . The integration over $d\sigma$ may be carried out directly and yields

$$4\pi\Psi = IS \frac{\partial}{\partial n} \frac{1}{r}. \quad (21)$$

At the same time we recall Eq. (7.10b) for the potential of a single magnetic pole p . From it we obtain for the potential of a dipole of the very small separation l between poles and the direction n of the axis:

$$4\pi\Psi = M \frac{\partial}{\partial n} \frac{1}{r}, \quad M = pl = \text{moment of the dipole}. \quad (22)$$

Comparison of (21) and (22) indicates: *The magnetic field of a current I bounding a surface S is, at large distance, equal to that of a dipole, we might also say a short bar magnet, which is placed perpendicular to the surface S and has the moment $M = IS$.*

A non-plane current path may be projected on three mutually perpendicular planes and the equivalent bar magnets may be arranged perpendicularly to the resulting plane current paths. Vectorial addition of their moments yields an obliquely oriented dipole, which at large distance again produces the same magnetic field as the original current path.

This *equivalence of current and magnetism* is the basis of the famous "electrodynamic determination of units" of Wilhelm Weber. Furthermore the electromagnetic system of units, which hails back to Weber, is based on it, i.e. on putting equal

$$I \cdot S = M. \quad (23)$$

The *electric* quantity I thus becomes a *magnetic* quantity. Or rather: For the electric quantity I a quantity M/S , which appears different in character, is substituted. This is possible only if a definite relation is established between the dimension of the magnetic pole, which as before we shall designate as P , and the dimension Q of charge. By (23) this relation is

$$Q \cdot \frac{\text{area}}{\text{time}} = P \cdot \text{length}$$

or

$$P = Q \cdot \frac{\text{length}}{\text{time}} = Q \cdot \text{velocity}.$$

We thus arrive at *Ampère's hypothesis* according to which magnetism is merely electricity in motion. However, we mentioned already on p. 47 that this hypothesis is today, after the discovery of the neutron as a basic element of all nuclear matter, no longer as binding as a hundred years ago; we also saw in §8B that Cohn's system of units is independent of this hypothesis and is recommended particularly by that fact.

Our system of the four units MKSQ bears a peculiar relation to the electromagnetic cgs-system introduced by Weber. As we know, our unit $Q = 1$ coulomb = 1 ampere-second is defined as 1/10 of the electromagnetic unit of charge. The fundamental constants of vacuum, with due regard for the experimental fact $\epsilon_0 \mu_0 = 1/c^2$, were therefore found to be

$$\mu_0 = 4\pi \cdot 10^{-7} \frac{\text{joule S}^2}{Q^2 M} = 4\pi \cdot 10^{-7} \frac{\text{henry}}{M}, \text{ Eq. (15.18b)} \quad (24)$$

$$\epsilon_0 = \frac{1}{\mu_0 c^2} = \frac{10^9}{4\pi c^2} \frac{Q^2 M}{\text{joule S}^2} \simeq \frac{10^{-9}}{36\pi} \frac{\text{farad}}{M}, \text{ Eqs. (7.17) and (10.3b)} \quad (25)$$

$$\sqrt{\frac{\mu_0}{\epsilon_0}} = 4\pi c 10^{-7} \frac{\text{joule S}^2}{Q^2 M} \simeq 120\pi \Omega, \text{ Eqs. (7.19) and (4.5c).} \quad (26)$$

However, we know that, apart from the electromagnetic (more briefly *magnetic*) system, also an electrostatic (more briefly *electric*) system is in use. Here the arbitrary, and only historically justifiable, convention (7.8) is made:

$$f = 4\pi e_0 = 1 \quad (27)$$

and from this an *electrostatic unit* of charge e_{st} is defined. We ask how Q is to be expressed in this unit, i.e. what value Q/e_{st} may have, having fixed the value of Q measured in terms of the *electromagnetic unit* of charge e_{mag} by

$$\frac{Q}{e_{mag}} = \frac{1}{10}. \quad (28)$$

From Eqs. (25) and (27):

$$4\pi\epsilon_0 = 1 = \frac{10^9}{c^2} \frac{(Q/e_{el})^2 \cdot 10^3 \text{ cm}}{10^7 \text{ erg sec}^2}.$$

From this and (28) it follows that

$$1 = \frac{1}{c^2} (e_{\text{magn}}/e_{el})^2, \quad \frac{e_{\text{magn}}}{e_{el}} = c \simeq 3 \cdot 10^{10} \frac{\text{cm}}{\text{sec}}. \quad (29)$$

The unit of charge in the magnetic system is $3 \cdot 10^{10}$ times larger than the unit of charge in the electric system. This corresponds to our metaphor of river and waterfall on p. 53. The numerical values of a given physical charge behave of course in inverse fashion. Thus the coulomb has, in the electric cgs-system, the numerical value

$$Q = \frac{1}{10} \cdot c = 3 \cdot 10^9;$$

see also our data on the charge of the electron in §8D:

$$4.80 \cdot 10^{-10} \text{ electric and } 1.60 \cdot 10^{-20} \text{ magnetic units.}$$

The conversion rule for the numerical value e of an arbitrary charge in and MKSQ system to the corresponding numerical values e_{magn} and e_{el} is

$$10^9 \left(\frac{e^2}{4\pi\epsilon_0} \right)_{\text{MKSQ}} = c^2 e_{\text{magn}}^2 = e_{el}^2. \quad (30)$$

Since the quotient D/e on the one hand and the product Ee on the other are independent of our fourth unit, the conversion of D and E may readily be derived from Eq. (30); for the conversion of E (30) yields

$$10 (4\pi\epsilon_0 E^2)_{\text{MKSQ}} = \frac{1}{c^2} E_{\text{magn}}^2 = E_{el}^2. \quad (31)$$

Rules (30) and (31) replace the rule given by H. A. Lorentz on p. 87 of Vol. V₂ of the *Mathematische Enzyklopädie*.

With this the unpleasant business of the electrical units may be regarded as definitely disposed of.

§17. Detailed Treatment of the Field of a Straight Wire and a Coil

We consider the apparently trivial case of an infinitely long straight wire carrying a stationary current with a return path in a coaxial hollow cylinder surrounding it. Let the radius of the wire be a , the inner radius of the hollow cylinder b , and the outer radius $c \rightarrow \infty$. For reasons of symmetry

the magnetic field is known directly, and similarly the current density. As in §4, Eqs. (10) to (13), we have

$$\begin{aligned} r < a, \quad H &= \frac{r}{a} \frac{I}{2\pi a}, \quad J = \frac{I}{\pi a^2}, \\ a < r < b, \quad H &= \frac{I}{2\pi r}, \quad J = 0, \\ b < r < \infty, \quad H &= \frac{I}{2\pi r}, \quad J = 0. \end{aligned} \quad (1)$$

The direction of H is everywhere azimuthal: $H = H_\varphi$.

In the interior the electric field is everywhere axial in direction and has by Ohm's law the value

$$E = E_z = \frac{J}{\sigma} = \frac{I}{\pi a^2 \sigma}, \quad r \leq a. \quad (2)$$

Similarly by Ohm's law we have within the hollow cylinder (conductivity σ_1)

$$E = \frac{J}{\sigma_1} = 0, \quad b \leq r < \infty. \quad (3)$$

In the region between wire and hollow cylinder the field is yet to be determined, from the differential equations

$$\mathbf{E} = -\text{grad } \Psi, \quad \Delta \Psi = 0 \quad (4)$$

and the boundary conditions

$$\frac{\partial \Psi}{\partial z} = -E_z = \begin{cases} -\frac{I}{\pi a^2 \sigma} & \text{for } r = a, \\ 0 & \text{for } r = b. \end{cases} \quad (5)$$

Since these conditions are independent of z and φ we can write for the solution of $\Delta \Psi = 0$

$$\Psi = \Psi_1(r)z. \quad (6)$$

We can omit an additive term $\Psi_2(r)$ independent of z since we can satisfy all the conditions of the problem with formula (6). We then obtain from (5)

$$\Psi_1(a) = -\frac{I}{\pi a^2 \sigma}; \quad \Psi_1(b) = 0. \quad (7)$$

The differential Eq. (4) demands

$$\frac{d}{dr} r \frac{d\Psi_1}{dr} = 0, \quad \Psi_1 = A \log r + B,$$

which yields, with (7)

$$\Psi_1(r) = -\frac{I}{\pi a^2 \sigma} \log \frac{r}{b} / \log \frac{a}{b}. \quad (8)$$

Now the field \mathbf{E} is known also in the intermediate space $a < r < b$. According to (6) and (8) it is represented by

$$E_z = -\Psi_1 = \frac{I}{\pi a^2 \sigma} \log \frac{r}{b} / \log \frac{a}{b}, \quad (9)$$

$$E_r = -\frac{\partial \Psi_1}{\partial r} z = \frac{Iz}{\pi a^2 \sigma r} / \log \frac{a}{b}. \quad (9a)$$

Thus the field is here by no means axial in direction, as in the interior of the wire; rather, its radial component is of the same order of magnitude as its axial component.

In passing from the interior to the exterior of the wire there occurs a jump in E_r and hence also in the corresponding component of the excitation D , which indicates the existence of a *surface charge*:

$$\omega = D_r = eE_r = \frac{eIz}{\pi a^2 \sigma} / \log \frac{a}{b}. \quad (10)$$

This surface charge decreases linearly along the wire, from positive to negative values, in formal language from $+\infty$ to $-\infty$. It depends only slightly, i.e. logarithmically, on the radius b of the outer return conductor. The zero point of the charge remains undetermined since the point $z = 0$ can be fixed arbitrarily. We may eventually identify it with the "center" of the wire, which, for infinite length, also remains indefinite.

We can obtain an idea as to the magnitude of this charge in the following manner: The dielectric constant in (10), which refers to the exterior of the wire, does not differ materially from that in the interior of the wire (though for metals it is rather hypothetical). Hence the quotient e/σ does not differ materially from the relaxation time T_r , defined in (4.9a), for the material of the wire; this is of the order of *microseconds*. The product eI/σ occurring in (10), which represents a charge, is thus not of the order of an ampere-second = Q , but of the order of a microampere-second = $10^{-6} Q$. The peripheral charge of the wire and the radial field strength corresponding to it are hence very small. This is the reason why they generally remain unnoticed both in theory and in experiment although, as we shall see, they are essential for an understanding of the current transport.

Implicit in the existence of a radial electric field is the appearance of a potential difference between wire and return conductor. According to (9a) it is given by

$$V = \int_a^b E_r dr = -\frac{Iz}{\pi a^2 \sigma}. \quad (11)$$

We compare it with the charge on unit length of the wire, $e = 2\pi a\omega$, or the equal and opposite charge on unit length of the return conductor. We find

$$\frac{e}{V} = \frac{2\pi e}{\log \frac{b}{a}}. \quad (11a)$$

This is the capacity per unit length of the cylindrical condenser formed by the wire and the return conductor (see Problem II.5). We speak here and in similar cases of a "distributed capacity."

Fig. 23 shows the shape of the *equipotential lines* $\Psi = \text{const.}$ in the z, r -plane, given according to Eqs. (6) and (8) by

$$z \log \frac{b}{r} = C. \quad (12)$$

For $C = 0$, $z = 0$ and $r = b$, corresponding to the broken lines ABC and ABD of the figure. The equipotential lines for $C > 0$ accommodate themselves within the area bounded by them. The angles under which they meet the surface of the wire deviate increasingly from a right angle with increasing distance from A . The orthogonal trajectories to the equipotential lines represent the *lines of force*; the arrows on them indicate the direction from positive to negative surface charge ω . Two bounding curves passing through the "equilibrium point" B (see footnote 2 after Eq. (9.14b)) belong to this family of curves. According to (12) the equipotential lines satisfy the differential equation

$$\log \frac{b}{r} dz - z \frac{dr}{r} = 0;$$

on the other hand, the lines of force, which are orthogonal thereto, (replacement of dz/dr by $-dr/dz$) are given by

$$z dz + r \log \frac{b}{r} dr = 0.$$

In the neighborhood of B we find, with $\rho = b - r$,

$$z dz - \rho d\rho = 0.$$

Thus *two* lines of force, with tangent directions $z = \pm\rho$, pass through the point B forming a right angle with each other. At a greater distance from these bounding curves, above and below them, the lines of force pass more or less radially from the wire surface to the outer conductor.

The equipotential lines represent at the same time the paths of the *energy flux* \mathbf{S} ; the arrows marked on them indicate the direction of \mathbf{S} . From

the formula $\mathbf{S} = \mathbf{E} \times \mathbf{H}$, \mathbf{S} is perpendicular to \mathbf{H} and hence lies in the plane of the drawing, since \mathbf{H} is everywhere perpendicular thereto; in addition \mathbf{S} is perpendicular to \mathbf{E} and hence has everywhere the direction of the family of curves $\Psi = \text{const.}$ An application of the right-screw rule for the three vectors \mathbf{E} , \mathbf{H} , \mathbf{S} shows that the arrows are properly oriented.

FIG. 23. Energy flux about a straight wire carrying stationary current with coaxial return conductor. Equipotential lines = stream lines of the energy drawn out full, electrical lines of force = excitation lines drawn dotted. They form tubes of constant charge starting and ending on the surface of the wire and the return conductor, respectively. Their number per unit length of the wire indicates the surface charge on the latter and its linear increase with distance from A , positive for $z < 0$, negative for $z > 0$.

Since $\mathbf{E} = \mathbf{J}/\sigma$ the lines of force within the wire (not drawn in the figure) are axial in direction; hence the vector \mathbf{S} is directed inward, perpendicular to the surface of the wire; here also it lies in the equipotential surfaces $\Psi = \text{const.}$ The energy flux is dissipated in the interior of the wire since it becomes zero for $r = 0$, in view of $\mathbf{H} = 0$. This is indicated in the figure by the terminated arrows at A . Such arrows should be imagined along the

entire surface $r = a$. The energy entering from the surface is converted into Joule heat in the interior of the wire.

According to (9) and (1) the magnitude of the energy flux for $r = a$ is

$$|S| = E \cdot H_r = \frac{I}{\pi a^2 \sigma} \frac{I}{2\pi a};$$

the energy supply to unit length of the wire from all sides hence becomes

$$2\pi a |S| = I^2 R_1, \quad R_1 = \frac{1}{q\sigma}, \quad q = \pi a^2. \quad (13)$$

R_1 is the ohmic resistance of unit length of the wire; (13) thus yields, in fact, the Joule heat claimed by this unit length.

Accordingly we obtain the following total picture of the behavior of the energy: *Outside of the wire the energy flows from the electrodes $z = \pm\infty$ from all sides toward the surface of the wire. After entering it it flows radially toward the axis of the wire, being converted at the same time into heat. There is no energy flux parallel to the wire axis within the wire.*

This picture is materially different from the popular concept of the energy transfer in a wire carrying current. From the Maxwellian standpoint there is no doubt, however, about the inner consistency and unique validity of our picture. It indicates the fundamental change which Maxwell's theory has brought in the concepts conductor and nonconductor: *The conductors are nonconductors of energy. Electromagnetic energy is transported without loss only in nonconductors; in conductors it is destroyed, or rather transformed.* The notation "conductor" and "nonconductor" refers only to the behavior with respect to *charge*; it is misleading if applied to behavior with regard to *energy*.

We thus come to the conclusion that our simple example is after all not as trivial as it appeared.

The next-simplest case of the circular conductor is already beyond elementary treatment. Even in the limiting case of the linear conductor the geometrical formula for the solid angle involves an elliptic integral. In fact, if we use the polar coordinates r, φ, z for the reference point and $\rho, \alpha + \varphi - \pi, 0$ for the point of integration we find from Eq. (16.8), denoting the distance between point of integration and reference point by R ,

$$\begin{aligned} \int \frac{\partial}{\partial n} \frac{1}{R} d\sigma &= \int_0^\pi \rho d\rho \int_0^{2\pi} d\alpha \frac{\partial}{\partial z} (r^2 + \rho^2 + 2r\rho \cos \alpha + z^2)^{-1/2} \\ &= 4 \frac{\partial}{\partial z} \int_0^\pi \frac{\rho d\rho}{\sqrt{(r+\rho)^2 + z^2}} \int_0^{\pi/2} \frac{d\beta}{\sqrt{1 - k^2 \sin^2 \beta}} \\ \beta &= \alpha/2 \\ k^2 &= \frac{4r\rho}{(r+\rho)^2 + z^2} \end{aligned}$$

The preceding integral with respect to β is a "complete elliptical integral of the first kind in the Legendre standard form," and k is the "modulus" thereof. We cannot of course here delve further into the treatment of this formula.

The exact treatment of a coil of wire of finite thickness with finite pitch would be even more complex. We hence pass directly to the limiting case of very small thickness and pitch, i.e. Ampère's solenoid, whose magnetic field was already discussed in Eq. (4.14), though only superficially. We now wish to compare it with the field of a permanent uniformly magnetized bar magnet of the same dimensions as the coil. We shall here assume the interior of the coil and the coil wire to be unmagnetic ($\mu = \mu_0$).

We shall show that the \mathbf{H} -field of the coil corresponds to the \mathbf{B} -field of such a bar magnet. As proof we write down the boundary conditions and differential equations for the two cases side by side:

<i>Coil</i>	<i>Bar Magnet</i>
$(\mathbf{H}_n - \mathbf{H}_t)_s = N_1 I,$	$(\mathbf{B}_n - \mathbf{B}_t)_s = \mu_0(\mathbf{H}_n - \mathbf{H}_t - \mathbf{M})_s = -\mu_0 \mathbf{M}_s,$
$(\mathbf{H}_n - \mathbf{H}_t)_n = 0,$	$(\mathbf{B}_n - \mathbf{B}_t)_n = 0,$
$\Delta\psi = 0,$	$\text{div } \mathbf{B} = \mu_0 \text{div } \mathbf{H} = -\mu_0 \Delta\psi = 0.$

The first line relates to the *mantel surface*. Its left half states simply, in the terminology introduced at Eq. (4.4e), that the surface curl on the mantel surface of the coil is equal to $N_1 I$, where N_1 is the number of turns per unit length. The right half of the first line follows from our equation $\mathbf{B} = \mu_0(\mathbf{H}_t + \mathbf{M})$ for the interior of the bar magnet, which for the exterior becomes $\mathbf{B} = \mu_0 \mathbf{H}_n$. It states that the surface curl of \mathbf{B} on the mantel surface of the bar is equal to $-\mu_0 \mathbf{M}$. A comparison of the two halves of the first line shows that, in the bar magnet, the quantity $-\mu_0 \mathbf{M}/N_1$ corresponds to the current I in the coil.

We apply the second line in particular to the two *end surfaces*. Here both \mathbf{B} and \mathbf{H} are of course continuous for the solenoid, for the bar magnet only \mathbf{B} . Since we have assumed $\mu = \mu_0$ the same equations apply also for the mantel surface.

The third line applies in the two cases both for the interior and for the exterior; here we must recall our assumption regarding the bar magnet that its magnetization was supposed to be uniform, since otherwise the term $\mu_0 \text{div } \mathbf{M}$ would have to be added to the term $\mu_0 \text{div } \mathbf{H}$ and this would spoil the comparison of the two cases.

We see therefore that our earlier Fig. 17, which represented the \mathbf{B} -field of the bar magnet, reproduces simultaneously the \mathbf{H} -field of the solenoid. Accordingly the earlier Eq. (4.14), which applies only for an infinitely long coil, is rounded out graphically by Fig. 17. This provides us now with a complete picture of the spreading of the lines of excitation at the ends of the coil and of their exit through the convex surface.

With respect to the representation of the coil field by the potential Ψ we wish to point out expressly its familiar multivalued character; the branch cut S , which makes it single valued, is a helical surface of infinitely small pitch which follows the turns of the wire. It follows that the equation

$$\oint \mathbf{H} \cdot d\mathbf{s} = 0$$

which is universally valid for the bar magnet loses its validity for the coil if the path of integration links one or several turns. Hence also the conclusion with regard to the demagnetizing character of the \mathbf{H} -field of the bar magnet is not applicable to the coil. For to reach this conclusion, we employed (see p. 85) a path which inside was along the axis of the bar and on the outside led back to the bar axis. This same path, for the coil, intersects the above-mentioned helical surface and therefore is not a permissible path of integration.

We can also make the following statement: The \mathbf{H} -field of the *bar magnet* is *lamellar* throughout, that of the *coil* is *not*; instead it has the *curl I concentrated* at the turns of wire. The \mathbf{H} -field of the coil is *solenoidal* throughout, since everywhere $\mathbf{B} = \mu_0 \mathbf{H}$, that of the bar magnet is *not*. For the uniformly magnetized bar the bar ends have a *surface distribution of divergence*. In view of the proportionality of \mathbf{B} and \mathbf{H} for the coil, Fig. 17 evidently also represents the \mathbf{B} -field of the coil. The \mathbf{H} -field of the bar magnet, Fig. 18, is materially different from Fig. 17.

The near-uniformity of the internal field evident in Fig. 17 suggests the computation of the magnetic energy W of the coil by the formula

$$W = \frac{\mu}{2} \mathbf{H}^2 V, \quad (14)$$

where $V = \pi a^2 l$ is the volume of the interior of the coil. In view of the relation $Hl = NI$ (Eq. (4.14)), where N is the number of turns along the full length of the coil, (14) takes the form

$$W = \frac{\pi a^2}{l} \mu N^2 \frac{I^2}{2}. \quad (14a)$$

A comparison with our energetic definition of selfinductance in (15.17) leads to the following value of the latter:

$$L = \frac{\pi a^2}{l} \mu N^2. \quad (15)$$

This formula applies, of course, as may also be seen from Fig. 17, only for a *very long* coil and hence can scarcely be used for forms encountered in practice. On the other hand, it retains its validity if the straight coil is bent into a *ring electromagnet*, because of the close approach to field uniformity

within the latter. Here the factor μ in (15) also becomes significant if the ring is provided with a soft-iron core. Eq. (15) shows that this arrangement, first suggested by Ampère, has a much greater selfinductance and hence realizes a much greater concentration of energy than the electromagnet without iron *for equal coil current*.

This increase in energy concentration applies qualitatively also to the straight coil with soft-iron core. The quantitative computation of field and energy would, however, be much more complex, since a boundary-value problem, corresponding to the passage of the magnetic lines of force from iron into air, would be added to the summation problem which we have treated.

§18. Quasi-Stationary Currents

Most of the problems of electrical engineering and of laboratory physics lie within the domain of the *slowly variable fields*. It is true that there is no one-word answer to the question "slow compared with what?". For vibrations which are periodic in time or exhibit a damped periodicity the answer may be identified with the demand that the light path corresponding to the period τ of the vibration be large compared to the dimensions l of the apparatus:

$$c\tau \gg l. \quad (1)$$

It is then permissible to neglect the "retardation of the fields" to be introduced in §19. At the end of this paragraph we shall, however, treat successfully also very long lines, which do not obey this condition, on a quasi-stationary basis, by subdivision into differential segments.

In general terms the *quasi-stationary* approximation consists in calculating all fields as for *stationary* processes. In this manner it becomes possible to establish a *linear* relation between the expressions occurring in the integral form of the Maxwell equations. We refer to the magnetic flux Φ through a closed curve, the current I through a cross section, and the electromotive forces V_a along segments of the path of integration, which add up to the loop e.m.f. V for this path:

$$\Phi = \int B_n d\sigma, \quad I = \int J_n d\sigma, \quad V_{12} = \int_1^2 E_s ds,$$

$$V = \sum V_a = \oint E_s ds.$$

We know that, under stationary conditions, the following relations exist between them:

$$\Phi_1 = L_{11}I_1 + L_{12}I_2 + L_{13}I_3 + \dots \text{ (magn. flux through circuit 1)}$$

$$I = \frac{V}{R} \text{ (Ohm's law), } I = \dot{V}K \text{ (condenser charge).}$$

The inductances L , resistances R , and capacities K depend, apart from the material constants, only on the geometry of the field and are the result of an integration over the *space* coordinates. Hence only an integration with respect to the *time* remains to be carried out. The mathematical simplification achieved in this manner is considerable: While the exact treatment of rapidly variable fields demands the integration of the Maxwell *partial differential equations*, the integration of *ordinary differential equations* with constant coefficients suffices for slowly varying fields; for periodic processes these reduce even to *algebraic equations*.

This method was developed by Gustav Kirchhoff (see beginning of §15) and was applied to metal wire loops and networks composed of them. It is in general appropriate to choose the closed path of integration along the metal wires; an interruption of the metallic path by nonconducting gaps (condensers) does not interfere with the method, however. The case of *thin* wires is particularly convenient, since here the field within the wire is practically uniform.

The *first* Maxwell equation in integral form then yields for the chosen closed path of integration

$$-\dot{\Phi} = V = \text{loop e.m.f.} \quad (2)$$

The *second* Maxwell equation finds expression in the computation of the coefficients of induction insofar as it represents the production of magnetic fields by currents and in the computation of the resistances and capacities insofar as it represents the origin of these currents from the electric field.

For a simple current loop without branching the two sides of (2) may be expressed in terms of the current I which is the *same* for all cross sections:

$$-I \sum L = I \sum R + \int I \, dt \sum \frac{1}{K} + E. \quad (3)$$

It is seen that here the selfinductance coefficients of all the magnetic fields can be combined in a single expression, which may be represented by an imaginary coil at an arbitrary point of the circuit. The same applies for the resistances and the capacitances. E is the presumably known e.m.f. between the terminals by which the current enters and leaves, i.e. the so-called *terminal e.m.f.* The introduction of this e.m.f. E conveniently avoids carrying the path of integration through apparatus whose action is not covered by the Maxwell theory (galvanic or thermoelements, photoelectric cells, electron tubes) or through "machines" which, though they function fully within the framework of the theory, would unduly complicate the problem.

If *several* loops are joined in a *network*, the latter may be regarded as made up of elements connecting the "junction points". Let the n th element carry a current I_n from one junction point to another. Since we do not as yet know its sign, we place a marker arrow on the element which is to

indicate in what direction we shall reckon the current as positive. In view of the absence of current sources we have for the junction points

$$\sum I_n = 0 \quad (4)$$

and for every circuit made up of arbitrary elements Eq. (2) applies again in the form

$$\sum I_n R_n + \sum V_{em} = -\dot{\Phi} \quad (= \text{e.m.f.}). \quad (5)$$

(4) and (5) are known as the "first" and "second" Kirchhoff equations. They date from the time preceding Maxwell's theory. Hence Kirchhoff places on the right side of (5) not $-\dot{\Phi}$, but the older concept of the *electromotive force* (e.m.f.) of all "current sources" which are inserted in the closed circuit. If we are dealing with currents which result from Faraday induction, e.g. in coils of machines, this e.m.f. becomes exactly identical with $-\dot{\Phi}$ and its concept is superfluous. It has, however, the advantage of covering also the effect of other current sources (batteries etc.) without requiring an examination of the physical processes taking place therein.

A. Energetic Interpretation of the Wave Equation

We consider in particular an unbranched circuit with selfinductance, capacitance, and ohmic resistance, which we imagine connected in series and, as in Eq. (3), concentrated at certain points of the circuit. Thus we insert a resistance box in place of the resistance which is distributed over the wire; a coil in place of the distributed selfinductance with which we became familiar in connection with the two-wire line in §15E; and we shall not consider distributed capacities in the circuit but assume instead the presence of an electric plate condenser.

The law of conservation of energy offers a particularly convenient approach to the treatment of such a system, just as to the treatment of material vibrations in mechanics. We write it in the form of Eq. (5.7a):

$$\dot{W}_m + \dot{W}_e + Q = \oint S_n d\sigma. \quad (6)$$

W_m is the magnetic energy concentrated in the coil, given according to Eq. (17.14a) by

$$W_m = \frac{L}{2} I^2. \quad (6a)$$

W_e is the electric energy within the plate condenser, according to Eq. (10.11) given by

$$W_e = \frac{1}{2K} e^2. \quad (6b)$$

Here $\pm e$ are the varying charges on the two condenser plates and

$$I = \frac{de}{dt}. \quad (6c)$$

Q is the Joule heat generated within the resistance box:

$$Q = RI^2. \quad (6d)$$

The energy flux S refers to the current source. By Eq. (15.40) we write for the energy supplied by it in unit time

$$\oint S_n d\sigma = EI(\text{volt-ampere} = \text{watt}). \quad (6e)$$

E is the terminal e.m.f. of the current source mentioned above.

From (6a, b) follows

$$\dot{W}_m = LI\dot{I}, \quad \dot{W}_e = \frac{1}{K} e\dot{e} = \frac{1}{K} eI. \quad (6f)$$

Substitution of (6d, e, f) in (6) leads to, after canceling of a factor I :

$$L\dot{I} + RI + \frac{1}{K} e = E, \quad (7)$$

and, after a second differentiation with respect to t , to the wave equation

$$L\ddot{I} + R\dot{I} + \frac{1}{K} I = \dot{E}. \quad (7a)$$

In the terminology of point mechanics there corresponds thus

\dot{E} to the exciting force,

L to the inertia, more particularly the mass of the vibrating particle,

R to the damping, and

K to the coefficient of the restoring force.

As in mechanics, we distinguish between free and forced vibrations.

a. Free Vibrations

We set $E = 0$ and ask for the solution of the homogeneous equation

$$L\ddot{I} + R\dot{I} + \frac{1}{K} I = 0. \quad (8)$$

We can assume a trigonometric form for I , but know from point mechanics that it is definitely preferable to use instead the exponential form at the start and to pass to the real part of I only after the integration. We therefore set¹

$$I = I_0 e^{i\omega t} \quad (8a)$$

¹ Temporarily we adhere to custom in employing the usual positive sign of i in the exponent, although we generally prefer the negative sign. See e.g. §6, Eq. (11).

and obtain for the circular frequency $\omega_0 = 2\pi/\tau_0$ of the free vibration the quadratic equation

$$-L\omega_0^2 + iR\omega_0 + \frac{1}{K} = 0. \quad (8b)$$

For no damping we find

$$\omega_0^2 = \frac{1}{KL}, \quad \tau = 2\pi\sqrt{KL}. \quad (9)$$

This is the Kirchhoff-Thomson formula. If it is necessary to take account of damping the solution of (8b) yields

$$\omega_0 = \frac{iR}{2L} \pm \sqrt{\frac{1}{KL} - \frac{R^2}{4L^2}}. \quad (9a)$$

The process is aperiodic or periodic, depending on whether

$$\frac{R}{2L} > \frac{1}{\sqrt{KL}} \quad \text{or} \quad \frac{R}{2L} < \frac{1}{\sqrt{KL}}. \quad (9d)$$

In the aperiodic case ω_0 is purely imaginary and the current (8a) decreases *monotonically*. In the periodic case usually found with condenser discharges the angular frequency is

$$\sqrt{\frac{1}{KL} - \frac{R^2}{4L^2}}. \quad (9c)$$

Since the ohmic damping occurs here only as a correction of the second order as compared with the first term on the right of (9a), (9c) can usually be replaced by (9)—in analogy with the mathematical pendulum, where the formula $\tau = 2\pi\sqrt{l/g}$ is not affected appreciably by air resistance etc; hence it is generally permissible to write in place of (8a):

$$I = I_0 e^{-Rt/(2L)} \cdot e^{\pm 2\pi i t/\tau_0}, \quad (9d)$$

where τ_0 now represents the value (9) with no damping. The double sign in (9d) evidently becomes unimportant when finally passing to the real part, but permits taking account of the phase of the oscillation which, like the amplitude, may be prescribed arbitrarily, through superposition of the two solutions.

b. Forced Vibrations

Here we proceed preferably from Eq. (7) and set

$$E = E_0 e^{i\omega t};$$

ω is the angular frequency of the alternating current source. The circuit oscillates with the same rhythm as soon as its characteristic vibrations,

which are determined by an arbitrary initial state, have decayed. We have therefore

$$I = I_0 e^{i\omega t}, \quad \dot{I} = i\omega I, \quad e = \frac{I}{i\omega} \quad (\text{see (6c)}).$$

We thus obtain from (7)

$$\left(i\omega L + R + \frac{1}{i\omega K} \right) I = E,$$

for which we shall write more briefly

$$\mathbf{R}I = E. \quad (10)$$

(10) is *Ohm's law for alternating currents*; the real ohmic resistance R is here replaced by the complex impedance

$$\mathbf{R} = R + i \left(\omega L - \frac{1}{\omega K} \right). \quad (10a)$$

If we put

$$\mathbf{R} = |\mathbf{R}| e^{i\alpha}, \quad (10b)$$

we evidently have

$$|\mathbf{R}| = \sqrt{R^2 + \left(\omega L - \frac{1}{\omega K} \right)^2}, \quad \tan \alpha = \frac{\omega L - 1/(\omega K)}{R}. \quad (10c)$$

We introduce the following designations:

$$\begin{aligned} R &= \text{resistance} \\ \omega L - 1/(\omega K) &= \text{reactance} \\ \omega L &= \text{inductive reactance} \\ 1/(\omega K) &= \text{capacitive reactance} \\ |\mathbf{R}| &= \text{impedance.}^1 \end{aligned}$$

We give an interpretation of Eq. (10) in the complex Gaussian plane of Fig. 24. The two-dimensional "vector" I lags by the constant angle α behind the two-dimensional "vector" E . Of course only the real parts of E and I have physical meaning.

The engineer calls this representation a rotating vector diagram; The figure should in fact be thought of as rotating with the angular velocity ω as time progresses. The projections of the two-dimensional vectors E and I on the real axis give the instantaneous values of these quantities.

We shall establish furthermore how the energy flowing into the system

¹ In electrical engineering this term, incidentally, is used not only for $|\mathbf{R}|$, but also for our impedance operator \mathbf{R} itself.

is used up. To this end we multiply Eq. (7) with I , where now I and E are to represent their real parts. We find

$$\frac{L}{2} \frac{d}{dt} I^2 + RI^2 + \frac{1}{2K} \frac{d}{dt} e^2 = IE. \quad (11)$$

If we average over a period $\tau = 2\pi/\omega$ of the vibration, we obtain:

$$\frac{1}{\tau} \int_0^\tau RI^2 dt = \frac{1}{\tau} \int_0^\tau IE dt,$$

so that

$$R\bar{I}^2 = \bar{IE}. \quad (11a)$$

The contributions derived from L and K vanish since they are given by differentials. The average power \bar{IE} introduced into the system is thus dis-

FIG. 24. Representation of the complex E and I in the Gaussian plane. Lag of I with respect to E by the angle α .

sipated entirely in the ohmic resistance R . The imaginary part of our impedance operator R has a purely wattless effect on the e.m.f., i.e. it does not consume energy on a time average. We can calculate directly

$$\bar{I}^2 = \frac{1}{\tau} \int_0^\tau I_0^2 \cos^2(\omega t - \alpha) dt = \frac{1}{2} I_0^2; \quad (11b)$$

$$I_{eff} = \frac{1}{\sqrt{2}} I_0 \text{ and correspondingly } E_{eff} = \frac{1}{\sqrt{2}} E_0; \quad (11c)$$

I_{eff} is called the "effective current", E_{eff} the "effective voltage". For the average power we find

$$\begin{aligned} \bar{EI} &= \frac{1}{\tau} \int_0^\tau E_0 I_0 \cos \omega t \cos(\omega t - \alpha) dt \\ &= \frac{1}{\tau} E_0 I_0 \left\{ \int_0^\tau \cos^2 \omega t \cos \alpha dt + \int_0^\tau \cos \omega t \sin \omega t \sin \alpha dt \right\} \quad (12) \\ &= \frac{1}{2} E_0 I_0 \cos \alpha = I_{eff} E_{eff} \cos \alpha. \end{aligned}$$

Analog: Work = Path · Projection of the force on the path, where the projection must be carried out in the complex plane in the present example. This analogy applies however only for the time average, in which the second

integral of the middle line of (12) vanishes. The latter signifies an oscillation of the energy between storage (K, L) and the current source (E).

B. The Wheatstone Bridge

We distinguish between the four bridge arms a, b, c, d and the arms e and f , containing the current source and the galvanometer, respectively. The disappearance of the current in the galvanometer arm is attained by adjustment of the slide-wire contact S (or eventually the two sliding contacts S and T). Thus a *null method*, viewed with such favor in physical

FIG. 25. Wheatstone bridge: a, b, c, d branches of bridge with resistance boxes and induction coils connected in series and, eventually, capacitances connected in parallel; f and e , branches containing galvanometer and voltage source; S and T slide contacts.

measurements, is realized. The geometrical structure of the bridge is best represented by a tetrahedron (Fig. 26), the six arms being transformed into the six sides without altering their relationship, as in analysis situs. The two arms e and f then become opposite sides, similarly the arms a, d and b, c , while the arms a, b etc. become "adjoining sides".

FIG. 26. Space representation of Wheatstone bridge as tetrahedron; adjoining and opposite branches.

From the great range of applications of the Wheatstone bridge we select two characteristic special cases; the trivial case of the comparison of two ohmic d.c. resistances will be a by-product:

a. Comparison of two selfinductances

b. Comparison of a selfinductance and a capacitance

a. Let the two selfinductances L_a and L_b be inserted in the adjoining arms a and b , in series with the ohmic resistances a and b , as shown in Fig. 25. In order that there may be no current in the arm f , we adjust the sliding contacts S and T so that there is no difference of potential between them. Starting from A we have, from (10) and (10a),

$$(a + i\omega L_a)I_1 = cI_2 \quad (13)$$

and starting from B :

$$(b + i\omega L_0)I_1 = dI_2, \quad (13a)$$

so that

$$(a + i\omega L_0)d = (b + i\omega L_0)c. \quad (14)$$

If this equation is to be satisfied, the equality must exist individually for the real and for the imaginary parts. Thus:

$$\begin{aligned} ad &= bc, & L_0 d &= L_0 c. \\ \frac{a}{b} &= \frac{c}{d} = \frac{L_0}{L_0}. \end{aligned} \quad (14a)$$

The first half of this double equation applies also for the equilibrium of an inductance-free bridge, irrespective of whether it is traversed by direct or by alternating current.

b. Let the selfinductance and the capacitance lie in two opposite arms of the bridge, e.g. a and d , in such fashion that the selfinductance L and the ohmic resistance a are connected in series, the capacitance K and the ohmic resistance d , in *parallel*. According to Kirchhoff (see p. 101) the potential drop across two parallel ohmic resistances R' and R'' with the currents I' and I'' is given by

$$RI \quad \text{with} \quad I = I' + I'', \quad \frac{1}{R} = \frac{1}{R'} + \frac{1}{R''}.$$

The corresponding voltage drop for alternating current is evidently

$$RI \quad \text{with} \quad I = I' + I'', \quad \frac{1}{R} = \frac{1}{R'} + \frac{1}{R''}. \quad (15)$$

For our bridge arm d the total current at its end points is I_2 (see Fig. 25); we therefore set

$$I = I_2, \quad R' = d, \quad R'' = \frac{1}{i\omega K}, \quad \frac{1}{R} = \frac{1}{d} + i\omega K$$

and obtain in place of Eq. (13a)

$$bI_1 = \frac{I_2}{\frac{1}{d} + i\omega K} \quad (15a)$$

In combination with the unchanged Eq. (13) this leads to:

$$\frac{I_2}{I_1} = \frac{a}{c} + i\omega \frac{L}{c} = \frac{b}{d} + i\omega bK,$$

which yields, separating real and imaginary parts,

$$ad = bc = \frac{L}{K}. \quad (16)$$

In the notation of p. 138 the last term of this double equation is the *product* of inductive and capacitive reactance. Eq. (16) shows that the determination of a capacity from bridge equilibrium rests, apart from ohmic resistances, on a known selfinductance (or vice versa).

In our examples we have restricted ourselves to cases in which the equilibrium conditions, Eqs. (14a) and (16), do not depend on ω . In such cases the bridge equilibrium exists not only for the purely periodic alternating current here assumed, but for an arbitrary time variation, e.g. excitation by an interrupter. There are other cases in which the equilibrium conditions depend on ω ; bridge equilibrium then exists only for sinusoidal alternating current.

C. Coupled Circuits

The law of conservation of energy sufficed to set up the oscillatory equation for one degree of freedom. For a system of two circuits (two degrees of freedom I_1 and I_2) the energy theorem no longer is adequate for setting up the differential equations, just as in mechanics. On the other hand, Kirchhoff's law (5) yields directly

$$\begin{aligned} L_{11}I_1 + L_{12}I_2 + R_1I_1 + \frac{e_1}{K_1} &= E_1, \\ L_{22}I_2 + L_{21}I_1 + R_2I_2 + \frac{e_2}{K_2} &= E_2. \end{aligned} \quad (17)$$

The generalization for more than two circuits is obvious.

From (17) we can calculate, on the one hand, the *free* vibrations of our coupled system, on the other, the forced vibrations produced by an e.m.f. In the first case we set $E_1 = E_2 = 0$ and reduce the resulting homogeneous system of equations, with the assumption

$$I_1 = A_1 e^{i\omega t}, \quad I_2 = A_2 e^{i\omega t}$$

to a biquadratic equation for ω , after elimination of the ratio A_2/A_1 . We can be brief in discussing the conclusions derived therefrom since the same problem has been treated in detail in Vol. I, §20 and the results are represented there in Figs. 34 and 36. The characteristic *beat phenomena* of the coupled pendulums in the case of *resonance* occur, in terms of our present notation, when the periods of the uncoupled circuits are equal, which leads to $K_1L_{11} = K_2L_{22}$, and when in addition the two "coupling coefficients" L_{12}/L_{11} and L_{21}/L_{22} are equal, which leads, in view of the universal equality

of L_{12} and L_{21} , to $L_{11} = L_{22}$. These beat phenomena become particularly impressive if we assume, as for the coupled pendulums, that damping is slight, in our case $R_1 \cong 0$, $R_2 \cong 0$.

Also for *forced* vibrations the treatment in Vol. I, §19 may serve as a model. If the free and forced frequencies are identical, $\omega = \omega_0$, damping becomes essential and the amplitude maximum and phase lag represented in Fig. 33 of Vol. I occur.

At the beginning of the §20 mentioned above it was pointed out that in the early stages of wireless telegraphy coupled mechanical oscillations commonly served as model for the coupled electrical oscillations which occurred in the open primary antenna circuit and the tuned secondary circuit introduced by Ferdinand Braun. It is true that for these rapid oscillations the quasistationary treatment is only a crude approximation; only the complete integration of the Maxwell equations in §19 can yield a satisfactory representation.

D. The Telegraph Equation

Quasistationary calculations may also be applied to short sections of a long two-wire line, for which condition (1) is not fulfilled. If the length of these sections is permitted to approach zero the total differential equations of the system become a *partial differential equation*. This was set up by W. Thomson even *before* Maxwell in the treatment of the propagation of telegraph signals in marine cables. Between two oppositely located and oppositely charged points of the double line there is a charging current with a change in voltage; Hence, in addition to the voltage $V(x)$, *also the current $I(x)$ varies continuously* along the length of the line. According to Kirchhoff's second law these two variables are related by

$$L \frac{\partial I}{\partial t} + RI + \frac{\partial V}{\partial x} = 0; \quad (18)$$

L and R relate to unit length of the double line. Furthermore, it follows from the absence of current sources, i.e. Kirchhoff's first law (4), that

$$\frac{\partial I}{\partial x} + K \frac{\partial V}{\partial t} + GV = 0. \quad (18a)$$

For the sake of completeness a conduction current GV through the eventually semiconducting dielectric has been added to the charging current $K\partial V/\partial t$. This term may also account for hysteresis losses in the dielectric. G is known as the "leakage" per unit length of the double line; K also refers to this unit length.

Elimination of V from (18) and (18a) leads to the partial differential equation

$$\left\{ LK \frac{\partial^2}{\partial t^2} + (RK + LG) \frac{\partial}{\partial t} + RG - \frac{\partial^2}{\partial x^2} \right\} I = 0, \quad (19)$$

which applies also for V . If, in particular, the dissipative coefficients R and G are set equal to zero, it assumes the simple form of the differential equation of the vibrating string:

$$\left\{ LK \frac{\partial^2}{\partial t^2} - \frac{\partial^2}{\partial x^2} \right\} I = 0$$

and is integrated, for a phenomenon advancing in the positive x -direction, by

$$I = af(x - ct), \quad c = \sqrt{\frac{1}{LK}}. \quad (20)$$

According to (18) and (18a) the corresponding value of V is in this special case

$$V = Lcaf(x - ct) = \sqrt{\frac{L}{K}} I. \quad (21)$$

The ratio of voltage V and current I is thus the quantity $(L/K)^{\frac{1}{2}}$, which is independent of x and t and represents a resistance. It is known as the *wave resistance*.

The following practical conclusion may be drawn from (21): If a finite double line is terminated by an ohmic resistance of the magnitude $(L/K)^{\frac{1}{2}}$, no discontinuity occurs in the current and voltage variation at the end, hence also *no reflection*.

Eq. (20) states that the current and hence also the voltage propagate themselves along the line *without distortion* and *without damping*. We may also ask for the condition for *undistorted damped* propagation along the line, i.e. that

$$I = e^{-\alpha x} f(x - ct) \quad (22)$$

represents a solution of the differential equation (19). By substituting (22) in (19) and setting the resulting factors of f'' , f' , and f equal to zero we find

$$c = \sqrt{\frac{1}{LK}}, \quad \alpha = \frac{1}{2} \frac{RK + LG}{\sqrt{LK}} = \sqrt{RG}. \quad (23)$$

The velocity of propagation c is the same as in (20). The double equation for α leads to

$$RK + LG = 2\sqrt{RKL G}, \quad \text{i.e. } \sqrt{\frac{RK}{LG}} + \sqrt{\frac{LG}{RK}} = 2,$$

and hence

$$\sqrt{\frac{RK}{LG}} = 1 \quad \text{or also} \quad \frac{K}{G} = \frac{L}{R}. \quad (23a)$$

This signifies equal decay time for the pure displacement current $K\dot{V} + GV = 0$ (Eq. (18a) with $\partial I/\partial x = 0$) and of the pure conduction current $LI + RI = 0$ (Eq. (18) with $\partial V/\partial x = 0$). By (23) and (23a) our damping coefficient α then becomes equal to $R\sqrt{K/L}$.

In the general case the current variation changes with progress along the line. It is then proper to analyze the process into component waves of the form $\exp i(kx - \omega t)$ with complex, frequency-dependent k which are periodic in time and damped spatially. The total phenomenon is now no longer *distortion-free*.

The ideal case of undamped *plane* waves is approached if the two wires are imagined flattened into wide bands, the intermediate space being vacuum and the band material a perfect conductor. Then, apart from the marginal portions, the electric field in the intermediate space is uniform, similarly the magnetic field. \mathbf{E} is perpendicular to the bands in direction, \mathbf{H} , parallel thereto. The current becomes $I = |\mathbf{H}|b$ (b = band width), the voltage $V = |\mathbf{E}|d$ (d = separation of the bands). The charge per unit length is $e = \epsilon_0 |\mathbf{E}|b$ and the capacity $K = e/V = \epsilon_0 b/d$. The magnetic flux per unit length, i.e. through a rectangle with the sides 1 and d , becomes $\Phi = \mu_0 |\mathbf{H}|d$, so that the selfinductance $L = \Phi/I = \mu_0 d/b$. From K and L we compute, by (20) and (21),

$$\text{wave velocity } c = \frac{1}{\sqrt{KL}} = \frac{1}{\sqrt{\epsilon_0 \mu_0}},$$

$$\text{wave resistance } \frac{V}{I} = \sqrt{\frac{L}{K}} = \sqrt{\frac{\mu_0 d}{\epsilon_0 b}}.$$

Herewith we have again come upon the quantity $(\mu_0/\epsilon_0)^{1/2}$, which in §6 we had described as the wave resistance of vacuum for the propagation of a plane wave. (To obtain agreement we must refer it now to a quadratic section of the wave surface, i.e. set $b = d$.)

We have inserted this sketchy note on the telegraph equation partly to refer the concept of the wave resistance (more generally wave impedance or surge impedance) to its historical origin, partly to prepare the way for the transition to rapidly variable fields in the next section.

§19. *Rapidly Variable Fields. The Electrodynamic Potentials*

Only in this paragraph do we make full use of the unabbreviated Maxwell equations. We indicate a general method of integration, which however is limited to the case of a uniform medium, e.g. vacuum. Hence throughout space we put $\epsilon = \epsilon_0$, $\mu = \mu_0$ and in addition imagine the charge density ρ and the current density \mathbf{J} to be given in all of space and for all times $t < t_0$ (t_0 = instant of observation). In this formulation of the problem we already take cognizance of the electron theory, which, however, we

shall take up only in the third part. We start from the Maxwell equations in the form (4.4) with the auxiliary conditions (4.4a, b, c). In view of our assumptions $\epsilon = \epsilon_0 = \text{const}$, $\mu = \mu_0 = \text{const}$ we can write instead

$$\dot{\mathbf{B}} = -\text{curl } \mathbf{E}, \quad (1)$$

$$\frac{1}{c^2} \dot{\mathbf{E}} + \mu_0 \mathbf{J} = \text{curl } \mathbf{B}, \quad (2)$$

$$\text{div } \mathbf{E} = \frac{\rho}{\epsilon_0}, \quad (3)$$

$$\text{div } \mathbf{B} = 0, \quad (4)$$

$$\text{div } \mathbf{J} + \frac{\partial \rho}{\partial t} = 0. \quad (5)$$

We satisfy Eq. (4) by our earlier formulation (15.3)

$$\mathbf{B} = \text{curl } \mathbf{A}. \quad (6)$$

Substituting this in (1) we obtain

$$\text{curl } (\mathbf{E} + \dot{\mathbf{A}}) = 0.$$

This has the necessary consequence that the vector after the curl sign is a gradient. Thus

$$\mathbf{E} = -\text{grad } \Psi - \dot{\mathbf{A}}. \quad (7)$$

We call Ψ *scalar potential*, \mathbf{A} *vector potential*.

We substitute expressions (6) and (7) in (2) and obtain

$$-\frac{1}{c^2} (\dot{\mathbf{A}} + \text{grad } \dot{\Psi}) + \mu_0 \mathbf{J} = \text{curl curl } \mathbf{A} = -\Delta \mathbf{A} + \text{grad div } \mathbf{A}. \quad (8)$$

We have here utilized the transformation of curl curl which has been repeatedly employed before (e.g. in Eq. (6.2)), but applies only for Cartesian components of the vector \mathbf{A} . We shall simplify Eq. (8) by splitting it up into two vector equations, namely into

$$\Delta \mathbf{A} - \frac{1}{c^2} \frac{\partial^2 \mathbf{A}}{\partial t^2} = -\mu_0 \mathbf{J} \quad (9)$$

and

$$\text{grad} \left(\text{div } \mathbf{A} + \frac{1}{c^2} \dot{\Psi} \right) = 0. \quad (9a)$$

If we refrain from the inappropriate addition of a function depending on t only, i.e. of a kind of "integration constant", the second of these becomes

$$\text{div } \mathbf{A} + \frac{1}{c^2} \dot{\Psi} = 0. \quad (10)$$

Our initial equations (1), (2), and (4) are thus satisfied; there remains, apart from Eq. (5), Eq. (3). In view of (7) this takes the form

$$\Delta\Psi + \operatorname{div} \dot{\mathbf{A}} = -\frac{\rho}{\epsilon_0}$$

or, taking account of (10),

$$\Delta\Psi - \frac{1}{c^2} \frac{\partial^2 \Psi}{\partial t^2} = -\frac{\rho}{\epsilon_0}. \quad (11)$$

Our two potentials \mathbf{A} and Ψ thus satisfy two differential equations of the same form. We call them "wave equations". As noted above, their right sides are given functions of x, y, z and of "past time," $t < t_0$. The desired solutions are related by condition (10).

We recognize that this condition is appropriate from the following: If we call its left side X and if we form

$$\operatorname{div} (9) + \epsilon_0 \mu_0 \frac{\partial}{\partial t} (11),$$

we obtain

$$\Delta X - \frac{1}{c^2} \frac{\partial^2 X}{\partial t^2} = -\mu_0 \left(\operatorname{div} \mathbf{J} + \frac{\partial \rho}{\partial t} \right). \quad (12)$$

The right side of this equation vanishes however because of our Eq. (5), which here at last is drawn into the consideration. Thus X also satisfies the *homogeneous* wave equation, which represents a wave process without external excitation, i.e. not a forced, but a free vibration. It can be foreseen from this that a suitable integration of the differential equations for \mathbf{A} and Ψ , which excludes the appearance of free vibrations, not only leads to Eq. (12) for X being satisfied, but also to $X = 0$, i.e. the satisfying of Eq. (10). Nevertheless this equation is neither superfluous nor obvious, since the splitting up of Eq. (8), i.e. the transition from (8) to (9) and (11), rests expressly on condition (10).

A. The Retarded Potentials

With respect to the integration of our wave equations (9) and (11) we shall be brief, since the next section will indicate the rational procedure. We write down directly the result of the integration:

$$4\pi\epsilon_0\Psi = \int \frac{[\rho]}{r} d\tau, \quad (13a)$$

$$4\pi \frac{1}{\mu_0} \mathbf{A} = \int \frac{[\mathbf{J}]}{r} d\tau. \quad (13b)$$

Ψ and A refer to the reference point x, y, z and the "reference time" t , for which we wish to calculate the values of Ψ and A . ξ, η, ζ is the point of integration and $d\tau$ is equivalent to $d\xi d\eta d\zeta$. The integration is carried out over all of infinite space and we have

$$r^2 = (x - \xi)^2 + (y - \eta)^2 + (z - \zeta)^2.$$

$[\rho]$ and $[J]$ are, however, *not* the values of charge and current density at the time of observation t , but at the *earlier* time

$$t' = t - r/c. \quad (13c)$$

r/c is the time required by the "light" to travel from the point of integration to the reference point. Hence the expressions (13) are called *retarded potentials*. They are calculated from charge and current density at a time which is *set back* by r/c relative to the time of observation.

The method of integration (13) is mathematically unique if, for physical reasons, the addition of *advanced potentials*, which correspond to the later time

$$t'' = t + r/c, \quad (13d)$$

is excluded. It should be noted, however, that such advanced potentials have tentatively been introduced by Dirac into the theory of the electron and play an important role in more recent investigations (see §37).

If we apply the same method of calculation (13) to our quantity X we find directly

$$X = 0$$

since the right side of (12) was equal to zero. This result is also mathematically unique with the exclusion of "advanced" solutions, which alone, in combination with the retarded solutions, could give rise to free vibrations. This may be taken as confirmation of our earlier statement that condition (10) is satisfied automatically in the integration of the differential equations for A and Ψ . We note finally that a full understanding of the structure of the above formalism including the significance of our retarded and advanced potentials can be obtained only on the basis of the theory of relativity. What up to now may have appeared arbitrary and asymmetric will there assume an astonishingly unique and symmetrical form.

B. The Hertzian Dipole

We will explain our method of integration (13) for a particular case, the case of the *Hertzian dipole*. This is obtained if we combine a moving charge $+e$ with a neighboring stationary charge $-e$ to form a moment $p(t) = el$ varying with time, where l signifies the separation of the two charges.

We substitute $\mathbf{J} = \rho \mathbf{v}$ in (13b), denoting the space density of the moving charge by ρ and its velocity by \mathbf{v} , and obtain on carrying out the integration, where r and \mathbf{v} may be regarded as constant in space,

$$\int \frac{[\mathbf{J}]}{r} d\tau = \frac{[\mathbf{v}]}{r} \int \rho d\tau = \frac{e[\mathbf{v}]}{r} = \frac{e}{r} \left[\frac{\partial \mathbf{l}}{\partial t} \right] = \frac{1}{r} \left[\frac{\partial \mathbf{p}}{\partial t} \right].$$

We hence obtain from (13b), if we take due account of the meaning of the bracket symbol as given by (13c)

$$4\pi \mathbf{A} = \frac{\mu_0}{r} \frac{\partial}{\partial t} \mathbf{p} \left(t - \frac{r}{c} \right). \quad (14)$$

It is historically customary and convenient to introduce, in place of the vector potential \mathbf{A} , the *Hertzian vector* Π by writing

$$\mathbf{A} = \mu_0 \frac{\partial \Pi}{\partial t}, \quad 4\pi \Pi = \frac{1}{r} \mathbf{p} \left(t - \frac{r}{c} \right). \quad (15)$$

With this notation we follow the great paper of Hertz, already discussed in §1, p. 5:¹ "The Forces of Electrical Oscillations, Treated by Maxwell's Theory."

In all of space except at the origin of the coordinate system Π satisfies, by (9), the differential equation

$$\Delta \Pi - \frac{1}{c^2} \frac{\partial^2 \Pi}{\partial t^2} = 0, \quad (16)$$

which can also readily be verified from the explicit representation of Π given in (15). By (10) the corresponding value of Ψ becomes

$$e_0 \Psi = - \operatorname{div} \Pi. \quad (16a)$$

From (6) and (7) we obtain then as the representation of the electromagnetic field

$$\mathbf{H} = \operatorname{curl} \Pi, \quad e_0 \mathbf{E} = \operatorname{grad} \operatorname{div} \Pi - \frac{1}{c^2} \frac{\partial^2 \Pi}{\partial t^2}. \quad (17)$$

As an example we assume that the path of the mobile charge e is rectilinear and make its direction, which is also that of the vector Π , the axis of a spherical coordinate system r, ϑ, φ . We then have²

$$\Pi_r = \cos \vartheta \cdot \Pi, \quad \Pi_\vartheta = - \sin \vartheta \cdot \Pi, \quad \Pi_\varphi = 0,$$

¹ Ann. d. Physik 56, p. 1, 1888; Gesammelte Werke, Vol. II, p. 147.

² The positive r -direction forms the angle ϑ with the direction of Π , the positive ϑ -direction, the angle $\vartheta + \pi/2$; hence the factors $\cos \vartheta$ at Π_r and $\cos (\vartheta + \pi/2) = - \sin \vartheta$ at Π_ϑ .

where, according to (15), Π depends only on t and r , i.e. is independent of ϑ and φ . In these coordinates we obtain, by Problem I.3 of Vol. II,

$$\text{curl}_\vartheta \Pi = \frac{-\sin \vartheta}{r} \left(\frac{\partial(r\Pi)}{\partial r} - \Pi \right) = -\sin \vartheta \frac{\partial \Pi}{\partial r}, \quad \text{curl}_r \Pi = \text{curl}_\varphi \Pi = 0,$$

$$\text{div} \Pi = \frac{\cos \vartheta}{r^2} \frac{\partial}{\partial r} (r^2 \Pi) - \frac{1}{r \sin \vartheta} \frac{\partial}{\partial \vartheta} (\sin^2 \vartheta \Pi) = \cos \vartheta \frac{\partial \Pi}{\partial r},$$

$$\text{grad}_r \text{div} \Pi = \cos \vartheta \frac{\partial^2 \Pi}{\partial r^2}, \quad \text{grad}_\vartheta \text{div} \Pi = \frac{-\sin \vartheta}{r} \frac{\partial \Pi}{\partial r}, \quad \text{grad}_\varphi \text{div} \Pi = 0.$$

Hence, by (17):

$$H_r = H_\vartheta = E_\varphi = 0 \quad (18)$$

and by (15)

$$\begin{aligned} 4\pi H_\varphi &= -\frac{\sin \vartheta}{r} \left(\frac{\partial}{\partial r} \dot{p} - \frac{1}{r} \dot{p} \right), \\ 4\pi e_0 E_r &= \frac{\cos \vartheta}{r} \left(\frac{\partial^2}{\partial r^2} p - \frac{2}{r} \frac{\partial}{\partial r} p + \frac{2}{r^2} p - \frac{1}{c^2} \ddot{p} \right), \\ 4\pi e_0 E_\vartheta &= -\frac{\sin \vartheta}{r} \left(\frac{1}{r} \frac{\partial}{\partial r} p - \frac{1}{r^2} p - \frac{1}{c^2} \ddot{p} \right). \end{aligned} \quad (19)$$

We conclude from (18): The magnetic lines of force are circles about the direction of \mathbf{p} , while the electric lines of force lie in the meridional planes through this direction.

Because of the argument $t - r/c$ of p it is possible, in Eqs. (19), to transform the differentiation with respect to r into one with respect to t . We have

$$\frac{\partial p}{\partial r} = -\frac{1}{c} \dot{p}, \quad \frac{\partial^2 p}{\partial r^2} = \frac{1}{c^2} \ddot{p}. \quad (19a)$$

Then the term with $\frac{\partial^2 p}{\partial r^2}$ cancels that with \ddot{p} in the equation for E_r in (19).

At the same time we will limit ourselves to the "distant zone" (large distances from the origin, i.e. set $r \rightarrow \infty$). We will indicate the more precise meaning of this in a moment, in discussing the periodically oscillating dipole. Accordingly we neglect all terms in (19) which contain higher powers of $1/r$ than the first. We then obtain

$$\begin{aligned} 4\pi H_\varphi &= \frac{\sin \vartheta}{cr} \dot{p} \left(t - \frac{r}{c} \right), \\ 4\pi e_0 E_r &= 0, \\ 4\pi e_0 E_\vartheta &= \frac{\sin \vartheta}{c^2 r} \dot{p} \left(t - \frac{r}{c} \right). \end{aligned} \quad (20)$$

The vectors \mathbf{H} and \mathbf{E} are perpendicular to each other and to the radius vector r from the origin. Both \mathbf{H} and \mathbf{E} vanish on the axis $\vartheta = 0$ and $\vartheta = \pi$; the \mathbf{H} - and \mathbf{E} -fields have their maxima in the equatorial plane $\vartheta = \pi/2$.

From (20) we calculate

$$\frac{E_{\vartheta}}{H_{\varphi}} = \frac{1}{e_0 c} = \sqrt{\frac{\mu_0}{\epsilon_0}}. \quad (21)$$

This is the same ratio as that which was obtained from Eqs. (6.11) and (6.13) for the ratio E_y/H_z . The structure of the radiated electromagnetic field is thus that of a plane light wave. It is customary to say instead, in both cases, that \mathbf{E} and \mathbf{H} are equal, which however is dimensionally meaningless.

The amount of energy radiated per unit area and per unit time becomes

$$\mathbf{S} = \mathbf{E} \times \mathbf{H} = E_{\vartheta} H_{\varphi} = \frac{1}{16\pi^2 \epsilon_0 c^2} \frac{\sin^2 \vartheta}{r^2} \dot{p}^2. \quad (22)$$

The total energy radiated in unit time is obtained by integration over the spherical surface of radius r :

$$S = \int S d\sigma = 2\pi r^2 \int S \sin \vartheta d\vartheta = \frac{\dot{p}^2}{6\pi \epsilon_0 c^2}. \quad (23)$$

Since $\mathbf{p} = e\mathbf{l}$ (l = separation of the mobile and the stationary charge) $\dot{p} = e\dot{v}$, $\dot{p} = e\dot{v}$, where, of course, in accord with the meaning of \dot{p} , \dot{v} denotes the value of the acceleration at the earlier time $t - r/c$. We thus obtain from (23)

$$S = \frac{e^2 \dot{v}^2}{6\pi \epsilon_0 c^2}. \quad (24)$$

In atomic physics it is customary to write, in electric or magnetic cgs-units,

$$S = \frac{2}{3} \frac{e^2 \dot{v}^2}{c^2} \quad (24a)$$

or

$$S = \frac{2}{3} \frac{e^2 \dot{v}^2}{c} \quad (24b)$$

which, according to (16.30), corresponds to (24). J. J. Larmor¹ first gave this fundamental law of radiation in the form (24b).

Fig. 27 shows the radiation density S as function of ϑ . It is simply the

¹ Phil. Mag. 1897, p. 512. Larmor points out the relationship to Hertz's paper of 1888 in his book *Aether and Matter*, Cambridge, 1900, p. 225.

polar diagram of $\sin^2 \vartheta$. In the theory of wireless telegraphy (see Vol. VI, Chapter VI) it finds extensive application in the treatment of a linear antenna radiating freely into space. In fact such an antenna does not radiate energy in its own direction; the maximum of the radiation is directed *transversally*.

In place of a single dipole p we may, of course, also consider a discrete or continuous sequence of dipoles. In the latter case we write in place of (15):

$$4\pi\Pi = \int_C \frac{dp(t - r/c)}{r}. \quad (25)$$

Here the integration is to be extended over a given curve C and the difference in direction of the vectors dp must be considered.

FIG. 27. Radiation of an electron accelerated longitudinally in the direction $\vartheta = 0$. Lower pair of curves: Hertz's formula (22), $v \ll c$. Upper pair of curves: corrected relativistically, v comparable with c .

A comparison of the preceding with Hertz's calculation in Cartesian coordinates, which is found in most textbooks, demonstrates the superiority of our vector representation of the problem or eventually, of our spherical polar coordinates, which fit the symmetry of the problem. It seems even more important that our presentation clearly indicates the dimensions of all field quantities, while the Gaussian system of units employed by Hertz obscures them.

C. Specialization for Periodic Processes

We obtain the simplest model for a *light source* by assuming that the electric moment p oscillates monochromatically with a certain circular frequency ω . For example we set

$$\begin{aligned} p(t) &= A \cos \omega t = A \operatorname{Re} e^{-i\omega t}, \\ p(t - r/c) &= A \operatorname{Re} \exp \{-i\omega(t - r/c)\}. \end{aligned} \quad (27)$$

If, as in (6.10a, b), we introduce the wave number $k = \omega/c$ and omit the sign indicating the real part, which is permissible for all field quantities except the quadratic ones S, S , we find

$$\frac{1}{r} p(t - r/c) = A \frac{e^{ikr}}{r} e^{-i\omega t}. \quad (27a)$$

We have thus arrived at the representation of the *spherical wave* in Vol. II, Eq. (13.18) if we also suppress the time factor in (27a). This may and will be done in the following. We then obtain from Eqs. (20) the following representation of the electromagnetic field:

$$E = E_{\vartheta} = -\frac{Ak^2}{4\pi\epsilon_0} \sin \vartheta \frac{e^{ikr}}{r}, \quad H = H_{\varphi} = -\frac{Ak\omega}{4\pi} \sin \vartheta \frac{e^{ikr}}{r}. \quad (28)$$

This applies, as already noted above (20), for the "distant zone"; we are now however in a position to define this term exactly. For, if we let the wave-length

$$\lambda = \frac{2\pi}{\omega} c$$

correspond to the angular frequency ω , the distant zone includes all distances for which

$$r \gg \lambda, \quad (29)$$

i.e. excludes only the immediate neighborhood of the light source. For aperiodic processes (29) is replaced by the inequalities

$$\frac{1}{c} |\dot{p}| \gg \frac{|\dot{p}|}{r}, \quad \frac{1}{c^2} |\dot{p}| \gg \frac{|\dot{p}|}{cr} \gg \frac{|p|}{r^2}. \quad (29a)$$

These statements justify precisely the approximations made in passing from (19) to (20).

As compared with a natural light source our model is specialized both with regard to its monochromatism and its intensity distribution. It radiates no energy in the directions $\vartheta = 0$ and $\vartheta = \pi$; for also now Fig. 27 and Eq. (22) apply to the radiation vector S . In (22) both the time factor and the phase factor e^{ikr} drop out in the time average. In fact, by (27),

$$\frac{\dot{p}}{r} = -\frac{A\omega^2}{r} \cos(kr - \omega t)$$

and the time average of the square thereof is

$$A^2 \omega^4 / (2r^2) = A^2 c^4 k^4 / (2r^2). \quad (29b)$$

Since $k = 2\pi/\lambda$ this is *inversely proportional to the fourth power of the wave-length*.

If (29b) is substituted in (22) or (23) we obtain the famous law of Lord Rayleigh, explaining the *blue sky*. The sun rays falling on the particles of the air generate in them electric moments which vibrate in harmony and radiate light in turn. Their radiation is much stronger at the blue end of the spectrum than at the red end. Since $\lambda_{\text{red}} \cong 2\lambda_{\text{blue}}$ their ratio is about 2^4 . The same law explains also the red color of the sun and moon when rising

and setting. In its path through the atmosphere, which is here particularly long, the blue light is scattered much more strongly out of its direct path than the red light; primarily red sun- or moonlight reaches our eyes. We shall not inquire whether a certain selectivity of water vapor in the atmosphere plays an added role.

D. The Characteristic Vibrations of a Metallic Spherical Oscillator

The problem of *electromagnetic* characteristic vibrations became significant as a result of Hertz's experiments. A metallic body consisting of two oppositely charged halves (Hertzian oscillator) discharges with the formation of a spark and radiates exponentially damped vibrations toward infinity. How do we calculate their frequency and damping? In the case of the sphere, which we imagine as subdivided into two closely adjoining oppositely charged halves, the question is answered directly by formulas which are already familiar to us. It is true that we must not start here from Eq. (20) for the distant zone, but must employ the more general formulas (19), since the wave length of the characteristic vibration generated will understandably be of the order of magnitude of the radius of the sphere; the surface of the sphere thus belongs to the near zone. If the sphere is assumed to be perfectly conducting we have on the surface, i.e. for $r = a =$ radius of sphere, $E_r = 0$ for all θ . Hence, by (19), we have as boundary condition

$$\left(\frac{1}{r} \frac{\partial}{\partial r} - \frac{1}{r^2} - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \right) p = 0. \quad (30)$$

We let p take the same form as in (27), treating k not as a real number as up to now, but as an unknown complex number. The same applies then also for $\omega = ck$. To determine k (30) yields

$$\frac{ik}{a} - \frac{1}{a^2} + k^2 = 0. \quad (31)$$

The solution of this equation, which is quadratic in ka , is

$$ka = \frac{-i \pm \sqrt{3}}{2}. \quad (31a)$$

The imaginary part is negative, as we must demand, since we are dealing with a vibration which decreases with time. In the real part the positive sign is to be chosen in order that wave-length and frequency be positive. We thus obtain

$$\frac{2\pi a}{\lambda} = \frac{\sqrt{3}}{2}, \quad \lambda = \frac{4\pi}{\sqrt{3}} a,$$

i.e. in fact λ of the order of magnitude of the radius of the sphere. Damp-

ing is very great; as follows from (31a), the amplitude decreases by a factor

$$e^{-\lambda/(2a)} = e^{-2\pi/\sqrt{3}}$$

in the course of a single vibration.

Herewith the nature of the *fundamental* vibration of our spherical oscillator is described. There is however also an infinite number of harmonics for which the sphere is not divided into two oppositely charged halves, but into 4, 6, \dots alternately charged zones. While the fundamental vibration corresponds to the Hertzian dipole, these harmonics cannot be derived from the Hertzian vector Π . For them we must refer to Vol. VI and more particularly to Appendix II of Chapter V of that volume.

The case of the prolate spheroid, which comes closer to the Hertz oscillator than the spherical shape, was treated by Max Abraham,¹ after the problem of the spherical oscillator had been solved generally by J. J. Thomson as early as 1884.

E. Application to the Theory of X-Rays

The primary x-rays are produced by the incidence of cathode rays on the anticathode. Classically the initial velocity v of the incident electrons is reduced to a low value; the electrons experience a retardation $-v$. From Fig. 27 we expect that no radiation occurs in the direction of the cathode rays, insofar as this coincides with the direction of v . The proof of this is possible with extremely thin anticathodes (films a few microns in thickness), if the transmitted x-rays are observed; this has been shown by Kulenkampff and his students. For solid metal anticathodes the retardation takes place along a zigzag path; hence the variation with direction is smoothed out. We will show relativistically in §30, at Eq. (11), that the maximum of the radiation does not lie, as indicated by the pair of curves in Fig. 27, at $\vartheta = \pi/2$, but that it advances, instead, with increasing hardness of the cathode rays (increasing magnitude of v) more and more toward $\vartheta = 0$. The fact that the continuous or "brems"-spectrum discussed here has a short-wave limit is a consequence of the quantum theory, with which we shall not deal here. The same applies for the regular increase in hardness and intensity of the x-rays with the hardness of the cathode rays.

Here we shall only discuss the proof of the *transversal* nature of x-rays, which was given by Barkla in 1905, ten years after Röntgen's discovery. In planning his experiment Barkla assumed this transversality, drew the consequences of this assumption, and confirmed them by the experiment.

We consider, in Fig. 28, a broken line consisting of three mutually perpendicular segments, the "primary", "secondary", and "tertiary" segment. The *primary x-rays*, regarding whose polarization we shall make no assump-

¹ See Enzykl. d. mathem. Wiss., Vol. V, section 18, p. 498.

tion, travel along the first segment (for a very thin anticathode even these would be partly polarized). We imagine their electric field strength to be analyzed into its components along the directions 2 and 3 of the two other segments. They fall on a first scatterer Z_1 , whose electrons they set into vibrations. Those parallel to 2 have no effect along the secondary segment, while those parallel to 3 produce on it *secondary x-rays*, which vibrate parallel to 3 and are *totally polarized*. They fall on a scatterer Z_2 and set its electrons into vibrations in direction 3. In this fashion *tertiary x-rays* are produced which, however, have the *intensity zero* along the tertiary segment. They have maximum intensity in the direction of the primary segment. This behavior of the tertiary x-rays proves both the transversal nature of the primary and the total polarization of the secondary x-rays.

FIG. 28. Barkla's arrangement for demonstrating the transversal nature of x-rays. Z_1 , Z_2 scatterers (spheres of paraffin).

The scatterers Z_1 and Z_2 were spheres of paraffine; for heavier materials the "characteristic radiation" might have falsified the result.

§20. General Considerations on the Structure of Wave Fields of Cylindrical Symmetry. Applications to Alternating Current Impedance and Skin Effect

In the following section we will concern ourselves almost exclusively with *surface waves* which are *guided* along bodies of *cylindrical shape*. Let the excitation be such that the process is periodic in time with the circular frequency ω . The calculation of the *propagation and damping* of the waves as they progress in the direction of the cylinder axis, which we shall choose as the direction of the x -coordinate axis, then becomes of primary interest. We leave the cross section of the cylindrical conductor (or also nonconductor) temporarily indeterminate. We express propagation and damping by a single *complex wave number* h , which differs from the real wave number $k = \omega/c$ in vacuum. We consider thus a wave type with the dependence on x and t

$$\exp \{i(hx - \omega t)\};$$

for the assumed cylindrical structure of the wave field, h has necessarily the same value outside of and inside of the guiding surfaces; the same applies of course to ω .

We define, in the plane perpendicular to the x -axis, an orthogonal coordinate system u, v ; dx, du, dv , in this order, are to form a right-handed coordinate system. For the line element in space we write, in accord with (2.22) of Vol. II:

$$ds^2 = dx^2 + g_u^2 du^2 + g_v^2 dv^2. \quad (1)$$

g_u and g_v are here given functions of u and v . The cross section (which is constant, i.e. independent of x , for every conductor) may differ for different conductors. The coordinates u, v are to be fitted, in each particular case, to the shape of the cross section: polar coordinates for the single wire, bipolar coordinates for the two-wire line, Cartesian coordinates for semi-infinite space (limiting case of the single wire of infinitely great radius).

We set ourselves the problem of computing the transversal components E_u, E_v, H_u, H_v from the longitudinal components E_x, H_x . This is possible without making any special assumptions regarding the cross sections of the cylindrical conductors guiding the wave, without discussing the corresponding boundary conditions, and also without assuming that the wave equation is separable in the coordinates u, v . The general structure of the wave field so obtained applies not only for the exterior of the conductors, but also, with altered choice of the material constants, to their interior.

A. Longitudinal and Transversal Components

The longitudinal components E_x and H_x , which we shall designate by the single symbol X , satisfy, as Cartesian components, the simple wave equation

$$\left(\Delta - \epsilon\mu \frac{\partial^2}{\partial t^2} - \sigma\mu \frac{\partial}{\partial t} \right) X = 0. \quad (2)$$

It has been written in this form for the interior of the conductors, but applies also to the exterior, where $\sigma = 0$, $\epsilon = \epsilon_0$, $\mu = \mu_0$. We put

$$\Delta = \frac{\partial^2}{\partial x^2} + \Delta_{uv},$$

where Δ_{uv} is the *two-dimensional* Laplace operator transformed to the curvilinear coordinates u, v . In view of the dependence of the phase factor on x and t we can write in place of (2)

$$(\Delta_{uv} + k^2 - h^2)X = 0, \quad k^2 = \epsilon\mu\omega^2 + i\mu\sigma\omega. \quad (3)$$

In the exterior of the conductors k is real ($= \sqrt{\epsilon_0\mu_0}\omega = \omega/c$), in the interior

it is complex. However, by introducing the complex dielectric constant ϵ' from Eq. (6.18) we can employ the same formula

$$k = \sqrt{\epsilon\mu}\omega \quad (3a)$$

in both cases, if we set

$$\begin{aligned} \epsilon &= \epsilon_0, & \mu &= \mu_0 & \text{in the exterior,} \\ \epsilon &= \epsilon', & \mu &= \mu & \text{in the interior.} \end{aligned} \quad (3b)$$

Actually to integrate Eq. (2) it would of course be necessary to pass to specific coordinates u, v , which are adapted to the shape of the conductor; we shall avoid this for the present, however. Nevertheless we may regard, for what follows, the longitudinal components E_z and H_z as known functions of space.

To calculate from them the transversal components we utilize the definition of the curl of an arbitrary vector \mathbf{A} in any curvilinear coordinates p_1, p_2, p_3 contained in Eq. (2.26) of Vol. II:

$$\text{curl}_1 \mathbf{A} = \frac{1}{g_2 g_3} \left(\frac{\partial(g_3 A_3)}{\partial p_2} - \frac{\partial(g_2 A_2)}{\partial p_3} \right) \quad (4)$$

and set in accord with (1),

$$p_1 = x, \quad p_2 = u, \quad p_3 = v; \quad g_1 = 1, \quad g_2 = g_u, \quad g_3 = g_v.$$

By cyclic interchange of the indices 1, 2, 3 and the coordinates x, u, v we obtain from (4) all the components of the curl occurring in the Maxwell equations.

We thus calculate from the first and second group of three Maxwell equations, taking account at the same time of the x, t dependence of the phase factor,

$$\begin{aligned} i\omega\mu H_z &= \text{curl}_z \mathbf{E} = i\hbar E_z - \frac{1}{g_u} \frac{\partial E_z}{\partial u} \\ -i\omega\epsilon E_z &= \text{curl}_z \mathbf{H} = -i\hbar H_z + \frac{1}{g_v} \frac{\partial H_z}{\partial v}. \end{aligned}$$

On the basis of our convention (3a, b) we substitute on the left $\omega = k/\sqrt{\epsilon\mu}$ and obtain

$$\begin{aligned} i \left(k \sqrt{\frac{\mu}{\epsilon}} H_z - \hbar E_z \right) &= -\frac{1}{g_u} \frac{\partial E_z}{\partial u} \\ i \left(\hbar \sqrt{\frac{\mu}{\epsilon}} H_z - k E_z \right) &= \frac{1}{g_v} \sqrt{\frac{\mu}{\epsilon}} \frac{\partial H_z}{\partial v}. \end{aligned}$$

From these equations E_u and H_v are obtained by simple elimination:

$$\begin{aligned} i(k^2 - h^2)E_u &= -\frac{h}{g_u} \frac{\partial E_z}{\partial u} - \frac{k}{g_v} \sqrt{\frac{\mu}{\epsilon}} \frac{\partial H_z}{\partial v} \\ i(k^2 - h^2) \sqrt{\frac{\mu}{\epsilon}} H_v &= -\frac{k}{g_u} \frac{\partial E_z}{\partial u} - \frac{h}{g_v} \sqrt{\frac{\mu}{\epsilon}} \frac{\partial H_z}{\partial v}. \end{aligned} \quad (5)$$

Thus our objective regarding the two transversal components E_u and H_v has been attained, since on the right there occur only the longitudinal components which are assumed to be known.

The calculation for E_v and H_u is carried out similarly. Here the Maxwell equations

$$\begin{aligned} i\omega\mu H_u &= -ihE_v + \frac{1}{g_v} \frac{\partial E_z}{\partial v} \\ -i\omega\epsilon E_v &= ihH_u - \frac{1}{g_u} \frac{\partial H_z}{\partial u} \end{aligned}$$

are employed, and ω substituted in them once more in accord with the convention (3a, b). After eliminating one of the two unknowns H_u or E_v , we obtain

$$\begin{aligned} i(k^2 - h^2)E_v &= -\frac{h}{g_v} \frac{\partial E_z}{\partial v} + \frac{k}{g_u} \sqrt{\frac{\mu}{\epsilon}} \frac{\partial H_z}{\partial u}, \\ i(k^2 - h^2) \sqrt{\frac{\mu}{\epsilon}} H_u &= \frac{k}{g_v} \frac{\partial E_z}{\partial v} - \frac{h}{g_u} \sqrt{\frac{\mu}{\epsilon}} \frac{\partial H_z}{\partial u}. \end{aligned} \quad (6)$$

We will be able to make good use of these rather brief and abstract considerations in the following §21–25, where we shall replace our general coordinates u, v partly by polar, partly by bipolar coordinates. Thus, they show directly, e.g., that for polar coordinates r, φ and non-dependence of the field on φ , the pairs of equations (5) and (6), which in general are coupled, separate into one pair which contains only E_z, E_r, H_φ and another which contains only H_z, H_r, E_φ . This simplification corresponds to the symmetry of the single wire. In the present paragraph we shall deal with the still simpler case of rectangular coordinates $u = y, v = z$ for non-dependence of the field on z . This corresponds to the transition to the limit: radius of wire $\rightarrow \infty$ in Fig. 30. In all these special cases the preceding general relations take on a readily understood form and may, as we shall see, be verified directly.

Independently of the choice of u and v a further conclusion may be drawn which applies for all cylindrical perfect conductors: *The velocity of propagation on them is always equal to the velocity of light.* We note first

that the electric lines of force must be perpendicular to the surface of the conductor and conclude hence $E_z = 0$. Since, furthermore, the energy flux can have no component in a direction toward the conductor, we must also have $H_z = 0$. To begin with this applies only to the surface of the conductors. We shall assume however that both longitudinal components vanish *everywhere* in the nonconductor without coming into conflict with the Maxwell equations. It then follows from (5) and (6) (excluding the trivial solution $E_u = E_v = H_u = H_v = 0$), that we must have $h = k$. The wave equation (3) which applies for every Cartesian component of the electric and magnetic field then passes over into the potential equation. We shall make use of this conclusion in a specific example (§25A).

B. The Wave Field of Semiinfinite Space and its Skin Effect

Let the metallic semiinfinite space be bounded by the plane $y = 0$. Let the positive y -axis point upwards into the empty space (eventually filled with air) $y > 0$ and the wave progress toward the right (positive x -axis). Of the two possible solutions (5) and (6) we choose the first, since it corresponds to the wire traversed by alternating current. We hence make the reasonable assumption

$$\left. \begin{array}{l} E_x = E(y) \\ E_y = F(y) \\ H_x = G(y) \end{array} \right\} \exp \{i(hx - \omega t)\}; \quad \left. \begin{array}{l} E_z \\ H_z \end{array} \right\} = 0 \quad (7)$$

The differential equation (3) for E_x then takes the form

$$\frac{d^2 E}{dy^2} + (k^2 - h^2)E = 0, \quad \text{with } k^2 = \epsilon\mu\omega^2 + i\mu\omega. \quad (8)$$

Its solution is

$$E(y) = Ae^{i\sqrt{k^2 - h^2}y} + Be^{-i\sqrt{k^2 - h^2}y}. \quad (8a)$$

For $y < 0$ k^2 is complex, for $y > 0$ it is real. However, we shall, for the present, assume a very small $\sigma > 0$ even for $y > 0$ and pass over to the limit $\sigma \rightarrow 0$ at a later stage.¹

We shall choose the sign of $\sqrt{k^2 - h^2}$ once and for all so that it has a positive imaginary part.

Since the state must remain finite for $y \rightarrow \pm \infty$ we must set in (8a)

$$\text{for } y > 0 : B = 0,$$

$$\text{for } y < 0 : A = 0.$$

¹ In this manner we circumvent some basic questions regarding the exterior of the wire which will be deferred until §22.

Furthermore, since E_z must be continuous at $y = 0$, B must be set equal to A in the two resulting expressions.

In the following we shall reserve the letter k for the real wave number for $y > 0$ in the limiting case $\sigma \rightarrow 0$. For the sake of distinction the value of k within the conductor will be denoted by k_L . Then (8a) assumes the final form:

$$E(y) = \begin{cases} A e^{i\sqrt{k^2 - h^2}y} & y > 0, \\ A e^{-i\sqrt{k_L^2 - h^2}y} & y < 0. \end{cases} \quad (9)$$

With $u = y$, $v = z$, $g_u = g_v = 1$, and $\frac{\partial}{\partial z} = 0$ we obtain from (5)

$$F(y) = \begin{cases} -\frac{hA}{\sqrt{k^2 - h^2}} e^{i\sqrt{k^2 - h^2}y} & y > 0, \\ \frac{hA}{\sqrt{k_L^2 - h^2}} e^{-i\sqrt{k_L^2 - h^2}y} & y < 0. \end{cases} \quad (9a)$$

$$\sqrt{\frac{\mu_0}{\epsilon_0}} \left\{ G(y) = \begin{cases} -\frac{kA}{\sqrt{k^2 - h^2}} e^{i\sqrt{k^2 - h^2}y} & y > 0, \\ \frac{k_L A}{\sqrt{k_L^2 - h^2}} e^{-i\sqrt{k_L^2 - h^2}y} & y < 0. \end{cases} \right. \quad (9b)$$

The factors of G , on the left, denote "reciprocal wave impedances", the upper one the real reciprocal impedance of vacuum as on p. 36, the lower one the correspondingly defined complex quantity for our conductor. There we learned already that the dimensions of \mathbf{H} and \mathbf{E} must differ by a factor with this dimension.

We now take account of the continuity of H_z at $y = 0$. In view of (3a, b) this demands

$$\frac{\mu_0 \sqrt{k^2 - h^2}}{k^2} = -\frac{\mu \sqrt{k_L^2 - h^2}}{k_L^2}. \quad (10)$$

From this we derive

$$\frac{1}{h^2} = \frac{\mu_0^2 \frac{k_L^2}{k^2} - \mu^2 \frac{k^2}{k_L^2}}{\mu_0^2 k_L^2 - \mu^2 k^2}. \quad (10a)$$

This value depends in a *symmetrical fashion* on the constants μ_0 , k and μ , k_L of the two media air and metal. We find, in particular, for $\mu = \mu_0$

$$\frac{1}{h^2} = \frac{1}{k^2} + \frac{1}{k_L^2}. \quad (10b)$$

For a well conducting metal the conduction current (the σ -term in k_L) exceeds the displacement current (the ϵ -term). We may thus assume

$$k_L \cong \sqrt{i\mu\sigma\omega} = \sqrt{2i} \sqrt{\frac{\mu\sigma\omega}{2}} = (1+i)\kappa, \quad \kappa^2 = \frac{\mu\sigma\omega}{2}. \quad (11)$$

We have then simultaneously

$$\kappa \gg k, \quad \text{i.e. by (10b)} \quad h \cong k. \quad (11a)$$

In this case one obtains as phase velocity simply:

$$\frac{\omega}{h} \cong \frac{\omega}{k} = c,$$

as has already been pointed out at the end of section A.

From (9) and (9a) there follows with assumption (11a)

in the exterior of the conductor: $|E| \ll |F|$,

in the interior of the conductor: $|E| \gg |F|$.

The electric lines of force thus have essentially the direction of the y -axis outside of the conductor, that of the x -axis inside of the conductor.

We will now determine that value of the y -coordinate within the metal for which E_x and hence also J_x have decreased to a fraction $1/e$ of the value at the surface. We call this value of y , $-d$. According to our assumptions (11) and (11a):

$$\kappa d = 1, \quad d = \frac{1}{\kappa} \ll \frac{1}{k}. \quad (12)$$

Since $k = 2\pi/\lambda$ this is small compared to the wave-length λ corresponding to the frequency ω . *The current is confined to a thin skin at the periphery of the conductor, while the whole interior is practically free of current.* We speak of a *skin effect* which is known to play an important role in alternating current practice. The thickness of the skin is smaller in the degree that the frequency is higher (by (11) κ increases in proportion to $\sqrt{\omega}$). The following table gives some values of d for Cu ($\sigma = 57.5 \cdot 10^6 \Omega^{-1}\text{M}^{-1}$, $\mu = \mu_0 = 4\pi \cdot 10^{-7} \Omega\text{M}^{-1}\text{S}$).

	Alternating Current Line	Telephone	Wireless Telegraphy	Hertzian Oscillations
$\frac{\omega}{2\pi} =$	60/sec	1000/sec	$3 \cdot 10^8/\text{sec}$	$10^9/\text{sec}$
$\lambda =$	$5 \cdot 10^3 \text{ km}$	300 km	1 km	30 cm
$\kappa =$	116 m^{-1}	$4.7 \cdot 10^3 \text{ m}^{-1}$	$8.15 \cdot 10^3 \text{ m}^{-1}$	$4.7 \cdot 10^4 \text{ m}^{-1}$
$d =$	8.6 mm	2.1 mm	0.13 mm	$2.1 \cdot 10^{-6} \text{ mm}$

We illustrate this by Fig. 29, which, however, does not indicate the circumstances of a semiinfinite space, but the practically more interesting ones for a wire of circular cross section. The straight line 00 for direct current or commercial alternating current (60/sec) passes over into the slightly concave curve 11 for telephone frequencies (1000/sec); curve 22 applies for high frequencies proper (e.g. 1 km wave-length) and shows a

FIG. 29. Variation of alternating-current amplitude in cross section of wire: 00, direct current; 11, telephone current; 22 high-frequency current.

FIG. 30. Transition to the limit from the circular cross section of the wire (coordinates x, r, φ) to semi-infinite space (coordinates x, y, z).

pronounced skin effect. The three curves 00, 11, 22 have been drawn for the same total current I .

We also illustrate, by Fig. 30, the transition from the coordinates x, r, φ of the wire to the coordinates x, y, z of the semiinfinite space.

C. The Alternating-Current Impedance of a Semiinfinite Space

We cut out of the metallic semiinfinite space a rectangular parallelepiped which is infinitely long in the y -direction and whose upper end surface lies in the plane $y = 0$. Let the length of the side parallel to the z -direction be unity, that parallel to the x -direction be equal to the wave-length λ of the wave propagating itself in this direction. If, in the following, we neglect the imaginary part of h (the slight damping of the wave in the x -direction) we have $\lambda = 2\pi/h$. The total current flowing through the parallelepiped is:

$$I = \int_0^1 \int_0^\infty J_z dz dy. \quad (13)$$

We define the resistance of the parallelepiped energetically with the aid of the heat generated within it, which is given by the Joule heat Q integrated over the parallelepiped and averaged over the time. By Poynting's theorem we have for the parallelepiped:

$$\dot{W}_e + \dot{W}_m + Q = - \int S_n d\sigma. \quad (13a)$$

Here the first two terms on the left drop out on taking the time average because of the periodicity of the process. The Poynting vector on the right

is only that across the xz -surface (shaded in Fig. 31); the contributions of the xy -surfaces are zero since $H_z = H_y = 0$ and the contributions of the yz -surfaces cancel because of the periodicity with respect to x . Hence

$$\int S_n d\sigma = - \int_0^1 dz \int_0^\lambda S_x dx = \int_0^\lambda E_x H_z dx.$$

If, for E_x and H_z , we use the values within the metal (which, as we know, agree with those in air at $y = 0$ and may be simplified because $|h| \ll |k_z|$), we find from (9) and (9b), utilizing the representation (7)

$$\int S_n d\sigma = A^2 \int_0^\lambda \operatorname{Re}[e^{-i\omega t + ihx}] \cdot \operatorname{Re}\left\{\sqrt{\frac{e'}{\mu}} e^{-i\omega t + ihx}\right\} dx.$$

If, as a sufficient approximation, we substitute here $i\sigma/\omega$ for e' and write for \sqrt{i} its value $(1+i)/\sqrt{2}$, we can place the factor $(\sigma/(2\mu\omega))^{1/2}$ ahead of

FIG. 31. A block is cut out of the metallic semi-infinite space $y < 0$ by the two pairs of planes $x = 0$, $x = \lambda$; $z = 0$, $z = 1$. Computation of its resistance for a surface wave progressing in the x -direction.

the integral sign, while the factor $1+i$ remains in the argument of Re . If we make the further substitution

$$u = hx - \omega t, \quad dx = \frac{du}{h} = \frac{\lambda du}{2\pi}, \quad u_0 = -\omega t,$$

the preceding equation passes over into

$$\int S_n d\sigma = \frac{\lambda A^2}{2\pi} \sqrt{\frac{\sigma}{2\mu\omega}} \int_{u_0}^{u_0+2\pi} \cos u (\cos u - \sin u) du = \frac{\lambda A^2}{2} \sqrt{\frac{\sigma}{2\mu\omega}}. \quad (13b)$$

Since this value has become independent of t , it represents at the same time the time average of Q , which we require for the definition of the resistance. Taking a time average of the energetic definition of R in (18.6d) and thus extending it for alternating current we write

$$R\bar{I}^2 = \bar{Q} = \frac{\lambda A^2}{2} \sqrt{\frac{\sigma}{2\mu\omega}}. \quad (14)$$

In order to compute the value of \bar{I}^2 which occurs here we make use of the loop integral of \mathbf{H} about the parallelepiped, e.g. in the plane $x = 0$

(indicated in Fig. 31 by heavy arrows). In view of the direction of \mathbf{H} only the edge $y = 0, 0 < z < 1$ of the parallelepiped yields a contribution. We thus obtain

$$\begin{aligned} I &= \int_0^1 H_z dz = H_z = G(0)e^{-i\omega t} \\ &= \sqrt{\frac{\epsilon'}{\mu}} A e^{-i\omega t} = \sqrt{\frac{\sigma}{2\mu\omega}} A(1 + i)e^{-i\omega t} \end{aligned} \quad (14a)$$

Before taking the mean square of this we must pass to the real part:

$$I = \sqrt{\frac{\sigma}{2\mu\omega}} A (\cos \omega t + \sin \omega t).$$

We then obtain

$$\bar{I}^2 = \frac{\sigma}{2\mu\omega} A^2. \quad (14b)$$

Substitution in (14) yields

$$R = \lambda \sqrt{\frac{\mu\omega}{2\sigma}} = \frac{\lambda\kappa}{\sigma}, \quad \text{referring to (11).} \quad (15)$$

The meaning of this formula becomes clear if we substitute the skin thickness d from Eq. (12). It then becomes

$$R = \frac{\lambda}{d\sigma}. \quad (15a)$$

λ is the "length" of our conductor segment measured in the direction of propagation of the waves. If we compare (15a) with the elementary formula for direct current

$$R_0 = \frac{l}{q\sigma}, \quad (15b)$$

we see that the cross section q becomes, in our alternating-current case, the rectangle

$$d \cdot 1 \text{ (} d \text{ in the } y\text{-direction, } 1 \text{ in the } z\text{-direction).} \quad (15c)$$

In place of the infinite cross section (the yz -surface of our parallelepiped) available to it the alternating current utilizes, in a sense, only the rectangle (15c); expressed differently: the alternating current, which drops off exponentially within the conductor, behaves, with respect to its resistance, just as a direct current which is distributed uniformly over the skin thickness d .

D. The Rayleigh Resistance of a Wire

We now pass from the resistance formula (15) for a conductor with plane boundary to that for a *circularly cylindrical wire* of radius a . We assume here

$$a \gg d,$$

so that the skin effect may develop freely at the surface of the wire and its interior remains free of current. We must now, however, consider a width $2\pi a$ of the parallelepiped, rather than the width 1, and imagine its current-carrying layer to be bent into the current-carrying surface layer

FIG. 32. Resistance and inner inductive reactance for alternating current as function of frequency. The abscissa is proportional to the square root of the frequency. OA = bisector of the angle between the two axes. The inductive reactance curve approaches it asymptotically, whereas the resistance curve runs parallel to it in the limit.

of the wire. Herewith we have changed the cross section $q = d \cdot 1$ defined in (15c) to $q = d \cdot 2\pi a$ and the resistance R found in (15a) to R_0 :

$$R_0 = \frac{R}{2\pi a} = \frac{\lambda}{2\pi a \sigma d}. \quad (16)$$

If, furthermore, we introduce the direct current resistance of the wire

$$R_0 = \frac{\lambda}{\pi a^2 \sigma} \quad (16a)$$

which, like R_0 , we refer to the same length λ and the same conductivity σ as our R , we obtain simply:

$$\frac{R_0}{R_0} = \frac{1}{2} \frac{a}{d} = \frac{a}{2} \kappa. \quad (17)$$

This is *Rayleigh's resistance formula* for high-frequency alternating current. Fig. 32 indicates its limits of validity. For small ω (stationary and quasistationary currents) $R_0 = R_0$, in contradiction with (17): Our plotted curve at $\omega = 0$ is tangent to the horizontal at a distance 1 from the axis of abscissas (to a higher order of tangency). The approximate representation (17) applies only for sufficiently large ω . Because of our choice of the scale of abscissas the direction of the curve for increasing ω follows the asymptote OA , which is inclined by 45° to the axes. The intermediate

region between small and large ω requires a more detailed analytical treatment (see end of this section).

E. The Alternating Current Inductance

The method given so far could yield only the *resistance*. To obtain in similar manner the *reactance* we would have to compute the *magnetic energy* W as a function of the current I :

$$W_m = \frac{L}{2} I^2$$

and this not only for the conductor (inner selfinductance L_i , see p. 122), but also for the surrounding air space (outer selfinductance L_a). On the other hand our analysis of the external field, as carried out up to this point, would not be adequate for application to the wire, so that in the following we shall confine ourselves to the interior field and the inner selfinductance L_i .

For this however, we have a more general and also simpler method available, namely that of the impedance operator of Eq. (18.10):

$$RI = E, \quad R = R - i\omega L,^1$$

We put E equal to the field strength E_s (voltage per unit length of our conductor) at its surface $y = 0$, so that, suppressing the phase factor, we have by Eq. (9) $E = A$, where now both R and L have to be referred to unit length. We obtain I from (14a), where we again suppress the time factor:

$$I = \sqrt{\frac{\sigma}{2\mu\omega}} A(1 + i) = \frac{\sigma}{2\kappa} A(1 + i).$$

We find as the ratio of the two

$$\frac{E}{I} = (1 - i) \frac{\kappa}{\sigma},$$

so that, by (18),

$$R = \frac{E}{I} = (1 - i) \frac{\kappa}{\sigma}, \quad R = \omega L_i = \frac{\kappa}{\sigma}. \quad (19)$$

With respect to R this agrees with (15) if λ is replaced by our present unit of length, and shows at the same time that the inner *inductive reactance*

¹ We have changed the sign of the imaginary unit as compared with §18 in order to be able to employ the preceding formulas for I and E directly. In them the time factor was written in the form $\exp(-i\omega t)$, while in §18 $\exp(+i\omega t)$ occurred in the corresponding formulas.

ωL , is equal to the resistance R . This applies generally for a conductor bounded by a plane, but applies also to the circularly cylindrical wire in Rayleigh's limiting case of sufficiently high frequency.

*F. Further Treatment of the Alternating Current Field of a
Circularly Cylindrical Wire*

In order to close the subject of this section it is necessary to utilize some formulas which will not be derived systematically until §22. We are concerned first of all with the longitudinal alternating current field in a wire of radius a :

$$E_z = C J_0(kr). \quad (20)$$

J_0 denotes the Bessel function of order 0 which is continuous at $r = 0$.¹ (Just as previously, the phase factor should be imagined to be added.) In the following k is to signify the complex wave number in the interior of the wire, not, as before, the wave number in air. The coefficient C in (20) is determined from the current density $J = \sigma E_z$ in the wire and the total current I by the later Eq. (22.3d):

$$C = - \frac{kI}{2\pi a \sigma} \frac{1}{J'_0(ka)}; \quad (20a)$$

From (20) and (20a) we obtain for the current density J

$$\frac{J}{J_0} = - \frac{ka}{2} \frac{J_0(kr)}{J'_0(ka)}; \quad (21)$$

$J_0 = I/(\pi a^2)$ is the direct-current value of J

Eq. (21) may serve to check our Fig. 29. For low frequencies the arguments kr and ka are small in absolute value. Then the expansion (22.3c) and its derivative may be employed:

$$\begin{aligned} J_0(\rho) &= 1 - \left(\frac{\rho}{2}\right)^2 + \frac{1}{4}\left(\frac{\rho}{2}\right)^4 - \frac{1}{36}\left(\frac{\rho}{2}\right)^6 \pm \dots \\ J'_0(\rho) &= -\frac{\rho}{2} \left(1 - \frac{1}{2}\left(\frac{\rho}{2}\right)^2 + \frac{1}{12}\left(\frac{\rho}{2}\right)^4 \pm \dots\right) \end{aligned} \quad (21a)$$

substituted in (21) this leads, with due regard of (11), to

$$\frac{J}{J_0} = \frac{1 - \left(\frac{kr}{2}\right)^2 + \frac{1}{4}\left(\frac{kr}{2}\right)^4 - \dots}{1 - \frac{1}{2}\left(\frac{ka}{2}\right)^2 + \frac{1}{12}\left(\frac{ka}{2}\right)^4 - \dots} = \frac{1 - \frac{i}{2}(kr)^2 - \frac{1}{16}(kr)^4}{1 - \frac{i}{4}(ka)^2 - \frac{1}{48}(ka)^4}. \quad (21b)$$

¹ We employ here and in the following (unlike Vol. VI) the symbol J , in accord with the practice followed in Vol. II of these lectures and in American physics and engineering literature generally.

From this follows

$$\left| \frac{J}{J_0} \right|^2 = \frac{1 + \frac{1}{8} (\kappa r)^4}{1 + \frac{1}{48} (\kappa a)^4} \quad (21c)$$

As compared to the direct-current straight line 00 in Fig. 29 there occurs thus a dip, which on the axis of the wire ($r = 0$) has the depth $(\kappa a)^4/48$, and a rise at the periphery of the wire ($r = a$) to a height which is five times as great.

At high frequencies we obtain asymptotically, according to (22.7) and (22.6a):

$$J_0(\kappa r) = (\pi \kappa r/2)^{-1/2} \cos(\kappa r - \pi/4) \quad (22)$$

$$\frac{J}{J_0} = \frac{\kappa a}{2} \left(\frac{a}{r} \right)^{1/2} \frac{\cos(\kappa r - \pi/4)}{\sin(\kappa a - \pi/4)} \quad \left| \frac{J}{J_0} \right| = \frac{\kappa a}{\sqrt{2}} \left(\frac{a}{r} \right)^{1/2} e^{-\kappa(a-r)} \quad (22a)$$

In view of the sharp decrease for $r < a$ the whole interior of the wire is practically free of current; the magnitude at the edge is $\kappa a/\sqrt{2}$ times as great as in the direct-current case.

The same formulas also yield a closed expression for the operator R in Eq. (18). By (20) and (20a) we have

$$R = \frac{E_z}{I} = - \frac{k}{2\pi a \sigma} \frac{J_0(\kappa a)}{J'_0(\kappa a)} = - \frac{\kappa a}{2} \frac{J_0(\kappa a)}{J'_0(\kappa a)} R_0, \quad (23)$$

where R_0 is once more the direct-current resistance per unit length, i.e. $1/(\pi a^2 \sigma)$. Hence we have for *low* frequencies (by (21a), expanding in powers of κa):

$$\frac{R}{R_0} - \frac{i\omega L}{R_0} = 1 - \frac{i}{4} (\kappa a)^2 + \frac{1}{48} (\kappa a)^4.$$

The separation of the real and imaginary parts yields:

$$\frac{R}{R_0} = 1 + \frac{1}{48} (\kappa a)^4, \quad \frac{\omega L}{R_0} = \frac{1}{4} (\kappa a)^2. \quad (23a)$$

On the other hand, we obtain, from (22) and (22a), for very *high* frequencies simply:

$$\begin{aligned} \frac{R}{R_0} - \frac{i\omega L}{R_0} &= -i \frac{\kappa a}{2} = (1 - i) \frac{\kappa a}{2} \\ \frac{R}{R_0} &= \frac{\omega L}{R_0} = \frac{\kappa a}{2}. \end{aligned} \quad (23b)$$

This agrees with our earlier results (17) and (19), obtained for the conductor with the plane boundary.

Our approximations (23a, b) permit us to check also Fig. 32 and to interpolate for the intermediate region between low and high frequencies. At low frequencies, by (23a), the resistance curve approaches the straight line $R = R_0$ as a parabola of the fourth order and at high frequencies it approaches the straight line OA in Fig. 32 from above. The curve for the inner inductive reactance starts at low frequencies as a parabola of the second order¹ and approaches² at high frequencies the same straight line from below.

§21. The Coil Carrying Alternating Current

Inasmuch as in §17 we had to defer the treatment of the direct-current field of the circular wire as mathematically too complicated, the rigorous treatment of the alternating-current field of a long coil appears to be out of the question. We hence make the same approximation as on p. 25, i.e. replace the coil, which we assume to consist of a single closely-wound layer, by an infinitely long hollow cylinder of uniform metal. Let its axis (x -axis) be vertical and let it be traversed by horizontal circular currents whose intensity distribution we shall determine. Let the inner radius of the hollow cylinder be a , the outer radius $a + d$.

A. The Field of the Coil

As in the direct-current case we assume that the magnetic excitation is zero outside of the coil, uniform³ within it and parallel to the coil axis, so that we may write

$$H = 0 \text{ for } r \geq a + d, \quad H = H_z = H_0 e^{-i\omega t} \text{ for } r \leq a. \quad (1)$$

We must then assume the H -field to be parallel to the cylinder axis also in the metallic conductor, i.e.

$$H = H_z = H(r) e^{-i\omega t} \text{ for } a < r < a + d.$$

¹ This statement applies to the product ωL plotted in the figure; L itself has for $\omega = 0$, in accord with the meaning of $\epsilon^2 = \mu\sigma\omega/2$, the non-vanishing value

$$L = \frac{R_0 \mu \sigma a^2}{4 \cdot 2} = \frac{\mu}{8\pi},$$

in agreement with §16C.

² This approach is a true tangency for $\omega \rightarrow \infty$; on the other hand, the curve for the resistance remains even for $\omega \rightarrow \infty$ a finite amount $R_0/4$ above the straight line OA , as would be shown by a more precise formulation of the approximation (23b).

³ This customary and practically unavoidable assumption for infinite length of the coil is, strictly speaking, not permissible in Maxwell's theory. It contradicts the equation, applying for the nonconducting interior space, $\mathbf{D} = \text{curl } \mathbf{H}$ and is, in view of $\text{curl } \mathbf{H} = 0$ equivalent to the neglect of the displacement current $\dot{\mathbf{D}}$.

H_z must satisfy the general wave equation (20.2), which yields, for $H(r)$, the differential equation

$$\Delta H(r) + k^2 H(r) = 0, \quad k^2 = \epsilon\mu\omega^2 + i\mu\sigma\omega. \quad (2)$$

Transformed to polar coordinates x, r, φ it is integrated in terms of Bessel functions. We do not require here, however, the particular solution $J_0(kr)$ as in (20.20), but the general solution containing two constants, which we write preferably in the form

$$C_1 H_0^1(kr) + C_2 H_0^2(kr). \quad (2a)$$

H^1, H^2 are the two Hankel cylinder functions, about which we shall give some information in the next section. In particular we shall familiarize ourselves there with their asymptotic behavior for large values of the argument $\rho = kr \rightarrow \infty$:

$$H_0^1(\rho) \rightarrow \sqrt{\frac{2}{\pi\rho}} e^{i(\rho - \pi/4)}, \quad H_0^2(\rho) \rightarrow \sqrt{\frac{2}{\pi\rho}} e^{-i(\rho - \pi/4)}. \quad (2b)$$

Since for high-frequency alternating current invariably $|k|a \gg 1$, we can limit ourselves in the integration of (2) to these asymptotic values and can write

$$H(r) = \sqrt{\frac{2}{\pi kr}} (C_1 e^{i(kr - \pi/4)} + C_2 e^{-i(kr - \pi/4)}). \quad (3)$$

From Eqs. (1) we have the boundary conditions

$$H(a + d) = 0 \quad \text{and} \quad H(a) = H_s.$$

They are satisfied if, by special choice of C_1, C_2 , expression (3) is transformed into

$$H(r) = \sqrt{\frac{a}{r}} H_s \frac{\sin[k(a + d - r)]}{\sin(kd)}. \quad (4)$$

Having found in this manner H_z as function of r (we may also say as a function of the polar coordinates x, r, φ) we can now utilize §20 A. It is true that now we are not dealing, as there, with a wave advancing along the x -axis, but with ordinary (stationary) alternating current, for which the wave number h given there vanishes. In fact our present Eq. (2) passes over into the earlier (20.3) for $X = H_z, h = 0$. Furthermore we must not employ, as in the preceding paragraph, Eq. (20.5) (electric type), but Eq. (20.6) (magnetic type). This yields the transversal components H_r, E_φ expressed in terms of the longitudinal component H_z . We are particularly interested in E_φ . With $g_u = 1, g_r = r, H = 0$, (20.6) yields:

$$E_\varphi = -\frac{i}{k} \sqrt{\frac{\mu}{\epsilon'}} \frac{dH(r)}{dr} e^{-i\omega t} = \frac{J}{\sigma}. \quad (5)$$

If we carry out the differentiation with respect to r only in the factor $\sin\{k(a + d - r)\}$ (the square-root factor is "slowly variable") and if we denote the value of J on the inner surface of the coil by J_a , we obtain

$$J = J_a \sqrt{\frac{a}{r}} \frac{\cos\{k(a + d - r)\}}{\cos(kd)}, \quad J_a = i\sigma \sqrt{\frac{\mu}{\epsilon'}} H_a \frac{\cos(kd)}{\sin(kd)} e^{-i\omega t}. \quad (6)$$

Passing to the discussion of the field, we distinguish two cases:

$$a. |k|d \gg 1 \quad \text{and} \quad b. |k|d \ll 1;$$

we of course continue to adhere to the original assumption $|k|a \gg 1$.

a. High-Frequency Alternating Current with not too Small Coil Thickness. Since we take the imaginary part of k to be positive we have then

$$|e^{-ikd}| \gg |e^{ikd}|$$

and, more particularly near the inner coil boundary also:

$$|e^{-ik(a+d-r)}| \gg |e^{ik(a+d-r)}|.$$

Hence (4) yields, for $r \cong a$,

$$H(r) \cong H_a e^{ik(r-a)}, \quad (7)$$

which signifies a steep exponential falling off at the inner boundary of the coil. By (6) the current density shows a similar steep exponential decline:

$$J \cong J_a e^{ik(r-a)}, \quad (7a)$$

$$J_a = i\sigma \sqrt{\frac{\mu}{\epsilon'}} H_a e^{-i\omega t}. \quad (7b)$$

We thus have a *pronounced skin effect* at the inner surface of the coil.

b. Small Coil Thickness and Relatively Low-Frequency Alternating Current. We may then expand Eqs. (4) and (6) in powers of kd and, particularly in the neighborhood of $r = a$, also in powers of $k(a + d - r)$. We indicate only the first term of these expansions:

$$H(r) \cong H_a \frac{a + d - r}{d}, \quad J \cong J_a. \quad (8)$$

Fig. 33 illustrates this graphically: At the left is shown the behavior of $H(r)$, at the right that of J . The curves 0 correspond to the limiting case b , the curves 2 to case a , and the curves 1 to an intermediate case. All three pairs of curves refer to the same H within the coil and hence also to the same total current I in the coil.

B. Resistance and Inner Inductive Reactance of the Coil

We wish to compute these quantities per unit length of the coil and must first know the total current passing through this unit length. It is obtained by integration of (5) with respect to r :

$$\int_a^{a+d} J dr = C \{H(a+d) - H(a)\} e^{-\omega t} = -CH_a e^{-\omega t};$$

in view of the meaning of k and ϵ' we have

$$-C = \frac{i\sigma}{k} \sqrt{\frac{\mu}{\epsilon'}} \cong 1. \quad (9)$$

FIG. 33. Magnetic field and current distribution in a single-layer coil: At the left, magnetic field $H(r) = H_a$, at the right current density $J(r) = J_0$. The curves 0 and 2 correspond to the limiting cases of direct current and high-frequency alternating current, curves 1 to intermediate frequencies with the same total current as in the two limiting cases.

To refer this total current to the current I flowing in a *single wire* of the coil we set it equal to NI , where N is the number of turns per unit length:

$$I = \frac{1}{N} H_a e^{-\omega t}. \quad (9a)$$

With this value of I we write the equation

$$(R - i\omega L)I = E,$$

where we must set the voltage E equal to the field strength on the inner surface of the coil, i.e. equal to J_a/σ . We thus obtain from (6) and (9)

$$R - i\omega L = \frac{Nk \cos(kd)}{\sigma \sin(kd)} = i \frac{Nk}{\sigma} \frac{e^{ikd} + e^{-ikd}}{e^{ikd} - e^{-ikd}}. \quad (10)$$

For a discussion of this expression we write, as in (20.11), $k = (1 + i)\kappa$. The denominator of (10) then becomes

$$e^{(-1+i)\kappa d} - e^{(1-i)\kappa d}.$$

We multiply numerator and denominator with the complex conjugate of this quantity, whereupon they can be expressed in terms of the trigonometric and hyperbolic functions of $2\kappa d$. We obtain

$$R - i\omega L = (1 - i) \frac{N\kappa \sinh(2\kappa d) + i \sin(2\kappa d)}{\sigma \cosh(2\kappa d) - \cos(2\kappa d)} \quad (11)$$

so that, separating real and imaginary parts,

$$R = \frac{N\kappa \sinh(2\kappa d) + \sin(2\kappa d)}{\sigma \cosh(2\kappa d) - \cos(2\kappa d)}, \quad (11a)$$

$$\omega L = \frac{N\kappa \sinh(2\kappa d) - \sin(2\kappa d)}{\sigma \cosh(2\kappa d) - \cos(2\kappa d)}. \quad (11b)$$

For direct current ($\kappa d \rightarrow 0$) (11a) yields

$$R_0 = \frac{N}{\sigma d}, \quad (12)$$

corresponding to the direct-current resistance per unit length of a wire of rectangular cross section with the width d of the coil (not to be confused with the layer thickness d of p. 162) and the height $1/N$. We have therefore

$$\frac{R}{R_0} = \kappa d \frac{\sinh(2\kappa d) + \sin(2\kappa d)}{\cosh(2\kappa d) - \cos(2\kappa d)}, \quad (12a)$$

$$\frac{\omega L}{R_0} = \kappa d \frac{\sinh(2\kappa d) - \sin(2\kappa d)}{\cosh(2\kappa d) - \cos(2\kappa d)}. \quad (12b)$$

More particularly we consider the two limiting cases *a* and *b* of p. 172:

a. $\kappa d \gg 1$. Then $\sinh(2\kappa d) = \cosh(2\kappa d) \rightarrow \infty$, so that

$$\frac{R}{R_0} = \frac{\omega L}{R_0} = \kappa d, \quad (13a)$$

b. $\kappa d \ll 1$. By expansion in powers of $2\kappa d$, and retaining only the first nonvanishing term we find from (12a, b)

$$\frac{R}{R_0} = 1 + \frac{4}{45} (\kappa d)^4, \quad \frac{\omega L}{R_0} = \frac{2}{3} (\kappa d)^2. \quad (13b)$$

These results (13a, b) are represented qualitatively once more by Fig. 32. Also now the direct-current straight line $R/R_0 = 1$ is approximated at low frequencies to the fourth order and the axis of abscissas is parabolically tangent to the curve $\omega L/R_0$ at the origin. At high frequencies both curves again approach the 45° line asymptotically. Only the scale of abscissas, now given by κd , differs from that given before since the skin effect occurs here unilaterally, on the inner surface of the coil.

However much more important than the inner selfinductance, to which we have limited ourselves, is of course the *external selfinductance of the coil*. In the discussion of the coil traversed by direct current (§17, Eq. (15)) we were exclusively interested in the latter. With the limitation mentioned in footnote 3, p. 170 (neglect of the displacement current) we can transfer the value found there directly to the alternating-current case.

With our idealization of the problem (closed ring currents in horizontal planes) we could circumvent the determination of the electric field within the coil and leave the boundary conditions for this field out of consideration. Actually the currents are, in view of the finite pitch of the coil, not exactly horizontal and there exists, from turn to turn, an external electric field of complex character which is predominantly axial in direction. Our elementary treatment evidently does not suffice to determine this field.

C. The Multilayer Coil

We imagine the several layers, n in number, to be placed one over the other without intervening space, idealized as hollow cylinders of thickness d/n , and traversed in series by alternating current I of uniform magnitude. Let the insulation of the successive layers be perfect, though by assumption infinitely thin; the same is to apply for the insulation of successive turns in any single layer.

In view of the magnitude of the loop integral of \mathbf{H} about a single layer, i.e. over a rectangle of height 1 and width d/n , the magnetic field decreases by NI for each layer (N = number of turns per unit length along the axis of the coil). Hence we find at the boundaries of successive layers, from the inside outward:

$$H_0 = H, \quad H_1 = H - NI, \quad H_2 = H - 2NI, \dots, H_n = H - nNI = 0. \quad (14)$$

The factor $\exp(-i\omega t)$ must be thought of as added here, and in the following. In the ν th layer the magnetic field satisfies the differential equation and the boundary conditions:

$$\Delta H + k^2 H = 0, \quad H = \begin{cases} H_{\nu-1} & r = a + (\nu - 1) \frac{d}{n}, \\ H_\nu & r = a + \nu \frac{d}{n}. \end{cases} \quad (15)$$

The differential equation is again integrated by the superposition of the two Hankel functions, for which we can substitute their asymptotic values from Eq. (2b) since kr is very large; furthermore we can treat the denominator \sqrt{kr} as slowly variable in comparison with the exponential functions and

include it along with the remaining constants ($\exp\{-i\pi/4\}$ and $\sqrt{2/\pi}$) in the amplitudes C_1, C_2 . Eq. (3) is then simplified to

$$H = C_1 e^{ikr} + C_2 e^{-ikr}.$$

The following expression, which at the same time satisfies the boundary conditions (15) and hence represents the magnetic field in the ν th layer, is of this form:

$$H = H_{\nu-1} \frac{\cos \left\{ k \left(r - a - (\nu - \frac{1}{2}) \frac{d}{n} \right) \right\}}{\cos \left(k \frac{d}{2n} \right)} - NI \frac{\sin \left\{ k \left(r - a - (\nu - 1) \frac{d}{n} \right) \right\}}{\sin \left(k \frac{d}{n} \right)} \quad (16)$$

In particular we obtain for the first layer, $a < r < a + d/n$, $\nu = 1$

$$H = H_a \frac{\cos \left\{ k \left(r - a - \frac{d}{2n} \right) \right\}}{\cos \left(k \frac{d}{2n} \right)} - NI \frac{\sin \{ k (r - a) \}}{\sin \left(k \frac{d}{n} \right)}. \quad (16a)$$

We need consider only this formula if now we wish to determine the electric field E_r at the inner surface of the coil and from this the impedance operator $R = R - i\omega L$ of the multilayer coil.

To begin with we obtain for the current density J_r , for which we shall consider right away the value for $r = a$, from (5) (see also (9)):

$$J_a = c \left(\frac{dH}{dr} \right)_a = -Hk \frac{\sin \left(k \frac{d}{2n} \right)}{\cos \left(k \frac{d}{2n} \right)} + NI k \frac{1}{\sin \left(k \frac{d}{n} \right)}.$$

We here set $H = nNI$ (see last of Eqs. (14)) and obtain after simple trigonometric transformation,

$$J_a = NI k \frac{n \cos \left(k \frac{d}{n} \right) - (n - 1)}{\sin \left(k \frac{d}{n} \right)}.$$

Hence we obtain

$$E = E_p = \frac{1}{\sigma} J_n \quad \text{and} \quad R = \frac{E}{I} = \frac{Nk}{\sigma} \frac{n \cos\left(k \frac{d}{n}\right) - (n-1)}{\sin\left(k \frac{d}{n}\right)},$$

which, for $n = 1$, is identical with Eq. (10).

We divide R by the direct-current value R_0 of R , obtained by passing to the limit $\omega \rightarrow 0$, i.e. $k \rightarrow 0$:

$$R_0 = \frac{Nn}{\sigma d},$$

and find

$$\frac{R}{R_0} = kd \frac{\cos\left(k \frac{d}{n}\right) - \left(1 - \frac{1}{n}\right)}{\sin\left(k \frac{d}{n}\right)}. \quad (17)$$

The separation of (17) into real and complex parts is rather complicated. If as before we set $k = (1 + i)\kappa$, it yields

$$\frac{R/R_0}{\omega L/R_0} = kd \frac{\sinh\left(2\kappa \frac{d}{n}\right) \pm \sin\left(2\kappa \frac{d}{n}\right) - 2\left(1 - \frac{1}{n}\right) \cdot \left(\sinh\left(\kappa \frac{d}{n}\right) \cdot \cos\left(\kappa \frac{d}{n}\right) \pm \cosh\left(\kappa \frac{d}{n}\right) \cdot \sin\left(\kappa \frac{d}{n}\right)\right)}{\cosh\left(2\kappa \frac{d}{n}\right) - \cos\left(2\kappa \frac{d}{n}\right)}$$

Thus, thanks to our extensive (possibly excessive) idealization of the problem, we have obtained a quite simple final formula. The frequency band for which our formula is valid has an upper limit determined by the characteristic frequency of the coil; as we approach the latter our notion of equal current in all turns obviously becomes invalid. It should also be emphasized that our formula presumes the regular superposition of the layers and does not cover the spiral interweaving of the turns (Dolezalek, litz wire) which is preferred for practical reasons (suppression of the skin effect).

§22. The Problem of Waves on Wires

As is well known, the experiments of Heinrich Hertz dealt with "surface waves" progressing along wires as well as with "space waves" propagated freely through the air. Hertz expected their velocity also to be equal to c ,

but could confirm this result neither experimentally nor theoretically. The reason for his experimental failure was the influence of the walls of the laboratory; the reason for his theoretical failure, an excessive idealization of the problem. He treated the wire as infinitely thin and hence could not set up electromagnetic boundary conditions. This was first accomplished in a paper by the author¹ which yielded for the velocity of propagation a value nearly equal to—more precisely, slightly less than— c . It was here essential that a phase velocity exceeding c could be excluded by a condition at infinity. The experimental difficulties were overcome by E. Lecher (see §25) by using a *two-wire line*. In the present section we shall confine ourselves to Hertz's problem of the *single wire*.

A. The Field within and outside of the Wire

While in the preceding section the Maxwell equations were utilized only in part, inasmuch as not only was the displacement current within the conductor neglected, but to some extent also that in free space, we must now adhere strictly to these equations. The problem is symmetrical about the axis of the wire. We make it the x -axis of a cylindrical coordinate system x, r, φ . Then for all components $\partial/\partial\varphi = 0$ and only the components

$$E_x, E_r, H_\varphi \quad (1)$$

differ from zero. As in §20 we set them equal to products of the common factor

$$e^{-i\omega t + ikx} \quad (1a)$$

with a function of r only. Let the time variation be purely periodic, i.e. ω be real, and the phase propagation take place along the positive x -axis; k must then have a positive real part.

We deal first with the Cartesian longitudinal component E_x . It satisfies the wave equation (20.3), in which we put $u = r, v = \varphi$. If, in place of r , we introduce the dimensionless variable

$$\rho = \sqrt{k^2 - k^2} r \quad (1b)$$

and set

$$E_x = F(\rho)e^{-i\omega t + ikx}, \quad (2)$$

we obtain for F the differential equation

$$\frac{1}{\rho} \frac{d}{d\rho} \left(\rho \frac{dF}{d\rho} \right) + F = 0 \quad (3)$$

¹ Ann. d. Physik, Vol. 67, pp. 233-290, 1899.

or, with the differentiation carried out,

$$\frac{d^2 F}{d\rho^2} + \frac{1}{\rho} \frac{dF}{d\rho} + F = 0. \quad (3a)$$

This, as well as the more general equation

$$\frac{d^2 F}{d\rho^2} + \frac{1}{\rho} \frac{dF}{d\rho} + \left(1 - \frac{n^2}{\rho^2}\right) F = 0 \quad (3b)$$

is known as Bessel's differential equation. We have dealt with it already in Vol. II, §27. The solution which is continuous for $\rho = 0$ was represented there, in (27.7), by the series

$$J_n(\rho) = \frac{1}{n!} \left(\frac{\rho}{2}\right)^n - \frac{1}{1!(n+1)!} \left(\frac{\rho}{2}\right)^{n+2} + \frac{1}{2!(n+2)!} \left(\frac{\rho}{2}\right)^{n+4} - \dots \quad (3c)$$

For all that follows n may be assumed to be an integer. For $n = 0$ we obtain the representation (21a) for $J_0(\rho)$ employed in §20, from which we see directly

$$J_1(\rho) = -\frac{d}{d\rho} J_0(\rho), \quad \int_0^\rho \rho J_0(\rho) d\rho = \rho J_1(\rho). \quad (3d)$$

Within the wire, $r < a$ (a = radius of wire), where E_z must nowhere become infinite, our function F is thus determined but for a constant by its differential equation (3):

$$F = C J_0(\rho) \quad \text{for} \quad 0 < r < a. \quad (4)$$

Outside of the wire (in air) $\sigma = 0$, $\epsilon = \epsilon_0$, $\mu = \mu_0$, so that $k = \omega/c$ is real. For the sake of differentiation we shall denote the complex value of k , which applies within the wire, by k_L as in §20. Since the condition of continuity at $r = 0$ plays no role outside of the wire, Eq. (3) has to be integrated generally. This is done by the two "Hankel functions of order 0", already mentioned on p. 171:

$$H_0^1(\rho) \quad \text{and} \quad H_0^2(\rho).$$

We shall deal in detail with these and the general Hankel functions of order n in Vol. VI, §19. It must here suffice to enumerate some of their principal properties:

a. The functions H_0^1 and H_0^2 become *logarithmically infinite* for $\rho = 0$, since we have, for small ρ :

$$H_0^{1,2}(\rho) = 1 \pm \frac{2i}{\pi} \log \frac{\gamma\rho}{2} + \dots = \pm \frac{2i}{\pi} \log \frac{\gamma\rho}{\pm 2i} \dots \quad (5)$$

γ is related, to the Euler-Mascheroni constant

$$\lim_{n \rightarrow \infty} \left(1 + \frac{1}{2} + \frac{1}{3} + \cdots + \frac{1}{n} - \log n \right) = 0.5772 \dots;$$

For

$$\log \gamma = 0.5772 \dots, \gamma = 1.781 \dots \quad (5a)$$

(log here denotes, as always, the natural logarithm.)

b. The Hankel functions are branched in the complex ρ -plane, just as the logarithm. To make them single-valued we must provide a branch cut in the ρ -plane, e.g. along the negative imaginary axis. If we set $\rho = |\rho| e^{i\vartheta}$, we thus limit the angle ϑ to the values $-\pi/2 < \vartheta < 3\pi/2$. In this sense we speak of the principal branch of the Hankel functions, just as we speak of the principal branch of the logarithm.

c. The Hankel functions $H_n^1(\rho)$ and $H_n^2(\rho)$ of order n are defined as solutions of Eq. (3b) in such fashion that also their representation contains a logarithmic term for $\rho \rightarrow 0$, i.e. that the branching mentioned in b applies also to them. However, the determining factor for their singularity is not this logarithmic term, but the term which becomes most strongly infinite:

$$H_n^1(\rho) = \frac{(n-1)!}{i\pi} \left(\frac{2}{\rho}\right)^n, \quad H_n^2(\rho) = \frac{(n-1)!}{-i\pi} \left(\frac{2}{\rho}\right)^n. \quad (6)$$

The logarithmic singularity and the branching disappear for the sum of the two functions H_n . The regular solution of the differential equation (3b) is obtained in the form

$$J_n(\rho) = \frac{1}{2}(H_n^1(\rho) + H_n^2(\rho)). \quad (6a)$$

d. For $\rho \rightarrow \infty$ we have as asymptotic representation of the two principal branches:

$$H_n^1(\rho) = \sqrt{\frac{2}{\pi\rho}} e^{i(\rho - (n+1)\pi/2)}, \quad H_n^2(\rho) = \sqrt{\frac{2}{\pi\rho}} e^{-i(\rho - (n+1)\pi/2)}. \quad (7)$$

Thus H_n^1 vanishes for large ρ in the positively-imaginary ρ -halfplane, H_n^2 , in the negatively imaginary ρ -halfplane. The two together vanish for large ρ only on the real axis. J_n becomes, by (6a), infinite everywhere at infinity except on the real axis. In view of (6a) and (7) we have at infinity in the positively imaginary ρ -halfplane

$$\frac{J_n(\rho)}{J_n'(\rho)} = +i. \quad (7a)$$

After these insertions, which unfortunately were necessary for what follows, we return to our actual problem. We make the convention that the sign of the square root in (1b) is always to be chosen so that its imaginary

part is *positive*. This covers the case that the root is itself *complex*. We must however also take into account the possibility that the root is *real* and that $h < k$.

In the first case the only possible formula for the exterior of the wire is

$$F(\rho) = AH_0^1(\rho), \quad a < r < \infty, \quad A = \text{const}, \quad (8)$$

since, by (7), $H_0^2(\rho)$ becomes infinitely great for $r \rightarrow \infty$.

In the second case

$$F(\rho) = AH_0^1(\rho) + BH_0^2(\rho), \quad a < r < \infty. \quad (9)$$

is a possible formula since now, for real ρ , both H vanish, by (7), as ρ^{-1} . A and B are for the present arbitrarily disposable constants.

What is the meaning of this case? Since according to (2) the phase velocity of the wave is equal to ω/h and since ω/k is equal to c , it implies

$$\text{phase velocity} > \text{velocity of light}.$$

We supplement our representation of E_z by that of the transversal components E_r and H_ϕ , which is obtained most readily with the aid of the general rule (20.5) (where however the terms with H_z are of course omitted). If for the present we designate the functions of ρ appearing in E_r and H_ϕ with $G(\rho)$ and $V(\rho)$ this yields

$$G(\rho) = \frac{ih}{k^2 - h^2} \frac{\partial F(\rho)}{\partial r} = \frac{ih}{\sqrt{k^2 - h^2}} F'(\rho), \quad (10)$$

$$\sqrt{\frac{\mu}{\epsilon}} E(\rho) = \frac{ik}{k^2 - h^2} \frac{\partial F(\rho)}{\partial r} = \frac{ik}{\sqrt{k^2 - h^2}} F'(\rho). \quad (11)$$

B. The Boundary Condition at Infinity

As for the surface wave in §20 we are also now dealing with a process which draws its energy from the end of the wire at $x = -\infty$. We hence shall demand that the total energy flux through a cylindrical surface $r = R$ coaxial with the wire vanishes:

$$S = 2\pi \{r S_r\}_{r=R} = 0. \quad (12)$$

If as an abbreviation we designate the phase $hx - \omega t$ by Φ we obtain

$$S_r = E_z H_\phi = \text{Re}\{F(\rho)e^{i\Phi}\} \text{Re}\left\{\sqrt{\frac{\epsilon_0}{\mu_0}} \frac{-ik}{\sqrt{k^2 - h^2}} \frac{dF(\rho)}{d\rho} e^{i\Phi}\right\}.$$

We consider the *second case*, in which h , $\sqrt{k^2 - h^2}$, and ρ were real. Eq. (9) then applies for $F(\rho)$ and we obtain, indicating all immaterial constant factors by ... and utilizing the asymptotic expressions (7) with $n = 0$:

$$S = \dots \frac{r}{\rho} \{A^2 \cos^2(\Phi + \rho - \pi/4) - B^2 \cos^2(\Phi - \rho + \pi/4)\}. \quad (12a)$$

It is significant here that the factor r/ρ remains finite for arbitrarily large $r = R$ and that the phase Φ may take on any real values. Our requirement (12) can then be satisfied only by

$$A = B = 0.$$

This signifies: *In the second case wire waves cannot occur; they would have to be fed by an artificial arrangement of energy sources at infinity, which contradicts the physical meaning of the process.*

Conditions are different in the first case, where ρ has a positive imaginary part. According to Eqs. (8) and (7) the field outside of the wire decreases here exponentially as $r \rightarrow \infty$; the energy flux S vanishes in similar manner. Only this case is relevant for us. By Eqs. (2), (4), (8), (10), and (11) we calculate the corresponding field within and outside of the wire, and distinguish the complex k_L within from the real k outside, as well as the complex ϵ'/μ within from the real ϵ_0/μ_0 outside as in (20.9a, b). Furthermore it is convenient to redefine the constants C and A so that all components are multiplied with $\frac{\sqrt{k_L^2 - h^2}}{ih}$ inside and with $\frac{\sqrt{k^2 - h^2}}{ih}$ outside of the wire. We thus obtain the following tabulation:

$0 < r < a, \quad \rho = \sqrt{k_L^2 - h^2} r$ $E_z = \frac{\sqrt{k_L^2 - h^2}}{ih} C J_0(\rho)$ $E_r = C J'_0(\rho)$ $\sqrt{\frac{\mu}{\epsilon'}} H_\phi = \frac{k_L}{h} C J'_0(\rho)$	$a < r < \infty, \quad \rho = \sqrt{k^2 - h^2} r$ $E_z = \frac{\sqrt{k^2 - h^2}}{ih} A H_0(\rho)$ $E_r = A H'_0(\rho)$ $\sqrt{\frac{\mu_0}{\epsilon_0}} H_\phi = \frac{k}{h} A H'_0(\rho)$
------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------	--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

(13)

H_0 is identical with H_0^1 ; the prime at J_0 and H_0 indicates differentiation with respect to the argument ρ .

C. The Boundary Condition at the Surface of the Wire

E_z and H_ϕ must be continuous for $r = a$. Hence we must require

$$\rho_L C J_0(\rho_L) = \rho A H_0(\rho), \quad \sqrt{\frac{\epsilon'}{\mu}} k_L C J'_0(\rho_L) = \sqrt{\frac{\epsilon_0}{\mu_0}} k A H'_0(\rho) \quad (14)$$

$$\rho_L = \sqrt{k_L^2 - h^2} a, \quad \rho = \sqrt{k^2 - h^2} a.$$

By eliminating the amplitude factors A and C we obtain the *transcendental equation*

$$\frac{\rho H_0(\rho)}{H'_0(\rho)} = \sqrt{\frac{\epsilon_0 \mu}{\epsilon' \mu_0}} \frac{k}{k_L} \frac{\rho_L J_0(\rho_L)}{J'_0(\rho_L)}. \quad (14a)$$

We regard this as the determining equation for the as yet unknown wave number h . However, Eq. (14a) can be greatly simplified by taking account

of the fact that if the material of the wire is a good conductor ρ_L is a large complex number with positive imaginary part so that Eq. (7a) is applicable. With its aid the right side of (14a) may be transformed into

$$i \sqrt{\frac{\epsilon_0 \mu}{\epsilon' \mu_0}} \frac{k}{k_L} \rho_L \cong i \sqrt{\frac{\epsilon_0 \mu}{\epsilon' \mu_0}} ka. \quad (14b)$$

Since $|\epsilon'| \gg \epsilon_0$ its absolute value is small compared with 1. Furthermore the left side may also be simplified. Since it must be small we may use Eq. (5). We then obtain for the left side of (14a)

$$\rho^2 \log \frac{\gamma \rho}{2i} = -\frac{2}{\gamma^2} u \log u \quad \text{with} \quad u = \left(\frac{\gamma \rho}{2i} \right)^2. \quad (14c)$$

Comparison with (14b) then yields as the final form of our transcendental equation

$$u \log u = v \quad \text{with} \quad v = -\frac{i\gamma^2}{2} \sqrt{\frac{\epsilon_0 \mu}{\epsilon' \mu_0}} ka. \quad (15)$$

For its solution it is possible to employ a peculiar method reminiscent of the continued fraction. This rests on the fact that $\log u$ varies slowly in comparison with u . Hence if an n th approximation u_n has been found, an $n + 1$ st approximation may be obtained from

$$u_{n+1} \log u_n = v. \quad (15a)$$

We may begin, for example with $u_0 = v$ and put, in accord with (15a),

$$u_1 = \frac{v}{\log v}; \quad (15b)$$

the exact initial value is of little importance since it is corrected step by step in the subsequent approximations. Furthermore, by (15a):

$$u_2 = \frac{v}{\log u_1} = \frac{v}{\log \frac{v}{\log v}}, \quad u_3 = \frac{v}{\log \frac{v}{\log \frac{v}{\log v}}} \quad \text{etc.} \quad (15c)$$

Consider, for example, a copper wire with radius $a = 1$ mm and the frequency given farthest to the right on the table on p. 162, which corresponds to a wave-length of 30 cm and a value $ka = 2.1 \cdot 10^{-2}$. For the corresponding value of κ taken from the same table, (15) yields

$$v = -(1 + i) \cdot 7.2 \cdot 10^{-7}.$$

We begin with

$$u_1 = (1 + i) \cdot 3.6 \cdot 10^{-8}, \quad (16)$$

where $\log v$, occurring in (15b), has been approximated by -20 . We then find from (15a)

$$u_2 = (4.1 + 4.5i) \cdot 10^{-8}, \quad u_1 = (4.2 + 4.6i) \cdot 10^{-8}; \quad (16a)$$

We thus have already arrived at the limit of convergence of our "continued fraction."

From this value of u we find by (14c)

$$\rho^2 = -\frac{4}{\gamma^2} u = -(5.3 + 5.8i) \cdot 10^{-8}; \quad (16b)$$

and by (1b)

$$h^2 = k^2 + \frac{1}{a^2} (5.3 + 5.8i) \cdot 10^{-8}, \quad h = k \{1 + (6.0 + 6.6i) \cdot 10^{-4}\}. \quad (17)$$

We form

$$\frac{\omega}{h} = \frac{\omega}{k} \{1 - (6.0 + 6.6i) \cdot 10^{-4}\} \quad (17a)$$

and conclude from this, since $\omega/k = c$, that the *phase propagation lags behind c by only $6 \cdot 10^{-4} c$* . On the other hand we see from our field factor $\exp(ikh)$ that the amplitude is reduced by a factor $1/e$ only after traversal of a distance x given by

$$k \cdot 6.6 \cdot 10^{-4} x = 1, \quad x = 720 \text{ m.} \quad (17b)$$

This corresponds completely to what is expected: *Nearly undamped propagation with c as phase velocity.*

There are however also conditions for which this expectation proves to be erroneous. Consider, for example, a Wollaston wire of platinum with a radius $a = 2 \cdot 10^{-4}$ cm; the conductivity of platinum is 8 times less than that of copper. Let the wave-length in air be 1 meter. Then

$$\kappa = 9.2 \cdot 10^2 \text{ cm}^{-1}, \quad \sqrt{\frac{\epsilon_0 \mu}{\epsilon' \mu_0}} = (1 - i) \cdot 0.34 \cdot 10^{-4}, \quad \rho_L = (1 + i) \cdot 0.2.$$

The argument of J_0 in (14) is then no longer large, so that we must use Eq. (3c) in place of (7a). It yields

$$\frac{J_0(\rho_L)}{J'_0(\rho_L)} = -(1 - i) \cdot 5.0$$

and for the right side of (15), with the meaning of u unchanged, the value $v = -i \cdot 7.0 \cdot 10^{-9}$. Our transcendental equation thus becomes

$$u \log u = v, \quad v = -i \cdot 7.0 \cdot 10^{-9}$$

If, once again, we put $u_1 = -v/20$, we obtain by (15c),

$$u_2 = (-0.29 + 3.5i) \cdot 10^{-10} \cong u_3$$

and

$$\rho^2 = -\frac{4}{\gamma^2} u = (0.36 - 4.4i) \cdot 10^{-10},$$

a value of the same order of magnitude as that found before in (16b). However the further calculation becomes quite different because of the smallness of $a = 2 \cdot 10^{-4}$ cm. In place of (17) we find in cm^{-2}

$$h^2 = k^2 - 0.0009 + 0.011 i.$$

It is now no longer adequate to retain a first term in a binomial expansion, since here $k^2 = (2\pi/\lambda)^2 = 0.0039$. Instead we obtain

$$h = 0.085 + 0.065i.$$

From this follows for the length of wire along which the wave amplitude has been reduced by a factor $1/e$:

$$\frac{1}{0.065} = 15 \text{ cm}$$

and for the phase velocity $\omega/0.085$. Division by the velocity of light ω/k yields

$$\frac{k}{0.085} = 0.74$$

as the ratio of the velocity of wave propagation and the velocity of light. *The former lags behind the latter by 26 per cent.*

The reason for this abnormal behavior evidently lies in the extreme thinness of the wire, which increases the alternating current impedance and prevents the development of a normal skin effect. The interior of the wire is then no longer free of current; the current distribution no longer has the character of curve 22 of Fig. 29, but that of curve 11. The field is then no longer "immunized" against Joule heat loss. Damping and propagation become anomalous.

§23. General Solution of the Wire-Wave Problem

In the preceding section we have derived that particular solution which is related to Hertz's original problem of wire waves. The question arises as to whether there is a more general solution. This question was proposed to D. Hondros as subject for his Munich thesis.¹ At the time it seemed of

¹ Ann. d. Phys. 50, p. 905, 1909.

purely theoretical interest, remote from any practical application. It has been found since that it possesses close analogies with the theory of cavity conductors (§24), at present a favored field of communications engineering. Furthermore, it may be utilized advantageously for the theory of the Lecher two-wire line which first converted Hertz's single wire into a functioning system. Also the "wire waves in nonconductors" which fit into Hondros's formulation of the problem have found practical application

A. Primary Wave and Electrical Secondary Waves

We call the solution in §22 the *principal wave*; for it $|\rho|$ was small and hence $|\rho_L|$ large. In the converse case that $|\rho|$ is large we speak of a *secondary wave*. Then, by (22.7), the left side of (22.14a) becomes equal to $-i\rho$, i.e. also large in absolute value. The denominator on the right side of (22.14a) must then become very small. ρ_L must hence approximate one of the infinitely many and frequently tabulated roots of

$$J'_0(\rho) = 0, \quad \rho = w'_1, \quad w'_2, \dots, \quad (1)$$

generally w'_r , where we shall note in particular

$$w'_1 = 3.83. \quad (1a)$$

By Eq. (22.3d) these w'_r are identical with the roots of $J_1(\rho) = 0$. (We want to reserve the symbol w_r for the roots of $J_0(\rho) = 0$.) In view of the meaning of ρ_L given by Eq. (22.14) we have then approximately

$$h_r^2 \cong k_L^2 - \left(\frac{w'_r}{a}\right)^2. \quad (2)$$

For a well-conducting wire h_r is thus approximately equal to k_L and we can write, for all moderate values of r (see (20.11)):

$$h_r \cong (1 + i)\kappa. \quad (2a)$$

From the formula for phase and damping $\exp(-i\omega t + i\kappa x)$, which is to be interpreted as before, we find: *All secondary waves are exceedingly strongly damped in their progress along the wire*; their amplitude decreases by the factor $1/e$ in the short distance $1/\kappa$. *Their phase velocity ω/κ is small compared to the velocity of light $c = \omega/k$, the ratio of the two being equal to k/κ .*

The secondary waves also behave oppositely to the principal wave with respect to the character of the field. By (2a) we have *outside of the wire*

$$\rho = \sqrt{k^2 - h_r^2} r \cong (-1 + i)\kappa r$$

and by (22.7)

$$H_0^1(\rho) \sim e^{-\alpha + i\beta r} \quad \text{for} \quad a < r < \infty.$$

By (22.8) this signifies a *skin effect outside of the wire*. In its interior, on

the other hand, the argument of $J_0(\rho)$ is real since

$$\rho = \sqrt{k_L^2 - h^2} r = w' \frac{r}{a} \quad (w', \text{ real})$$

and hence $J_0(\rho)$ is of the order of magnitude 1 for $0 \leq r \leq a$.

The entire interior is filled by current. Considerable Joule heat is generated here, which explains the rapid damping of the wave in its progress along the wire and makes any observation of the secondary waves *illusory*.

B. Magnetic Waves

While we derived the electrical principal and secondary waves from the general Eq. (20.5), we obtain the magnetic waves from (20.6). We here set $E_z = 0$, H_z equal but for a constant to the Bessel function J_0 inside, and equal to the first Hankel function H_0 outside of the wire. If we take the corresponding transversal components from (20.6) we obtain, with $u = r$, $v = \varphi$, $g_u = 1$, $g_v = r$:

$$\begin{aligned} 0 < r < a, \quad \rho = \sqrt{k_L^2 - h^2} r & \quad a < r < \infty, \quad \rho = \sqrt{k^2 - h^2} r \\ \sqrt{\frac{\mu}{\epsilon'}} H_z = \frac{\sqrt{k_L^2 - h^2}}{ih} DJ_0(\rho) & \quad \sqrt{\frac{\mu_0}{\epsilon_0}} H_z = \frac{\sqrt{k^2 - h^2}}{ih} BH_0(\rho) \\ \sqrt{\frac{\mu}{\epsilon'}} H_r = DJ'_0(\rho) & \quad \sqrt{\frac{\mu_0}{\epsilon_0}} H_r = BH'_0(\rho) \\ -E_\varphi = \frac{k_L}{h} DJ'_0(\rho) & \quad -E_\varphi = \frac{k}{h} BH'_0(\rho). \end{aligned} \quad (3)$$

From the requirement of continuity of H_z and E_φ we now obtain the boundary conditions

$$\rho_L DJ_0(\rho_L) = \sqrt{\frac{\epsilon_0 \mu}{\epsilon' \mu_0}} \rho BH_0(\rho), \quad k_L DJ'_0(\rho_L) = k BH'_0(\rho). \quad (4)$$

Here we have put $\rho = \sqrt{k^2 - h^2} a$, $\rho_L = \sqrt{k_L^2 - h^2} a$, as in (22.14). The reader may prove to his own satisfaction that the second of these conditions assures at the same time the continuity of B_r , taking account of the relation $k^2 = \epsilon_0 \mu_0 \omega^2$, which we shall also use in the following.

Elimination of B and D in (4) leads to the transcendental equation

$$\rho \frac{H_0(\rho)}{H'_0(\rho)} = \sqrt{\frac{\epsilon' \mu_0}{\epsilon_0 \mu}} \frac{k}{k_L} \frac{\rho_L J_0(\rho_L)}{J'_0(\rho_L)}, \quad (5)$$

whose right side differs materially, even in order of magnitude, from that of (22.14a). We ask whether (5) has a solution of the type of the *principal wave* $h \cong k$, i.e. $\rho \ll 1$. Then the left side would, by (22.5), be of the order of $\rho^2 \log \rho$, i.e. in absolute value $\ll 1$, while the right side, by (22.7a) and since $\rho_L \cong k_L a$, would be approximately equal to $\{\epsilon' \mu_0 / (\epsilon_0 \mu)\}^{1/2} k a$, i.e. in ab-

solute value $\gg 1$ since $|\epsilon'| \gg \epsilon_0$. This applies even for soft iron where μ is much larger than μ_0 . The assumption $h \cong k$ thus leads to a contradiction. *There is no magnetic principal wave*; the magnetic waves all have the character of *secondary waves*:

$$|\rho| \gg 1, \quad J'_0(\rho_L) \cong 0, \quad h_r^2 \cong k_L^2 - \left(\frac{w_r}{a}\right)^2,$$

as in (1). The earlier comments on the *electric* secondary waves may be transferred without change to the *magnetic secondary waves*. Their field also shows a skin effect outside of the wire and is rapidly damped in the interior by Joule heat.

C. Asymmetric Waves of the Electromagnetic Type

We now consider processes without rotational symmetry about the axis of the wire and employ for the representation of E_z the more general solutions of the Bessel differential equation

$$J_n(\rho) \cos(n\varphi) \quad \text{or} \quad H_n(\rho) \cos(n\varphi) \quad (6)$$

in place of the functions $J_0(\rho)$ and $H_0(\rho)$. We readily convince ourselves then that the former three-component solutions E_z, E_r, H_φ and H_z, H_r, E_φ are no longer sufficient, but that all six components of \mathbf{E} and \mathbf{H} must occur in the solution. We must now combine with the formula (6) for E_z the formula

$$\left. \begin{matrix} J_n(\rho) \\ H_n(\rho) \end{matrix} \right\} \sin(n\varphi) \quad (6a)$$

for H_z , so as to give all terms in (20.5) the common factor $\cos(n\varphi)$, all terms in (20.6) the common factor $\sin(n\varphi)$. We thus obtain from (20.5, 6) for the interior of the wire, with $\rho = \sqrt{k_L^2 - h^2} r$

$$\begin{aligned} E_z &= \frac{\sqrt{k_L^2 - h^2}}{ih} C J_n(\rho) \cos(n\varphi) \\ E_r &= \left\{ C J'_n(\rho) + \frac{k_L n}{h \rho} D J_n(\rho) \right\} \cos(n\varphi) \\ -E_\varphi &= \left\{ \frac{n}{\rho} C J_n(\rho) + \frac{k_L}{h} D J'_n(\rho) \right\} \sin(n\varphi) \\ \sqrt{\frac{\mu}{\epsilon'}} H_z &= \frac{\sqrt{k_L^2 - h^2}}{ih} D J_n(\rho) \sin(n\varphi) \\ \sqrt{\frac{\mu}{\epsilon'}} H_r &= \left\{ \frac{n}{\rho} \frac{k_L}{h} C J_n(\rho) + D J'_n(\rho) \right\} \sin(n\varphi) \\ \sqrt{\frac{\mu}{\epsilon'}} H_\varphi &= \left\{ \frac{k_L}{h} C J'_n(\rho) + \frac{n}{\rho} D J_n(\rho) \right\} \cos(n\varphi). \end{aligned} \quad (7)$$

The phase factor $\exp(-i\omega t + i h x)$ is again to be thought as included. The constant coefficients in E_z and H_z have been so chosen that (7) passes over into (22.13) for $D = 0$ and $n = 0$ and (after the permissible interchange of \cos and \sin) into (3) for $C = 0$ and $n = 0$.

Proceeding likewise for the exterior of the wire we obtain, with $\rho = \sqrt{k^2 - h^2} r$

$$\begin{aligned}
 E_z &= \frac{\sqrt{k^2 - h^2}}{ih} A H_n(\rho) \cos(n\varphi) \\
 E_r &= \left\{ A H'_n(\rho) + \frac{kn}{h\rho} B H_n(\rho) \right\} \cos(n\varphi) \\
 -E_\varphi &= \left\{ \frac{n}{\rho} A H_n(\rho) + \frac{k}{h} B H'_n(\rho) \right\} \sin(n\varphi) \\
 \sqrt{\frac{\mu_0}{\epsilon_0}} H_z &= \frac{\sqrt{k^2 - h^2}}{ih} B H_n(\rho) \sin(n\varphi) \\
 \sqrt{\frac{\mu_0}{\epsilon_0}} H_r &= \left\{ \frac{n}{\rho} \frac{k}{h} A H_n(\rho) + B H'_n(\rho) \right\} \sin(n\varphi) \\
 \sqrt{\frac{\mu_0}{\epsilon_0}} H_\varphi &= \left\{ \frac{k}{h} A H'_n(\rho) + \frac{n}{\rho} B H_n(\rho) \right\} \cos(n\varphi).
 \end{aligned} \tag{8}$$

We now turn to the boundary conditions between interior and exterior at $r = a$. With $\rho = \sqrt{k^2 - h^2} a$ and $\rho_L = \sqrt{k_L^2 - h^2} a$ we obtain from the continuity of E_z and H_z

$$\rho_L C J_n(\rho_L) = \rho A H_n(\rho), \tag{9}$$

$$\rho_L D J_n(\rho_L) = q \rho B H_n(\rho), \quad q = \sqrt{\frac{\epsilon_0 \mu}{\epsilon' \mu_0}}. \tag{9a}$$

and from the continuity of E_φ and H_φ the two conditions

$$C \frac{n}{\rho_L} J_n(\rho_L) + D \frac{k_L}{h} J'_n(\rho_L) = A \frac{n}{\rho} H_n(\rho) + B \frac{k}{h} H'_n(\rho), \tag{10}$$

$$C \frac{k_L}{h} J'_n(\rho_L) + D \frac{n}{\rho_L} J_n(\rho_L) = A \frac{qk}{h} H'_n(\rho) + B \frac{qn}{\rho} H_n(\rho). \tag{10a}$$

The constants A , B , C , and D are to be eliminated from these four equations (9), (9a), (10), and (10a), most simply in the form of a four-row determinant. We divide their columns immediately by H_n and J_n and find:

$$\begin{vmatrix}
 \rho & 0 & \rho_L & 0 \\
 0 & q\rho & 0 & \rho_L \\
 \frac{n}{\rho} & \frac{k}{h} \frac{H'_n}{H_n} & \frac{n}{\rho_L} & \frac{k_L}{h} \frac{J'_n}{J_n} \\
 q \frac{k}{h} \frac{H'_n}{H_n} & \frac{qn}{\rho} & \frac{k_L}{h} \frac{J'_n}{J_n} & \frac{n}{\rho_L}
 \end{vmatrix} = 0 \tag{11}$$

This transcendental equation is to be regarded as the *equation determining the wave number h* , which occurs not only explicitly, but also implicitly in ρ , ρ_L , H'/H , and J'/J . The electric and magnetic components of the wave are *coupled* by it. An *uncoupling* occurs only in the symmetrical case $n = 0$, for which (11) may be separated:

$$\left\{ \rho k_L \frac{J'_0}{J_0} - \rho_L q k \frac{H'_0}{H_0} \right\} \left\{ \rho_L k \frac{H'_0}{H_0} - \rho q k_L \frac{J'_0}{J_0} \right\} = 0. \quad (11a)$$

When set individually equal to zero the two parentheses correspond exactly with the transcendental equations for the symmetric magnetic and the symmetric electrical case, i.e. with the earlier Eqs. (5) and (22.14a).

We utilize (11) below only to answer the question whether in the unsymmetrical case a state of the character of the *principal wave* is possible. We thus assume

$$h \cong k, \quad \rho \cong 0, \quad |\rho_L| \gg 1, \quad \frac{J'_n}{J_n} \rightarrow -i, \quad \frac{H'_n}{H_n} \rightarrow -\frac{n}{\rho};$$

the last two statements follow from Eqs. (22.6) and (22.7a). We then can neglect, in the first two rows of (11), not only $q\rho$, but also ρ in comparison with ρ_L . Then the determinant (11) breaks up into the product of the two subdeterminants

$$\begin{vmatrix} \rho_L & 0 \\ 0 & \rho_L \end{vmatrix} = \rho_L^2 \quad \text{and} \quad q \left(\frac{n}{\rho} \right)^2 \begin{vmatrix} 1 & -\frac{k}{h} \\ -\frac{k}{h} & 1 \end{vmatrix} = -\frac{qn^2}{a^2 h^2}. \quad (12)$$

The product of the two yields

$$(h^2 - k_L^2) \frac{qn^2}{h^2}$$

Set equal to zero this leads, for $n = 0$, to $h = \pm k_L$, which contradicts our requirement $h \cong k$. *There is hence no asymmetric principal wave.* We must refer to Hondros's thesis for the rather complicated solution of the transcendental equation for the secondary waves.

D. Wire Waves on a Nonconductor

The dissipation of the secondary waves on the metallic wire by Joule heat raises the question as to whether secondary waves on a *dielectric* wire might be observable. According to Hondros and Debye this question is to be answered in the affirmative.¹

¹ D. Hondros and P. Debye, *Ann. d. Phys.* 32, p. 465, 1910.

We shall consider a "water wire" (which may be imagined surrounded by an infinitely thin-walled glass cylinder). In view of the absence of absorption h is real, so that $\sqrt{k^2 - h^2}$ is either real or purely imaginary. The first possibility ($h < k$, propagation with a velocity exceeding that of light) is excluded by the prohibition of radiation, in accord with §22B. Hence $\sqrt{k^2 - h^2}$ and our former $\rho = \sqrt{k^2 - h^2} a$ become purely imaginary. On the other hand, $\rho_L = \sqrt{k_L^2 - h^2} a$ is real. For we have now, since $\sigma = 0$

$$k_L^2 = \epsilon \mu \omega^2 = \frac{\epsilon \mu}{\epsilon_0 \mu_0} \cdot \epsilon_0 \mu_0 \omega^2 = n^2 k^2,$$

where n is now to denote the *refractive index*, in accord with Maxwell's law in Eq. (6.7) (not, as up to now, the order of the Bessel functions!). For water we have in the high-frequency range (decimeter waves) $n \cong 9$.

We introduce the two *real* quantities

$$\xi = \sqrt{h^2 - k^2} a, \quad \eta = \sqrt{n^2 k^2 - h^2} a, \quad (13)$$

which will serve as rectangular coordinates for a graphical representation.

All our earlier formulas, in particular those for symmetrical waves, remain valid for our present case of real ξ , η insofar as they do not contain approximations. Eq. (22.14a) now takes the form

$$i\xi \frac{H_0(i\xi)}{H'_0(i\xi)} = \frac{\eta}{n^2} \frac{J_0(\eta)}{J'_0(\eta)}. \quad (14)$$

For $\xi \rightarrow 0$ and $\xi \rightarrow \infty$ its left side varies, according to (22.5) and (22.7) as

$$\frac{i\xi \log \frac{\gamma \xi}{2}}{1/i\xi} = \xi^2 \log \frac{2}{\gamma \xi} \quad \text{and as} \quad \frac{i\xi}{i} = \xi, \quad \text{respectively.}$$

It thus becomes equal to zero and infinity along with ξ . Hence the right side of (14) must also vanish for $\xi = 0$; this is not the case when $\eta = 0$ (since $J'_0(0) = 0$), but only when

$$J_0(\eta) = 0. \quad (15)$$
